All those peculiarities in form, structure, and properties of tissue, which characterize the multitudinous forms of life around us, and which enable us to distinguish them from one another, are imposed upon the matter of the moment when it passes from the living to the formed state, or succeed as the result of a long series of changes then initiated. These peculiarities are not found in any ordinary matter, and can only be accounted for on the supposition that some force, property, or power exists which is peculiar and belongs to the matter only while its life lasts. This exerts but a temporary influence on the material particles, which are by it constrained to take up such prearranged positions with respect to one another as must necessarily result in the formation of definite compounds. To this prearranged disposition of the atoms of matter must every character of formed material and every distinctive property of tissue be traced back. This is, indeed, the cause of the varying form, structure, and property of every tissue and every living form in nature. The instant the influence of vital power in restraining the combination of atoms, ceases to be exerted, definite compounds are formed, but these are not living. The matter of which they consist has ceased to live. There are no phenomena occurring in non-living matter in any way comparable with these vital phenomena. Scientific opinion on these matters has lately been unduly influenced by a materialist party, which, like a political caucus, has assumed the right to direct thought and to promulgate the particular dogma which alone is to be accepted by the faithful.

If now I permit myself to pass beyond the point to which I have been led by actual observation,—if I try to advance beyond the present microscopic limit, travelling as it were upon the same lines as when observing within it, and try to realize the phenomena which occur during the early period of development of some comparatively simple vegetable tissue, a leaf for example,—I think the following description will not be far from the truth: A mass of living matter, endowed with special powers working under certain definite conditions, takes up certain materials and increases in size thereby. Imparting to the new matter its powers, unweakened in force, as it grows, it soon divides into several portions, each of which in like manner grows and divides. The arrangement of the several masses, though fixed within certain limits, is determined not by any forces, powers, attractions, or repulsions acting upon all of them, but simply by the rate of growth of each, and division of the several masses under then existing external conditions; the dimensions each was to attain, as well as its properties, composition, color and the like being due to the life, force, or power each separate mass derived from the parental one which gave it origin, and from which it had been detached. But while the above phenomena are proceeding, changes are also occurring on the surface of each mass. The living matter in this situation, whether from the particles first formed, and being therefore the oldest, reaching the surface, and coming to the end of their living existence, or from some other cause I cannot say—passes out of the living state, and the component particles or certain of them combine, assume a certain form, and acquire physical properties they never possessed before. The formed material thus produced owes its colour, chemical composition, physical characters, internal structure, and the like, to the vital force or property in obedience to which the elements of the matter were made to occupy such positions and assume such relations with respect to one another just before death as must ensure the formation of the particular substances which result.

From the moment when the formation of the formed material occurred, the relative position of the several masses probably altered little. Growth may no doubt take place in certain directions by outgrowths, but none of the elementary parts with its surrounding formed non-living material cannot move from its place and get before or above any of its neighbors, as must at least be held to have been possible up to the time when its movements were restricted by the formed substances on its surface.

I would here remark generally, that if very little non-living matter is associated with the living matter, the latter may move in any direction with equal facility, and one part of a mass may place itself above or in advance of another portion just as easily as it could descend below it. But when a layer of formed material has been produced on the surface of the living matter, the entire elementary part becomes subject to gravitation in consequence of the quantity of non-living matter that is formed.

There is not, I think, any good reason for accepting the conclusion that one of a collection of elementary parts, at any period of development, can sympathize or otherwise influence the actions of others, as Virchow seems to think. The suggestion that any force or power acting, as it were, from a centre, governs, regulates, and determines the changes taking place in surrounding and more or less distant particles, is, in my opinion, inadmissible. We might, with as much show of reason, refer the harmonious action of the several parts of the adult organism to some controlling or governing power situated we know not where, influencing, we know not how, actions of many different kinds occurring at considerable distances from the seat of its existence. Although very high authorities have given their sanction to views of the kind, and have advocated the existence in connection with each individual organism of some power or force capable of operating through material of even considerable thickness and of controlling matter at a distance, I venture to assert that the conclusions are not supported by the results of observation and experiment. The idea of one particle of living matter influencing other particles at a distance from it, much less sympathizing with or being affected by vital changes occurring in them, cannot, I think, be entertained by any one who has studied the phenomena as they occur in living beings.

One can indeed conceive tissues of the most elaborate character, and new matter of the most wonderful properties and most complex composition, being developed in the most regular and orderly manner without supposing that any governing or controlling power acts upon them at all, as it were, from a centre. That the most wonderful order is manifest in the arrangement of the component elementary parts, say, of a growing leaf, must be obvious to every one who has ever examined it; but I feel confident that as soon as each living particle has been detached from the mass which preceded, it is no longer influenced by the latter, and does not influence neighboring masses. Each may be pressed upon by its neighbors, and press upon them in turn during growth, but there is no reason to suppose that any one determines the composition, governs the motion, or regulates the action of others. The nutrient matter is distributed to all by vessels or channels running amongst the several collections. Those elementary parts farthest from the nutrient supply will grow more slowly than those nearest to it, but no formative or constructive of synthetic or analytic influence is exerted by the nutrient fluid upon the living matter, nor by the several elementary parts upon one another. Each is under the influence of the vital power associated with the matter of which it in part consists; and whether each can exist independently if separated from its neighbors, or dies soon after it is detached, depends not upon any influence exerted upon it by those neighbors, but simply upon the inherent capabilities of its own vital power, transmitted to it from the living matter which existed before it, and of which it once formed a part.

Nevertheless, each individual elementary part, say, of a leaf, or other organ or tissue, must not in any case be regarded as an individual, independent, or self-dependent organism, for it constitutes but a part of a highly complex whole which has been gradually formed in accordance with a definite structural plan and arrangement, foreseen and prepared for as it were from the very first.

It is only by attributing the observed phenomena to the operation of a special force or power, having no analogy whatever with any known inorganic forces or powers, that a reasonable explanation of the facts can be framed. The phenomena which have been referred to cannot correctly be compared to any processes or actions which occur independently of life, neither can any true analogy be pointed out between these and any physical or chemical changes or actions of which we have at this time any knowledge or experience. That the formation of all tissues and organs is governed by "law" is no doubt true, but the "law" is unknown, and whatever may be its terms, the mode of its operation upon matter is as different from that of any laws that are known to operate in the non-living, as are the known and observed facts of life from those of the inorganic matter of the world.

Now as regards the nature of the actual phenomena of living matter which are at present beyond the range of observation, at least two diametrically opposite ideas are entertained.

1. There is the commonplace notion that structure exists which will account for the actions which take place, but that the details of this supposed structure are too minute or too delicate to be demonstrated by any magnifying powers which have yet been constructed. For this idea there is no sufficient justification. It is one of those assumptions in elaborating which the modern materialist is so ingenious. In this way he struggles, and with some success, to postpone for a time the inevitable fall of the system he has endeavored to make popular in spite of the overwhelming evidence of facts against it. Here I must remark that the word "structure" as employed by physicists is used in a sense utterly distinct from that in which we use the word. This is evident enough if we consider what is understood by the "structure" of a crystal and the "structure" of an organ or tissue. The first "structure" at once disappears when the crystal is dissolved and reappears whenever it is formed. The other structure results, or, as some say, is evolved, only after many series of changes of a very complex character have been completed. Once destroyed, the structure of an organism can only be restored by a long course of similar developmental processes. In fact, there is not the faintest analogy between the structure of an organism and the structure of a stone—the structure due to the operation of living forces and the structure which is inherent with other properties in non-living matter.

2. There is the view supported by myself, and in favor of which I have adduced evidence which I believe to be perfectly convincing, that living matter has no definite structure whatever—that, in fact, its particles, and very probably their constituent atoms, are in a state of very active movement, which renders structure and fixity of arrangement impossible—this active movement being an essential condition of the living state, which latter ceases when the movement comes to a standstill. According to this view the idea of structure as belonging to living matter is inconceivable.

Now we know of no state in which non-living matter exhibits any analogy with matter in the living state, so that the cause of the state under consideration must have reference to the living state, and to that only; and to reassert, as many continue to do, that the phenomena manifested by living matter are to be accounted for by the properties of the material particles, is silly and perverse; and though the view of the peculiar nature of the vital power here put forward and based upon a consideration of the phenomena of living matter, may be ridiculed by materialists, every one who thinks over the matter will see at once why this course is taken by them.

Professor Huxley, in his article "Biology," in the "Encylopædia Britannica"—without defining what he means by the words "molecular" and "machine"—assures his readers that "a mass of living protoplasm is simply a molecular machine of great complexity, the total results of the working of which, or its vital phenomena, depend, on the one hand, upon its construction, and, on the other, upon the energy supplied to it; and to speak of vitality as anything but the name of a series of operations, is as if one should talk of the 'horologity' of a clock."* This is the sort of teaching that has long retarded the progress of thought, and affords an example of the puerile objections palmed off on the public as scientific criticism, and supposed to be sufficient to controvert evidence founded upon observation, and arguments based on facts which any one may demonstrate. Is it not most wonderful that Professor Huxley can persuade himself that a single reader of intelligence will fail to see the absurdity of the comparison he institutes between the invisible, undemonstrable, undiscovered "machinery" of his supposititious "molecular machine" and the actual visible works of the actual clock, which any one can see and handle, and stop and cause to go on again?

Magnify living matter as we may, nothing can be demonstrated but an extremely delicate, transparent, apparently semi-fluid substance. But observations on some specimens under certain advantages of illumination, and with the aid of the very highest magnifying power that can be brought to bear, favor the conclusion that living matter should be regarded as consisting of infinite numbers of infinitely minute particles, varying much in size, and possibly capable of coalescing, free to move amongst one another, as they exist surrounded by a fluid medium which contains the materials in solution for their nutrition, and other substances. †

[To be concluded in our next issue.]

† From the Journal of the R. M. S.

TRICHINÆ IN MEAT.

A short time ago the public was greatly excited over the introduction into France of trichinated meat. It is remembered that the first case of trichina was noticed at Lyons on provisions exported from America. As regards the importance of this question, it is sufficient to state that, according to official documents, the importations of salt pork and of lard amounted in 1880 to 46,164,000 kilogrammes, of which 37,102,000 kilos. came from the United States. The prefecture of police ordered the inspectors of slaughter houses to examine all the incoming specimens of salt and smoked pork in the different stations and especially that of Batignolles. This station received indeed all the envoys of Havre, where four-fifths of American imports are disembarked. Unfortunately there was a great disproportion between the service of inspection and the continually increasing extent of the provisions. The result was an encumbering of provisions suspected of being contaminated at the points where the inspection took place. A certain number of merchants, moreover, desirous of entering into the possession of their merchandise, so as not to retard its delivery, have sought to evade inspection, and in order to obtain this end took advantage of the small number of inspectors, who, being grouped at certain points, thus allowed certain entries to be free from all verification; they have accordingly introduced their merchandise at these points.

The administration should put an end to this invasion. The Secretary-general of the police departments, anxious for the public health and its interests has, in concert with the Prefect of police, taken opportune measures and charged the municipal Laboratory to investigate the trichinated provisions that have passed the ports. The officers of the Laboratory, accompanied by a commissary of police, proceeded to those accused of introducing un-inspected provisions. Microscopic examination has in several cases shown the presence of trichinæ. We have, therefore, thought it useful to demonstrate the procedure, very simple, which is pursued in the investigation of this infection.

A specimen is taken from the muscular portion, and as much as possible in the vicinity of the bone or tendons, which is very easily accomplished by means of the instrument represented in figure 1. A small fragment of meat is

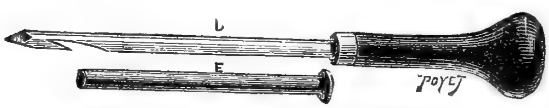

FIG. 1—INSTRUMENT FOR EXTRACTING SPECIMENS OF MEAT, AND ITS SHEATH.

cut with a scissors from the fibres, and stretched on a plate of glass. A drop of diluted alcohol is added or some potassa, and the preparation is levelled by covering it with a lamina of glass (fig. 2); then placed on the stage of the microscope. A magnification of 70 diameters is sufficient for seeing the trichina quite distinctly. It is preferable, nevertheless, in order to work more rapidly and to distinguish the trichinæ of the striated muscular fibres, to magnify it 140 diameters.

Fig. 3 represents one of these preparations seen under the microscope; two trichinæ are enclosed in their cyst and the third has free movement over the muscular tissue.

The parasites that are met with on the trichinated meats of America are not dead, as is proved by the following experiments. A cut is made is made into the trichinated meat; distilled water is used instead of alcohol, and we begin our search for a free trichina. The preparation is then placed upon Ranvier's hot platinum, and the temperature is raised to 40° C. At the end of a certain time, displacements of the trichina will be observed. These movements become stronger from 42° C. to 45° C, and at 50° C. the animal dies.

The municipal laboratory, in employing this very simple mode of investigation has, as we have mentioned, been able to detect contaminated provisions in Paris, and has caused their seizure.

Moreover, as soon as the invasion was known, the necessary precautions were announced to the public, and all the journals have reproduced the circular of the minister.

Trichinated meat, which has been sufficiently cooked in order that the central portions attain at the least a temperature of 60° C., can be eaten without danger; for this purpose, each kilogramme of meat should be cooked about an hour.

The municipal Laboratory adds that it would be advantageous to add vinegar during the cooking.

Such are the means taken at first by the administration to oppose the importation of trichinated provisions.

It remains still to give a decision in regard to provisions stopped at the port as suspected. The inspectors being few in number, rejected a whole chest as soon as they discovered a trichina. It was hardly possible to do otherwise, unless a veritable army of microscopists was at hand, as is done for instance, in Germany, or the pork shop keepers be responsible for the sale of trichinated pork—a procedure which would set 18,000 microscopes in pursuit of the infection.

M. Pasteur, who was consulted upon the question, whether all the provisions of a chest should be seized, if only a single trichinated fragment had been encountered, replied in the affirmative, basing his decision upon the following reasons:

"It is not because I believe in a direct contamination caused by the wanderings of trichinæ from one piece to another, but, in addition to the fact that this contamination can be made through the falling of trichinated *débris* upon those which are not, the separation becomes illusory through the difficulty of effecting it. Finally, a trichinated piece may appear healthy, even after a careful examination."

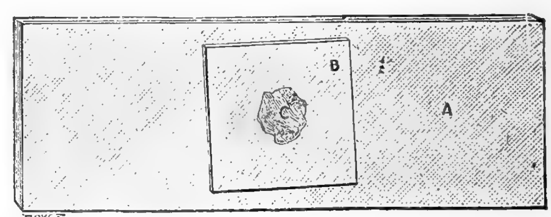

FIG. 2—TRICHINOUS MEAT PREPARED FOR MICROSCOPICAL EXAMINATION. A. GLASS SLIDE. B. THIN GLASS COVER. C. PORTION OF TRICHINOUS MEAT.

The "*Concile de l'Hygiène et de la Salubrité*" attached to the prefecture of police has noticed the impossibility of examining under the microscope all the salted provisions exported from America. As but a small quantity chosen from each cask can be examined, the Council has formed the opinion that the only efficacious means of saving the public health should be to prohibit absolutely the importation of American salted provisions into France. And to prevent the consumption of trichinated meats already introduced, the Council, adopting the view of M. Pasteur, has expressed the opinion that the admistration should destroy all the contents of casks enclosing several pieces that are known to be infected with trichina.

In this state of affairs, we believe that immediate prohibition would be the best course for the government to follow. We will recall, besides the fact that Spain, Portugal, Greece, etc., have prohibited American provisions; that Italy has prohibited all imports of pork; that Germany has interdicted the entrance of any minced pork meat coming from America, and finally that Hungary has taken like measures.

It has been objected that a prohibition would deprive the working class of a large quantity of cheap meat; another objection is the hinderance to commerce. These reasons do not appear valid to us, if there be real danger for the public health, and if there be, as we have said, and as the experiments of M. Chatin show still, living trichinæ in American hams. The danger resides especially in the use of strings preserved in brine, which enter into the composition of pig's cheese and of sausages and hashes of all kinds, such as the pork-seller delivers them, that is to say, always imperfectly cooked.

It is possible that a person may partake of trichinated meat, before its contamination has been noticed, and if a case of trachinosis be not remarked, it is only because the diagnostic of the disease is but little known, and has no positive character. Waiting until the labors of German physicians, which are but little spread in France, enlighten us on the symptoms of this affection, we deem it useful to examine under the microscope the faeces of those suffering from typhoid fever, in order to find out whether, under the cover of this malady, there is not, as often happens, a case in point of trichinæ eliminating themselves in part by this way.—*La Nature.*

TRICHINOSIS.

Dr. E. C. Wendt presented to the New York Pathological Society, April 13th, specimens illustrating Trichinosis. The slides under the microscope showed muscular trichinæ in a free state. They exhibited different degrees of parasitic development, although they were all taken from the same woman. The infested muscles were obtained from a recent fatal case of the disease which had occurred in Hoboken. For the history of the case he was indebted to Dr. W. T. Kudlich of that city. The whole course of the malady, from the initial enteric symptoms through a typhoid stage with intense muscular pains to the lethal termination, was so typical that the detailed clinical account of this case might be omitted. It should be stated, however, that shortly after the young robust wife fell ill, the husband also took to his bed with well-marked symptoms of trichinosis. In view of the present agitation of the public mind over the wholesale prohibition of American pork by the Continental powers, it might be of interest to remember that in the present instance the disease was unmistakably traced to a home product. The living parasites were used for

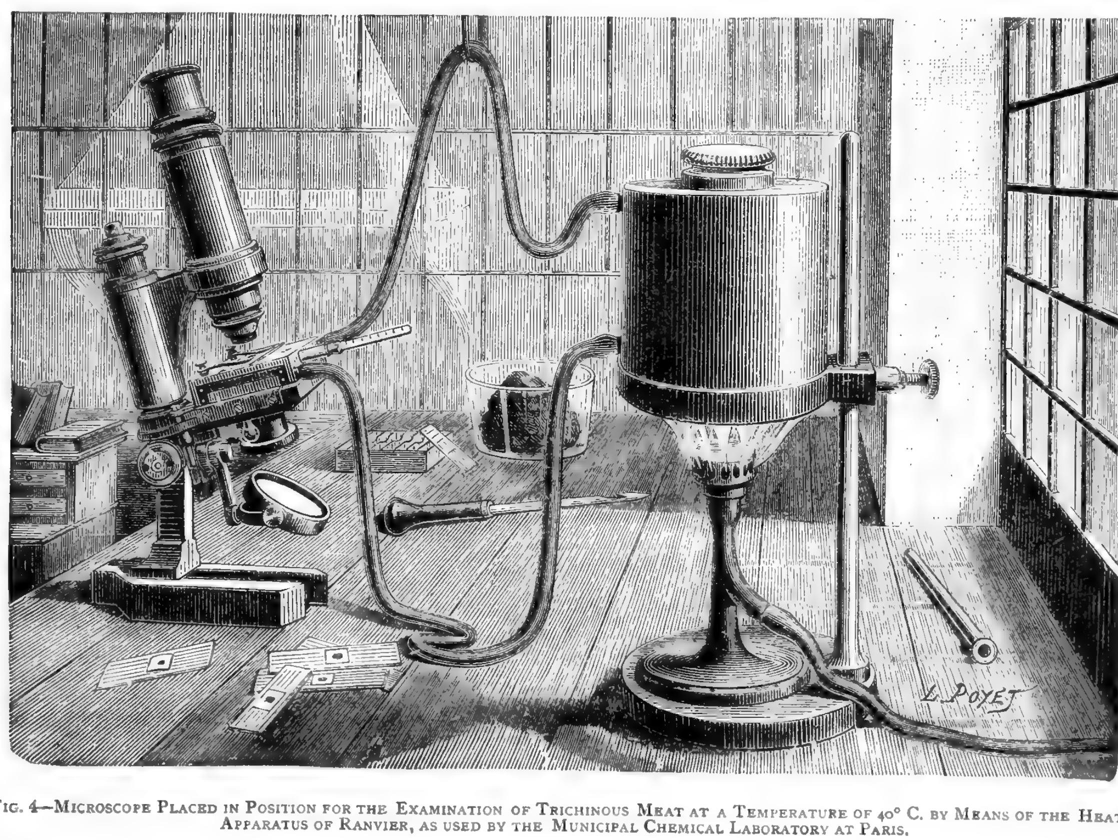

Fig. 4—Microscope Placed in Position for the Examination of Trichinous Meat at a Temperature of 40° C. by Means of the Heating Apparatus of Ranvier, as used by the Municipal Chemical Laboratory at Paris.

purposes of experimentation; and, while entirely new facts were not elicited, a few words might be said as to the results of various trials.

Encapsulated trichinæ were notoriously tenacious of life; but here were the immature, only recently emigrated parasites, still wandering about in the muscles. A few of the animals had indeed already assumed the position of a spiral coil, which was the preparatory stage of encapsulation. But the majority were either stretched out or twisted at either extremity. Little pieces of the woman's muscles were exposed to the action of cold, being several times frozen. Examination, four days afterward, found them apparently quiescent. A gradual elevation of temperature up to about 100° F. soon proved that life was not extinct, in so far, at least, as active motions can be interpreted as an indication of vitality. Ten days later the parasites were still alive. Some of the flesh was then allowed to undergo partial putrefaction. Even then the animals were living. This was thirteen days after the death of the woman.

On the day following the autopsy, some fresh muscle was teased, and, there being an abundance of living trichinæ, many thus became isolated. The animals were never seen to actually creep along in a definite direction. Their movements resembled the unfurling and recoiling of a pennon. Nevertheless, a change of place was now and then fortuitously effected. Next, the parasites were subjected to the action of different reagents. Saliva produced no visible effect upon them. Dilute acids resulted in increased activity of motions. Alkalies made them sluggish. Concentrated solutions of both rapidly killed them. In carbolic acid they squirmed and writhed before dying. Glycerine, contrary to what was supposed, did not immediately kill them. Some lived for ten minutes after its addition. Finally, however, the worms became shrivelled up into almost shapeless filaments. If previously heated, however, they retained their form to a great extent.

A little of the fresh muscle was submitted to artificial digestion by being placed in a suitable fluid and exposed for twelve hours to about body heat. The muscle was in great part dissolved at the end of this time, and many free parasites were found in the liquid. But they were, if anything, less active than they had been, and, as soon as the liquid was allowed to cool, their movements ceased, to be renewed, however, on reheating the slide. A noteworthy fact, and one of great interest, was that the trichinæ had unquestionably grown. But, though their size was now increased, and although indications of sex could be barely perceived, a distinct evolution into mature males and females was not obtained. It must be remarked, however, that future experiments at such artificial breeding may be more successful. Through an inadvertence the continuation of the artificial digestion was interfered with, the animals being killed by over-heating.

Portions of partially putrified muscle were placed in vials containing water, with the addition of a small proportion of glycerine, carbolic acid, and alcohol. In this liquid the parasites were maintained in a comparatively good state of perservation, showing the details of their interesting organization with satisfactory clearness. Permanent specimens, no matter what technique of preparation may be employed, were never found as perfect as recent ones made from bits of muscle thus kept. Of course, fresh would answer still better than partially decayed muscle.

Concerning the pathological condition of the infested muscles, the changes there found were the frequently described conditions of acute myositis accompanied by vitreous metamorphosis, cloudy swelling, and fatty degeneration. In some places the interfascicular hyperæmia and small-celled infiltration were beautifully seen.

The subject of trichinosis had occupied his attention for a number of years; but this was not the place to discuss the many questions which presented themselves; only one further remark as to the diagnostic value of examining small bits of muscle removed from accessible regions in patients suspected of trichinosis. If the animals were found, of course the evidence was incontrovertible. But, *vice versa*, a conclusion could not be arrived at. This he wished to emphasize, because a contrary opinion was prevalent in some quarters. In the present fatal case of trichinosis, small bits of the deceased woman's muscles were torn from the gastrocnemius and deltoid muscles; and while some specimens had contained numerous parasites, others had been found without them. In the diaphragm, intercostal muscles, and other well-known places of predilection, every examined specimen showed abundant parasites.

Dr. Carpenter's observation at the dead-house of Bellevue Hospital had been that encysted trichinæ were found more frequently in the pectoral muscles or the diaphragm than in the deltoids or the gastrocnemii.

The President (Dr. T. E. Satterthwaite), remarked that the subject of trichinosis was now of very great interest to the country at large, and we should be anxious to get all the light possible upon it. Though a vast amount of labor had been expended on the origin, clinical history, and treatment of trichinosis, we have good reason to suppose it was seldom recognized during life, and even after death would often escape notice, unless the examiner had his attention specially directed toward the possibility of its occurrence. Consequently our present statistics could not be relied upon in forming an opinion as to its prevalence. One of the points on which we needed more information was the period of incubation. This was variously placed at between ten and forty-two days; or, rather, according to our present ideas, it would take ten, but might take forty-two days for the young trichinæ to appear in the muscles after the infected meat had been eaten.

Now, it was just upon this variable period that the dealers relied chiefly when they were prosecuted for selling trichinous meat. As most infected persons are Germans, who are in the habit of eating uncooked meat, more or less continuously, it is generally easy for the accused to show that other hams or sausages were eaten during this period of forty-two days, and as statements are to be found that a limited number of living trichinæ have been eaten without harm, it is almost impossible to secure conviction. Dealers therefore do not ask for an examination of hogs or their products, nor are they afraid fo being convicted, even should they sell trichinous meat.

Now it is particularly important to determine whether or not there is in this variable time between the ingestions of the animal and the subsequent migration of the larval form, and more experiments should be made on animals to determine it.

Then another point is important, which is, How frequently is trichinosis met with? In Europe it is said to occur in from one to two per cent. of all cadavers. In this country we have as yet no trustworthy data; at least this conclusion may be drawn from the recent report of late Assistant-Surgeon Glazier, to the U. S. Marine Service. Still we know that eight hogs out of a hundred were once found trichinous in Chicago, and though this percentage has been once exceeded in Germany, it is a large one, and invites consideration.

Especially important was, he thought, the determination whether living trichinæ can really be swallowed with impunity, if in small numbers, and, if so, what quantity is necessary for infection; whether such trichinæ be the larval or fecundated forms; and whether emetics or purgatives were not afterward employed to expel them, as in this latter case it is reasonable to suppose they might have been removed without harm to the individual.

The President further remarked that there were now no specially appointed officials who made it their duty to inspect meat, as was formerly done. A diminished appropriation led to the suspension of this work.

BOOKS RECEIVED.

ISLAND LIFE; OR, THE PHENOMENA AND CAUSES OF INSULAR FAUNAS AND FLORAS, including a revision and attempted solution of the Problem of Geological Climates, by ALFRED RUSSEL WALLACE.—Harper Brothers, New York, 1881.

The authors of the theory of evolution undoubtedly feel the responsibility involved in revolutionizing one of the most important branches of Science; it is therefore natural to find both Dr. Darwin and Mr. Wallace devoting their best energies to aid evolutionists in placing "the theory" upon a sound basis.

Perhaps one of the strongest arguments that can be advanced in favor of evolution is the fact, that it offers a key for solving difficulties encountered by naturalists, which hitherto were inexplicable, or accounted for by a line of reasoning now shown to be erroneous.

The distribution of animal life upon the globe, which forms the subject of the present work, exhibits in a strong light some of the fallacies of the older naturalists, and the value of the theory of evolution in interpreting the work of Nature.

The old school of naturalists explained the geographical distribution of animals by believing, that "the several species of animals and plants" were special creations, and consequently assumed, that every animal was *exactly* adapted to the climate and surroundings amid which it lived, and that the only, or, at all events, the chief reason why it did not inhabit any other country was that the climate or general condition of that country was not suitable to it.

In the present state of knowledge respecting the fauna and flora of the whole world, it is not difficult to prove that other reasons must be found to account for the phenomena met with in the general distribution of animal life, and Mr. Wallace makes the case quite clear by giving some striking illustrations.

It is true that hot climates differ from cold ones in all their organic forms, but its effects are by no means constant, but are irregular and uncertain, and the contrast does not bear any proportion to the difference of temperature.

For instance, between frigid Canada and sub-tropical Florida there are less marked differences in the animal productions than between Florida and Cuba or Yucatan, which are much more alike in climate and so much nearer together. So the differences between the birds and quadrupeds of temperate Tasmania and tropical North Australia are slight and unimportant as compared with the enormous differences we find when we pass from the latter country to equally tropical Java, and if we compare corresponding portions of different continents, we find no indications that the almost perfect similarity and general conditions have any tendency to produce similarity in the animal world. The equatorial parts of Brazil and of the west coast of Africa are almost identical in climate and in luxuriance of vegetation, but their animal life is totally diverse. In the former we have tapirs, sloths, and prehensile-tailed monkeys; in the latter, elephants, antelopes, and man-like apes; while among birds, the toucans, chatterers and humming-birds of Brazil, are replaced by the plantation-eaters, bee-eaters and sun birds of Africa. Parts of South-temperate America, South Africa and South Austalia correspond closely in climate; yet the birds and quadrupeds of these three districts are as completely unlike each other as those of any parts of the world that can be named. The present work, although complete in itself, is one of a series prepared by Mr. Wallace to account for the geographical distribution of animal life, by the theory of evolution, and being the result of many years study by one of the most eminent of living naturalists, will command the attention of all who desire to find a true solution of the subject.

Some of the most remarkable and interesting facts in the distributions and affinities of organic forms are presented by *islands* in relation to each other and to the surrounding continents. Yet their full importance in connection with the history of the earth and its inhabitants has hardly yet been recognized; and in order to direct the attention of naturalists to this most promising field of research, Mr. Wallace has restricted himself in the volume now before us, to the elucidations of some of the problems there presented to us.

Such then is the scope and purpose of "Island Life, or the Phenomena and Causes of Insular Faunas and Floras," involving the study of a class of subjects embracing in their very nature the visible outcome and resudical product of the whole past history of the earth. There is no royal road to the acquisition of knowledge, and to prepare those readers who have not been trained in such studies to appreciate the conclusions drawn, Mr. Wallace in the first eight chapters devotes much space to the explanation of the mode of distribution, variation, modification and dispersal of species and groups, illustrated by facts and examples; of the true nature of geological change as affecting continents and islands; of changes of climates, their nature, causes and effects; of the duration of geological time and the rate of organic development.

The aim of Mr. Wallace in this work is the development of a clear and definite theory, and its application to the solution of a number of biological problems. That theory may be briefly stated as follows: That the distribution of the various species and groups of living things over the earth's surface, and their aggregation in definite assemblages in certain areas, are the direct result and outcome of a complex set of causes, which may be grouped as "*biological*" and "*physical*." The *biological* causes are mainly of two kinds—first, the constant tendency of all organisms to increase in numbers, and to occupy a wider area, and their various powers of dispersion and migration through which, when unchecked, they are enable to spread widely over the globe; and secondly, those laws of evolution and extinction which determine the manner in which groups of organisms arise and grow, reach their maximum, and then dwindle away, often breaking up into separate portions which long survive in very remote regions. The *physical* causes are mainly of two kinds. We have, first, the geographical changes which at one time isolate a whole fauna and flora, at another time lead to their dispersal and intermixture with adjacent faunas and floras, and here Mr. Wallace endeavored to ascertain and define the exact nature and extent of these changes, and to determine the question of the general stability or instability of continents and oceans; in the second place he also investigated the exact nature, extent and frequency of the changes of climate which have occurred in various parts of the earth, because, as it may be supposed, such changes are among the most powerful agents in causing the dispersal and extinction of plants and animals. The importance attached to the geological climates and their causes, induced Mr. Wallace to discuss this branch of the subject at some length, and the most recent investigations of geologists, physicists and explorers were fully called into requisition.

Mr. Wallace next applied these facts and theories to explain the phenomena presented by the floras and faunas of the chief islands of the globe, which are classified, in accordance with their physical origin, in three groups or classes, each of which is shown to exhibit certain well marked biological features.

Mr. Wallace then defines what are called "*areas of distribution*," as applied to species, genera and families, and, taking British mammals and land birds, he follows them over the whole area they inhabit, and obtains a foundation for the establishment of "*zoological regions*," and a clear insight is formed of their character as dis-

tinct from the usual geographical divisions of the globe.

All these facts are then shown by Mr. Wallace to be a necessary result of the "*law of evolution*." The nature and amount of "*variation*" are exhibited by a number of curious examples; the origin, growth and decay of species and genera are traced, and all the interesting phenomena of isolated groups and discontinuous generic and specific areas are shown to follow as logical consequences.

The remaining subjects discussed by Mr. Wallace carry him into the realm of fierce controversies, and relate to theories involving problems awaiting further investigations for their solution. One of these subjects —The Position of the Great Oceans and Chief Land Areas—is dealt decisively by Mr. Wallace, who claims that "on the whole they have remained unchanged throughout geological time." This declaration of the author has been already challenged, and we shall watch with interest if Mr. Wallace is capable of maintaining his position on this subject.

Perhaps the most valuable part ot this work is the discussion of the question of geological time as bearing on the development of the organic world, leading to an investigation as to the exact nature of past changes of climate.

In answer to those who may consider the subject last spoken of as unsuited to such a work as the present, the author claims that, although many of the causes introduced are far too complex in their combined action to enable us to follow them out in the case of any one species, yet their broad results are clearly recognizable, and we are thus enabled to study more completely every detail and every anomaly in the distribution of living things, in the firm conviction that by doing so we shall obtain a fuller and clearer insight into the causes of nature, and with increased confidence that the "mighty maze" of Being we see everywhere around us is "not without a plan."

No person should offer an opinion on the "theory of evolution" who has not studied this work of Mr. Wallace, for it forms an essential part of the literature ot the subject.

NOTE IN REGARD TO "PRIMITIVE DESIRES."

In a communication published in an earlier number of "SCIENCE," (No. 29, Jan. 15, 1881) Dr. Clevenger, of Chicago, discusses the relalation existing between the desire for food, and the desires connected with the multiplication of the species. He appears to draw the conclusion that hunger is the primitive desire.

There are some observations made by alienists, which strongly tend to confirm Dr. Clevenger's theory.

It is well known that under pathological circumstances, relations obliterated in higher development and absent in health, return and simulate conditions found in lower and even in primitive forms.

An instance of this is the *pica* or morbid appetite of pregnant women, and hysterical girls for chalk, slate pencil and other articles of an earthy nature. To some extent, this has been claimed to constitute a sort of reversion to the oviparous ancestry, which like the birds of our day sought the calcareous material required for the shell structure in their food (?)

There are forms of mental perversion, properly classed under the head of the degenerative mental states, with which a close relation between the hunger appetite and sexual appetite becomes manifest.

Under the heading "Wollust.'—Mordlust-Anthropophagie" Krafft. Ebing describes a form of sexual perversion, where the suffered fails to find gratification unless he or she can bite, eat, murder or mutilate the mate. He refers to the old Hindoo myth of *Çiva* and *Dúrgá* as showing that such observations in the sexual sphere were not unknown to the ancient races. He gives an instance, where after the act, the ravisher butchered his victim, and would have eaten a piece of the viscera, another where the criminal drank the blood and ate the heart, still another where certain parts of the body were cooked and eaten.*

In reference to this question, Dr. Clevenger some time ago sent me the following interesting letter, which, anticipating much that I should otherwise say, may find a place here.

CHICAGO, *February* 17, 1881.

Dear Doctor:

The suggestions that you made, in a recent note to me, on the extension of the Hunger Theory to Man, are of too much value not to be published. Professor E. D. Cope kindly sent me the reprint of an article of his entitled "The Origin of the Will" which appeared in the *Penn Monthly*, for June, 1877, wherein the Professor takes the ground that Hunger is the primitive desire. "The movement of the Amœba in engulfing a Diatom in its jelly is as much designed, as the diplomacy of the statesman or the investigations of the student, and the motive may be the same in all three cases; viz.: hunger" (p. 438). "In the lowest animal the first movement was doubtless a mere discharge of force; but the first designed action, the appropriation of food, was due to a sense of want or hunger, which is a form of pain. This was followed by gratification, a pleasure, the memory of which constituted a motive for a more evidently designed act, viz.: pursuit "(p. 446). I am rather inclined to reverse the conception of the unconscious being derived from the conscious act and conclude that the pain of hunger is akin to the desire barium may have for sulphuric acid or any molecule may have for another.

Yours truly,

S. V. CLEVENGER.

I cannot see the necessity of considering "the movement of the Amœba, as designed as the diplomacy of the statesman etc." It is either a truism according to one reading, or utterly erroneous—according to another. If "as designed" in the above means—based on the same broad summation of registered impressions potent in intellectual activity, I must say that due regards have not been paid to very fundamental facts in framing the clause criticized.

E. C. SPITZKA.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. No notice is taken of anonymous communications.*]

To the Editor of "SCIENCE:"

In reply to the remarks made by Mr. Morris about my communication to you (No. 43), I would like to say a few words.

In the first place I beg to enter a protest against the gentleman's suggestion with which he prefaces his reply, to wit:

"The main difficulty seems to be that I have gone counter to certain authors whom they are disposed to consider as authorities," meaning Prof. Dolbear and the writer. As to this objection, so often raised at the present moment, it seems to me that it is only applicable in case the authority is adduced in place of an argument, or in order to fortify it. As a rule, men of an independent turn of mind do not believe or accept theories because this or that authority has advanced them, but because they are plausible to them—perhaps only as long as they do not hear of any other in regard to the subject. But, if they should adopt another theory in place of one formerly held, it is certainly not on account of the fact that it has emanated from a certain authority, but because their mode of thinking and working out problems agrees with that which originated the theory, *i. e.* the authority's.

Since I have nowhere in my letter quoted any authority specifically, gathering my arguments from the works of those men whose writings are most congenial to my frame of mind, and from them weaving the net of my intellectual product with an occasional glimpse from my

* Ueber gewisse Anomalien des Geschlechts-triebes. Von Kraft-Ebing, Arch f. Psychiatrie VII.

own brains, I would seem to be justified in resenting this peculiar argumentation.

I might, in view of this unjust criticism, retort that perhaps it is altogether a better way to rely on an occasional authority, a good number of whom are towering up high above the sea of opinions as trustworthy beacons of light, than to steer along without looking up to them as guides now and then, and perhaps be wrecked on some unknown shore or unsuspected reef. The tendency to scoff at authorities because they are authorities, is just as pernicious as that to put faith in them for this same reason only.

As to my somewhat confused idea of heat, of which Mr. Morris takes the liberty to speak, I confess that I have supposed he understood the difference between radiant and conducted heat,* and he also was aware what was understood by universal consent with the expression "work." I should not have undertaken this discussion on physical subjects had I not been convinced that the terms to be used were agreed upon. However, Mr. Morris seems to be in a fair way to come down to the very last questions about the nature of motion and matter.

As to "*latent heat*," if Mr. Morris, Sir Wm. Thompson,* and many others persist in calling heat that which is not heat, they are at liberty do so; yet they are wrong.

This I have conclusively shown, and Mr. Morris has not even tried to argue on it. Nor has he thought necessary to argue in regard to my remarks on his erroneous conception of the action of gravity. He only reiterates his assertion that the energy with which a body weighing a million pounds would fall on a body weighing one pound is the same. In order to prove this he says "we must add," and add and add, and then *one* will develop just as much energy as a *million!*

It seems futile to argue longer on a proposition that is in direct conflict with Newton's first law. If Mr. Morris has no room for the latter in his Universe, I must respectfully decline to enter it, preferring to stay outside of it in company with Sir Isaac and various others equally sound and reliable.

If Mr. Morris says motion is motion and cannot possibly become anything else, he is certainly right; but he forgets that there are certain *forces* for which we have as yet not been able to *prove* conclusively that they *are* motions. Of course, Mr. Morris has told us how he conceives of this relation between gravity and molecular motion, so called. (And there is cohesion and magnetism yet to account for.) But his explanations are wide away from the mark, which lies in an entirely different direction.

The combined action of all the radiant energy emanating from an infinite number of celestial bodies is transmitted in every direction through the Universe, and by oscillations, vibrations, and undulations of the attenuated matter (*not ether*—there is no ether!) which fills the interstellar spaces. In striking the surface of the various orbs, great and small, it exerts a uniform pressure, gravity.

Respectfully,
GEO. W. RACHEL, M. D.

NEW YORK, *May* 30, 1881.

THE "*Astronomische Nachrichten.*"—It is announced that after the termination of the current volume, by authority of the Prussian Government, a new arrangement for the management of this journal will take effect. It will be edited by Prof. A. Krueger, the director of the Observatory at Kiel, in co-operation with the president of the "Astronomische Gesellschaft," of which association it will become a recognized organ.

* SCIENCE, Vol. I. p. 245. L. 24 fr. below.

** Admits that t is not heat, but favors the expression for convenience.

To the Editor of SCIENCE:

I can scarcely permit such curious statements as made by Prof. A. E. Dolbear, to pass unnoticed. In "SCIENCE" No. 43, he says:—"The decaying stump that shines by night, has a temperature not appreciably higher than surrounding objects." Can it be possible that he compares the state of matter in ancient wood, with the inconceivably rare gas whence Neptune was formed? Several cubic miles of it only weighed a grain, as has been proven by Helmholtz. It was in dissociation, no two atoms touched, therefore we assert with reason that it was absolutely cold and dark. The atoms in the stump had been in intimate association; indeed their organization was once so complex as to have been endowed with that most mysterious of all entities—LIFE!

When decaying, it was surrendering the force whose work organized it, and its faint luminosity was a portion thereof. The light was a result of preceding work, but in interstellar space, where atoms were yards apart, no previous work had been performed, and no force evolved whether heat, light, or any other save gravity and the slowest radial motion possible.

EDGAR L. LARKIN.

NEW WINDSOR OBS., Ill., *June* 13, 1881.

REPLY TO DR. J. J. MASON'S LETTER.

The writer of the review referred to, states that notwithstanding the construction which Dr. J. J. Mason now desires to see placed upon his words, the most careful reader would fail to draw any other conclusion from Dr. Mason's article, than that it was written in support of the theory that large cells are motor, and that sensory cells are small. It is true as Dr. Mason states that the sentence just preceding the one quoted in his letter refers specifically to the spinal cord of the turtle. But it is none the less true that the whole paragraph polemizes against a statement of Stieda's that the observations "have great weight against the conclusion that only the large nerve cells are connected with motor fibres," as not representing the ordinary view. In the earlier part of his article, Dr. Mason indeed goes so far as to question the statements of our best cerebral antomists that certain very large cells are connected with the auditory, *i. e.* a sensory nerve, and this in obedience to the same theoretical bias which is manifested a few lines further on in this wise. "I would suggest, however, to those who may feel disposed to regard these cells (large cells of auditory nucleus and oblongata) as connected with the sense of hearing, that such a view involves giving to this apparatus in its central portion, a structure almost identical with one universally admitted to be motor, like, for example, that concerned in raising the lower jaw; whereas in the central structures for vision and olfaction *the cells are all very small.*" (Italics are own.) What other than the size of the cells and their nuclei does Dr. Mason refer to when he speaks of a "structure universally admitted to be motor?" Especially when it is borne in mind that immediately after he claim that all sensory cells are very small. In view of all this Dr. Mason's statement that no such claims as the one imputed to him by the reviewer had ever been made by him "in any form by hint, inference or otherwise," must have been penned in strange forgetfulness of what he has laid down in his published article. The reviewer can only interpret the remonstrance as an abandonment by Dr. Mason of his previous position. Every statement in the quoted paragraphs is simply erroneous, and to bring Dr. Mason face to face with facts that he has questioned, the reviewer refers to Dr. Mason's statement that the cells connected with vision "are *very* small," and the reliable findings of Professor Packard, who happened to state that in the locust these cells are very large in relation to the other cells of the nervous system.

R. C. S

THE CONSERVATION OF ELECTRICITY.

The following is from the preface to "Elementary Lessons in Electricity and Magnetism," by SILVANUS P. THOMPSON, now in the press.

"The theory of electricity adopted throughout is that electricity, whatever its nature, is *one*, not *two*. That this electricity, whatever it may prove to be, is not *matter*, and *energy*; that it resembles both matter and energy in one respect, however, in that it can neither be created nor destroyed. The doctrine of the *Conservation of Matter*, established a century ago by Lavoisier, teaches us that we can never destroy nor create matter, though we can alter its distribution and its forms and combinations in innumerable ways. The doctrine of the *Conservation of Energy* which has been built up by Helmholtz, Thomson, Joule, and Mayer during the last half century teaches us that we can neither create nor destroy energy, though we may change it from one form to another, causing it to appear as the energy of moving bodies, as the energy of heat, or as the static energy of a body which has been lifted against gravity or some other attracting force into a position whence it can run down, and where it has the potentiality of doing work. So, also, the doctrine of the *Conservation of Electricity*, which now is growing into shape, but here first enunciated under this name, teaches us that we can neither create nor destroy electricity, though we may alter its distribution—may make *more* to appear at one place and *less* at another—may change it from the condition of rest to that of motion, or may cause it to spin round in whirlpools or vortices which themselves can attract or repel other vortices. According to this view all our electrical machines and batteries are merely instruments for altering the distribution of electricity by moving some of it from one place to another, or for causing electricity when heaped up in one place to do work in returning to its former level distribution. Throughout these lessons the attempt has been made to state the facts of the science in language consonant with this view; but rather to lead the young student to this as the result of his study than to insist upon it dogmatically at the outset.'

A WATER CARRYING TORTOISE.

At a meeting of the Academy of Sciences the other evening, a very fine specimen of the desert land tortoise, from Cajon Pass, San Bernardino county, California, was received. The specimen had been carefully prepared, and was as large as an ordinary bucket. The tortoise is a native of the arid region of California and Arizona, and Prof. E. T. Cox, who was present, related a curious circumstance connected with it.

He found on dissecting one of them that it carried on each side a membrane, attached to the inner portion of the shell, in which was about a pint of clear water, the whole amount being about a quart. He was of the opinion that this water was derived from the secretions of the giant barrel cactus, on which the tortoise feeds. This cactus contains a great deal of water.

The tortoise is found in sections of country where there is no water, and where there is no vegetation but the cactus. A traveler suffering from thirst could, in an emergency, supply himself with water by killing a tortoise. They are highly prized by Mexicans, who make from them a delicious soup. The foxes of the desert attack the tortoise and finally overcome them by dragging them at times for miles.

B. B. Redding said he would try to obtain a live one for the Academy in order that its habits and peculiarities may be carefully observed and noted. He instanced being on the Gallapagos islands in 1849 and assisting in the capture of 92 land tortoises, varying from 450 to 600 lbs. in weight, which the vessel brought to San Francisco and sold for more money than the whole cargo of lumber netted at that time. They were two months on board the vessel, yet ate nothing and those killed had in them considerable quantities of pure water. They live on the high lava rocks, which rise as mountains on the island, where there are no springs or streams, and the only dependence of animal life for water is necessarily upon the irregular and uncertain rain showers.

It may be mentioned that the tortoise are of different species, though they may have the same habit in respect of carrying water. The famous edible species of the coasts of the Pacific and Indies, of which the headquarters is at Gallapagos islands, is the *Testudo Indica*. They grow to five, six, and even seven hundred pounds or more. Those found in this State are smaller and are the *Agassii* species first described some years ago by Dr. J. G. Cooper, if we recollect aright. Those Mr. Redding describes from the Gallapagos were offered water while on the ship but refused it. Yet when killed they all contained water. The place they inhabit is a dry one, lacking water. It may be that they go to the high places and obtain it from the vegetation, the same as our species does.

DALTONISM.—A Belgian Commission is making investigations on Daltonism. Their method of procedure is as follows:—On a table exposed to the bright sunlight are placed skeins of wool varying in color. The subject under examination is given, for example, a green colored one and he is told to select another of the same color. If he does so without hesitation, he is not affected with Daltonism, but he is still subjected to other trials, as for instance, the observation of colored signals at a distance. This applies especially to those employed on railways.

NEW RECORDING APPARATUS OF MOVEMENTS.—About twenty years ago M. Marey proposed to inscribe the different movements of living animals by means of a lever, as light as possible, and protected from every cause tending to set it in vibration, Since this epoch a considerable number of operations have been accomplished by the aid of this instrument; thus, the phenomena of the circulation of the blood, of respiration and of the movements of the heart have, in the employment of this method, been conclusively solved. Nevertheless one objection has been raised against these instruments: in the sometimes excedingly complicated tracings of physiological acts, the proper movements of the lever have increased the real curve of the movement which is to be inscribed. M. Marey has therefore invented and presented to the Academy a new inscriptic apparatus, the lever being reduced, which gives microscopic inscriptions, and thus can inscribe rapid movements with the greatest precision. The tracings of this instrument, which may be produced by the vibrations of the voice, or by the breath, are afterwards enlarged by projection and reduced to the necessary size. The microscopic inscription given by the new apparatus extends to an almost indefinite degree phenomena susceptible of registration.

FLUORESCENT SUBSTANCES.

SUBSTANCE.	By transmitted light.	Fluoresces.
Magdala red.................	Red	Red
Induline (acid sol.)...........	Dirty green	Red
Nigrosine (acid sol.)..........	Dirty green	Red
Tri-sulpho-acid of induline....	Blue	Red
Resorcin (di-azo compound)*..	Yellow	Vermilion
Resorcin (di-azo compound)*..	Violet red	Vermilion
Resorcin (di-azo compound)...	Green	Dark red
Resorcin (phthalic acid compound)*	Yellow	Green
Resorcin (phthalic acid and bromine compound)........	Red	Green
Amido-phthalic acid..........	Colorless	Green
Murexide (di-azo compound)..	Yellow	Green
Beta-naphthole...............	Brown	Blue
Naphthalamine*....	Colorless	Violet-blue

The four marked * are the best for exhibition purposes, the last surpassing sulphate of quinine. The fluorescence of the di-azo resorcin compound in direct sunlight shows a fluorescence not inferior to vermilion paint in brilliancy.

THE NEW COMET.

The great comet which has so suddenly flashed into our Northern sky is one of the most brilliant comets that has appeared for many years. It has a large and very stellar like nucleus which is surrounded with envelopes, very much like those of the Donati comet of 1858, which was described so well by Professor George P. Bond of the Harvard College Observatory. The dense nuclei of such comets give one the idea of a mass and quantity of matter quite different from the ordinary telescopic comets, through which the faintest stars can be seen. The tail of the present comet is now about twelve or fifteen degrees in length, and altogether this comet presents a very beautiful spectacle at three o'clock in the northeastern morning sky. The motion of the comet is three or four degrees toward the north, and it will soon reach a position where it will be visible during the entire night in the greater part of the United States.

The first duty of the astronomers will be of course to get observations of its positions and to compute the orbit of the comet. Since for this purpose observations on three days are sufficient, we shall soon have a certain knowledge of its motion. The knowledge of the orbit will decide the question whether this is the large comet whose discovery was telegraphed to Europe from Buenos Ayres by Dr. B. A. Gould, on June. 1st, and also whether it is identical with the great comet of 1807. The observations of the comet of 1807 were discussed in a very complete manner by Bessel who found its periodic time to be between 1400 and 1900 years, and it will be a curious fact if the true period proves to be only seventy four years.

This great comet also presents a good opportunity for the spectroscopists to examine its chemical nature, and a rare occasion for the study of the physical constitution of comets. No doubt these questions will be well attended to by the astronomers and students of our country.

The question of the formation of a comet's tail, and how the particles of matter are driven out from the nucleus in the direction opposite the sun has not yet been answered in a satisfactory manner, and all the facts that can be gathered from observations of this comet will be extremely valuable. In his discussion of the physical constitution of Halley's comet in its appearance of 1835 Bessel found that a repulsive force from the sun was very decidedly shown by the observations of the tail. Similar results were reached by Professor Pierce of Harvard College, Professor Norton of Yale College and by Dr. Pope in their discussion of the Donati comet of 1858. This is an interesting question and it may have an intimate relation with the theory of a resisting medium in space which has been indicated by the motion of Encke's comet.

We learn that unfortunately the weather at Washington has been unfavorable for several days past; but from the numerous good telescopes scattered over the country, we doubt not that good observations of this interesting comet will be gathered.

THE ADDRESS OF THE PRESIDENT OF THE ROYAL MICROSCOPICAL SOCIETY.

LIONEL S. BEALE, F. R. S.

(Concluded from page 297.)

One may transport oneself in imagination into infinite space, amid the never-ceasing vibrations visible and invisible—"The lucid interspace of world and world, where never creeps a cloud, or moves a wind," and may perhaps all but see combined in one mental image, as they ever course through space, suns and worlds and systems. And although at first the mind is almost lost in the contemplation of the infinite physical vastness presented it, it is nevertheless able to seize in some degree a more than shadowy conception of the exactness and regularity of the eternal movements, and to recognize the never-ceasing operation in the material universe of inflexible, unchanging law.

But he who in imagination can succeed in mentally placing himself amid the atoms in the interatomic spaces of a living particle, will be in the very heart as it were of an infinity of a very different order—infinite movement and change affecting infinitely minute particles, so very near to one another that the matter of one may as it were run into that of the other, and the masses divide and subdivide again. Of all this movement and change of particles how very little of what occurs in a portion of matter not more than the one hundred-thousandth of an inch in diameter can be comprised in one mental image? But beyond all this there is the power of prospective change, acting through years it may be, which is somehow associated with the minute particles of living matter, as well as many complex phenomena of which the mind cannot take cognizance as a whole, but must consider, as it were, one by one in several successive pictures.

Could we peer into the very substance of the living particle itself as it was increasing in size and communicating to non-living matter its wonderful properties, what should we see? What is it that happens at the moment when a little complex organic matter dissolved

in water passes from the non-living to the living state? Should we see atoms being arranged and entering into new combinations according to some physical properties inherent in the very matter—atoms combining according to their chemical affinities; or should we see the complex chemical compounds of the pabulum being changed, their elements being somehow torn asunder from their combinations, or rather quietly separating from one another in obedience to some force or power of which we cannot form any accurate conception? The most extraordinary active atomic movements must be taking place, and in the quietest possible manner. Certainly the phenomena which accompany ordinary chemical decompositions in non-living matter do not occur. No two things in this world can be more dissimilar than man's chemical laboratory and nature's laboratory in this living matter. That the formation of the germ is to be accounted for by the operation of the ordinary forces of matter is one of the most absurd of absurd propositions; but that the idea of such an origin should still be entertained and taught by a physicist or chemist is unaccountable.

There are no actions in non-living matter with which the actions of living matter can with any degree of fairness or accuracy be compared. No argument in essential particulars can be pointed out which would justify the use of the word "analogy" without doing violence to truth and cheating the reason. To maintain the identity of the vital and inorganic forces on the ground of some fancied analogy between vital action and crystallization is most wrong and willfully misleading, for the fallacy has been many times exposed and exploded. Been a crystal and living matter there is not the slightest analogy, for the one can be destroyed and caused to re-form as many times as we like, while the living matter cannot be even dissolved. In the attempt to dissolve it, it dies, and cannot be reproduced.

It is obvious that before particles of living matter pass from the living into the formed state their component atoms, or groups of them, must somehow be made to take up a definite position with respect to one another. Such changes of place as must occur can only be brought about by some peculiar force, property, or power, the action of which is temporary. Seeing that the changes in question can take place only while matter is in the temporary living state—this matter having been detached from matter in the same living condition—the force or power in question must be of an exceptional nature, and of an order different from that to which the ordinary forces or powers of non-living matter belong. This wonderful living power which is postulated causes the atoms or the particles of the matter to take up certain positions favorable to their combination in a certain definite manner. Thus certain substances are formed which have a peculiar chemical composition, and in certain cases special properties and endowments not possessed by substances that can be formed in any other way. It seems to me it would be as unreasonable to maintain that the bricks, or rather the clay of which they are made, or the silica and alumina of the clay, or the properties of the elements entering into the composition of these substances, design, fashion and build the house, as to assert that the formation of living things is due to the physical properties of the materials of which their bodies are composed. Vital power impresses as it were its seal upon the matter—upon the structures of the living organism—and ought surely therefore to be considered as above and superior to the mere stuff that it moulds. Vitality, or vital power, forces, bends, arranges, and fashions just as man himself moulds and fashions the clay he works with, only silently, invisibly, more perfectly, and in a definite and prearranged manner, and without mind or will or ingenuity, or instruments or organs,

Judging from the facts, is it not indeed more probable that the ordinary properties, the attractions, the affinities of mere matter are in suspension rather than in action, while the matter continues to be in the living state? When these properties and affinities come into play, do we not get from the matter that was alive albuminous matters, fat and other things, of known properties and definite composition? But neither these nor any definite compounds existed when the matter was living. They came into being at the moment of its death. The idea of these substances existing in the living matter is inadmissible, for if they were there, some of them could be demonstrated. Such a substance as fatty matter cannot, of course, exist in the living state; fat cannot grow and form fat out of materials which contain the elements of the substance in different states of combination, any more than granite can. If it be conceded that during the living state the ordinary properties and affinities of the matter are suspended, it will be admitted that none of the ordinary properties of material particles can be reasonably credited with the ability to interfere with the exercise of affinities; and therefore it seems reasonable to conclude that some totally different power, *vitality* or *vital power* (which same, unlike the ordinary properties of the matter, is lost or ceases to act when living matter dies), is the true cause of the exceptional state in which the material particles are held while the matter remains living.

But thought may take us yet further. Gradually passing inwards towards the centre, through vast concentric layers of particles, we arrive at last in imagination near the centre of a particle far too minute to be visible, where the atoms of lifeless matter first live. As to the actual nature of this wonderful change which occurs, we are, and from a purely physical point of view must remain, in darkness. For it is certain that the new temporary living state is absolutely district from the non-living state in which the matter existed but an instant before. Before long this will, I doubt not, be generally admitted by those acquainted with the facts and not biassed by previous confessions or beliefs.

It is invariably in living matter devoid of structure and form, that all those wonderful actions of surpassing interest which result in the development of form the most striking and structure the most elaborate, are carried on. Forces or powers, but of a non-material order, transmitted through succeeding particles of the same kind, and continuously operating, it may be upon vast quantities of matter, through centuries or centuries of centuries (millions on millions of years"), are the activities by which the re-arrangement of the elements under certain fixed conditions which eventuate in definite and predetermined form, structure, and composition, is brought about. The changes, conversions, formations in question, at present invisible and undemonstrable, require considerable time for their completion. Compared with the visible phenomena which succeed them, and which may be watched, described and delineated by us, they are slow indeed. During days, weeks and months, in darkness and in silence, arrangements and re-arrangements of the most complex character incessantly and quietly proceed, as we say, in obedience to *laws* (though we do not *know*), ere the first visible traces of the new being can be discerned by the most careful investigation.

Remember that the changes in question affect a mere modicum of matter. A grain, nay, the hundredth, the thousandth part of a grain, and far less than this may at one time constitute the material substance from which springs a tree that in its maturity will comprise tons of matter, every grain of which will be stamped with individuality. Is it not, then, most strange that in these days which surpass all previous time in the passion exhibited by men to see into the nature of things, that attention should be so much absorbed in considerations relating to the mere matter of which a living thing is made, while the study of the forces and powers which have effected the forming and shaping of the material substance is not only almost wholly neglected, but positively discouraged?

And yet these forces or powers fashion the germ and cause it to be like its predecessors, or modify its character and cause it to give rise to forms perhaps not before attained. With what shall these forces of the living world, operating so marvellously upon infinitesimal particles of matter, be compared? The changes have been likened to those which take place in the formation of crystals, which can be dissolved and caused to re-form as often as we choose; to the aggregation of particles of lifeless matter which can be made to separate or aggregate as we will; to machines which are made by us in separate pieces and afterwards put together; and to many other things between which and living particles there is not the faintest resemblance or the slightest analogy. Uninquiring, unthinking persons have been, and are at this time, misled by crude and false comparisons, and deceived by forced and fancied analogies. The coarse materialism of our day ought long ago to have been dismissed with scorn as unworthy of the age in which we live, and of the acceptance of any one who would not disgrace himself by helping to force thought back again to the point it had reached more than two thousand years ago.

No one acquainted with the facts of vital change can doubt that phenomena of the same order as those in operation to-day attended the development of primeval forms of life. For not only do we meet with living matter producing the same structures as existed during early periods, but it is probable that some of the living things now growing and multiplying are identical with some that existed in the very dawn of life-history. Unbroken *continuity, descent, derivation,* in operation through the ages without change in power or property, or alteration in form or composition; *repetition* wi'hout gain or exaltation; *continuous descent* without degradation or improvement; monotonous succession without progression or advancing evolution. Nevertheless, we are expected to accept the dictum that amid these myriads of myriads of similar organisms, here and there one more fortunate or more gifted than the rest—we are not told why, when, or how—became endowed with the marvellous power of endless modification. We are asked to believe that rigid laws uniformly operating with the same consequences, for ages, suddenly changed, and that long-imposed uniformity gave place to capability of differentiation. But if we try to realize what, according to the terms of the hypothesis must have happened in the living matter, into what a sea of fantastic conjecture do we plunge! The new or modified powers must have originated in or emanated from particles in the very centre of minute living spherules. When we consider the minuteness and insignificance as far as the mere matter is concerned, of the living particles we are referring to, many will, I think, be inclined to admit that it is at least as probable that new forms of living matter of this infinitesimal minuteness originated anew, as that forces which had been in operation for ages, under inexorable unchanging laws, were entirely and suddenly changed or removed, and replaced or supplemented by additional and very different forces obeying very different laws.

Moreover, as no direct or positive evidence of a reliable character has yet been obtained in favor of the direct conversion of non-living matter of any kind into a living form, while there is nothing to indicate that the passage from the non-living to the living was effected by gradual change, as has been suggested by some, it is as reasonable to assume that several infinitesimal life-forms with very different powers of development sprang at once into life, though the ultimate form to be assumed was postponed for ages, as that one single living form only was so formed with the power both of endless monotonous repetition, as well as of infinite and never-ceasing capacity of variation and change, one or other of these opposite attributes being accidentally exercised or capriciously taken advantage of by such of the descendants as were assured that they were above all the most fitted to survive.

Doctrines of evolution are, no doubt, an advance upon the direct mechanical formation of fully formed organisms hypothesis; but although some evolutionists have so expressed themselves as to lead us to infer that an idea so absured as the above had been entertained, it need scarcely be said the inference is their own and totally unfounded, suggested by themselves for the satisfaction of ridiculing it and exposing its inferiority to their own hypothesis. No doctrine of evolution yet put forward seems to afford any help to those who are familiar with the characters of the living matter of different organisms, as far as these can be elucidated by any means at present known. Evolutionists generally do not take cognizance of the difficulties which are so patent to microscopical observers. Some of them have hardly condescended to notice the living matter, out of which and by which all the forms of life they profess to account for are developed. It is true that it has been suggested that there are structural differences in the apparently similar manner, which structural differences result in the production of such dissimilar beings; but speculations concerning hypothetical structure are as futile as those which deal with the hypothetical form and properties of the hypothetical inhabitants of Jupiter.

All living matter is, I repeat, structureless, and it is to the power rather than to the mere matter we must look for the explanation of the marvellous differences in the beings evolved by different kinds. The similarity of various embryos of different animals has often been alluded to, and it has been said, for example, that at a certain period of development the embryo of man could not be distinguished from that of a dog. That there is a general rough resemblance is perfectly true, but, on the other hand, any one who examined the minute structure of corresponding tissues and organs, would not find the likeness so great as is supposed, while he would be struck with a great number of points of difference. Not one structure could be found in any part of one embryo which did not exhibit peculiarities by which it could be distinguished. It would, therefore, scientifically be more correct to say that the embryos were *not like one another*, than that *they were like*. But any argument based upon the likeness, if it existed, would not help the evolutionist, inasmuch as the "likeness" is far greater at an earlier stage of existence, before any form or structure whatever has appeared. Every living form comes from an equally structureless material, and the forms near one another in the scale are not more like one another than they are like forms far above or far below them. If, for example, the evolutionist would examine embryonic living matter at a very early period of development, he would discover not only that man and dog were not to be distinguished, but that not one form of living matter could be distinguished from any other form in nature; nay, the living matter which might become dog or man could not be identified by any means at our disposal, or distinguished from that which belonged to amœba or plant, and yet it is put forward as a discovery of recent date that certain properties manifested by the tissues of animals also characterize some of those plants.

But after all, the assumed likeness is but a likeness in certain general points, and those who wish us to draw certain conclusions from their statements, ought to be asked to point out how it is that every cell, every issue of the embryos they regard as being alike or identical, exhibits peculiarities and individual characteristics of its own as regards elementary arrangement, rapidity of formation, rate of growth, duration of existence, and a number of other points. Again, the statements about the changes occurring during development in the lower animals being represented by identical changes occuring during the earlier periods of development in the higher, are correct only when taken in a very rough and general

way. Such phenomena, it is said, show unity of plan, and favor the hypothesis of the descent of jelly-fishes from sponges, and of man from apes. No doubt they do if the mind is already prepared to receive such ideas, Those, however, who really study the operations of nature in her inner recesses where and while she is at work, will certainly often find where identity is affirmed, diversity really exists. Rough general resemblances can no doubt be pointed out, and be made much of, by those who do not look too closely or intently; but those who examine minutely and patiently will find that in very many cases the general resemblances will be outnumbered and outweighed by specific irreconcilable differences and individual peculiarities.

If then we examine living matter in that early period of development ere any structural peculiarities whatever have been manifested, we shall be face to face with the problem of life. For it is at this time, when the matter is without form, that the dispositions of the material particles, which at length result in the development of form, are made. Preparation is made for the division of the mass of the living matter into several portions, and for the orderly disposition of these in respect to one another, as well as in respect of the new masses which at some future time are to be detached from them. Throughout the whole period of the life of many organisms, similar wonderful changes are continually taking place, at least as respects the living matter of certain parts and organs; but we have no means of distinguishing the living matter which continues monotonously repeating similar changes, from living matter which divides and subdivides into masses, which in turn gives rise to successive generations of living particles, which may differ from one another and from all that have gone before, in *power*.

As far as I am aware, no form of the doctrine of evolution yet enunciated takes into account the phenomena of the living matter in which and by which all the changes recognized and professed to be explained are carried on. And yet it is only by these actions in living matter that evolution can be made to appear a plausible hypothesis. Only by carrying out very careful investigations on this formless, structureless living matter can we reasonably hope to obtain anything approaching an accurate conception of the wonderful working of real living nature. It seems to me that the "nature" of the evolutionist is but a fanciful and highly colored picture in which ideas suggested by investigations in stockyards and shambles are depicted, with the addition of the horrible scenes assumed by a vivid imagination to be enacted in the supposed everlasting fight for existence and scramble for mastery, in which conquerors are always being conquered by creatures just a shade more fitted to survive than themselves. Here is creation by destruction in a never-ceasing scramble going on for millions on millions of years, in which the only thing certain seems to be that the greatest misery is assured to the greatest number; life succeeding life, without good or reason or joy or hope; peaceful nature a continual massacre of experimental forms to be massacred in their turn, and these by more; a constant struggle to survive, in which success is rewarded by extermination. The "nature" of evolutionists is a very strange nature indeed, in which oppression, destruction, and tyranny seem to be the chief agents in creation and formation, development and advancement.

But besides the evolution of living forms and of the different organs, we are to believe in an evolution of matter, an evolution of worlds, of suns, of systems. Religion, law, and justice, art, science, and even thought are all products of this universal, never-ending evolution. But what is evolution, and who has given to the term an accurate definition? We shall be told there is evolution and evolution. One man's evolution goes too far, another's not far enough, and there is no general agreement as to what is meant by evolution, and whether the use of the term should be restricted to the living world or extended to the universe—though it must be obvious to any one who considers the question that the evolution of a living form and the evolution of the matter of a stone are as far removed from one another as are the question of the nature and scope of Infinite Power and the nature and properties of a gas or a metal.

Herbert Spencer has defined his "evolution" to be a change from an indefinite incoherent homogeneity to a definite coherent heterogeneity, through differentiations and integrations. But is not every one of these polysyllabic words as elastic as the word the meaning of which they are to explain? Every assertion made is wanting in proof, and most of the words may be used in totally different and even in opposite senses.

Any one who ventures to express a doubt concerning the absolute correctness of the assemblage of vague and even contradictory conjectures comprised in any hypothesis of evolution, is in danger of being abused and called names. He may be denounced to the world as a contemptible person who has made a vile and abusive attack upon some infallible authority who affirms himself to be the real discoverer of all the secrets of all the molecular machinery of creation. We now live under the most ridiculous of all forms of despotism. It has been said that we must accept such and such views or be debarred from accepting anything! But is it possible for any unbiassed person to accept implicitly doubts, vague suggestions of what may be, or can be, or might be—speculations, hypotheses, conjectures concerning things that lived under conditions which are in great part only conjectural? Probably no living person accepts as it stands 'The Origin of Species,' and it is doubtful whether the first chapter, or even the first sentence of the first chapter, would hold its ground without considerable alteration and qualification if subject to searching critical examination.

The facts known to microscopical observers in connection with the act of living of the smallest particle of the simplest forms of living matter are no more to be accounted for by any of the extravagant crotchets lately advanced as explanations of the facts, than are the general broad phenomena of nature which are under the observation of all. Evolution is a wholly satisfactory explanation only to those whose minds have been trained to submission to evolutional authority, and who have brought themselves to regard things as they have been told they ought to regard them, instead of venturing to use their senses, and reasoningt on the facts presented to their observation—and indeed see for themselves with their own eyes instead of accepting, without ever seeing, what they are told has been seen by eyes which are supposed to be specially privileged to see.

As evidence of the nonsense often advanced in favor of some form of evolution, let me quote a few sentences from an article on "Butterfly Psychology," published in the *St. James's Gazette*. Like most advocates of evolution, the writer has the knack of telling his story in such a pleasant way as to make people imagine that he is explaining the nature and cause of things he describes, while in truth he is doing nothing of the kind. He explains nothing at all, but merely announces astounding assumptious based upon conjectures of his own, or of others.

"In early life the future butterfly emerges from the egg as a caterpillar. At once his many legs begin to move, and the caterpillar moves forward by their motion. But the mechanism which set them moving was the nervous system, with its ganglia working the separate legs of each segment. This movement is probably quite as automatic as the act of sucking in the new-born infant. The caterpillar walks, it knows not why, but simply because it has to walk. When it reaches a fit place for feeding, which differs according to the nature of the particular larva, it feeds automatically. Certain special external stimulants of sight, smell, or touch set up the appropri-

ate actions in the mandibles, just as contact of the lips with an external body sets up sucking in the infant. All these movements depend upon what we call instinct—that is to say, organic habits registered in the nervous system of the race. They have arisen by natural selection alone, because those insects which duly performed them survived, and those which did not duly perform them died out. After a considerable span of life spent in feeding and walking about in search of more food, the caterpillar one day found itself compelled by an inner monitor to alter its habits. Why, it knew not; but, just as a tired child sinks into a sleep, the gorged and full-fed caterpillar sank peacefully into a dormant state."

Of course all this may have been written in joke. The writer may possibly be laughing at evolutionists. The "inward monitor" of the "gorged and full-fed caterpillar" undoubtedly looks rather suspicious, but one hardly likes to hint at anything so serious. Evolutionists will, I dare say, repudiate such "evolution" as a mere travesty, but it is quite time that half-a-dozen evolutionists who agree on main points should clearly state their belief.

In conclusion, let me ask you as students of nature's processes, whether you have not seen enough to convince you that the revival of the assumption which has been abandoned and reintroduced many times during the last few centuries, that the lifeless is the sole origin of the living—that in fact the non-living and the living are one—is now unjustifiable, and cannot be reasonably entertained. This monstrous fallacy, though taught with the greatest confidence, is based on assumption, and is supported by arbitrarily selected facts, and by not a few misrepresentations and dogmatic assertions. Whenever any form of this false doctrine has been successfully forced into popularity, it has led to the adoption and propagation of the most grievous errors and grotesque conceits.

COMET OBSERVATIONS AT PRINCETON.

The weather has been so unfavorable at Princeton, that we have been unable to make any very satisfactory measures upon the spectrum of the comet. On Saturday evening the comet was visible fairly for an hour or so, before it descended into a bank of cloud. On Sunday evening it was beautifully seen for about half an hour, and then was obscured by a fog which still continues.

The spectrum of the nucleus is very bright. It is apparently continuous, though there may be a little special emphasis at the points where the usual carbon lines ought to appear. The spectrum of the coma and of the tail is precisely like that of most comets, showing three bands which coincide sensibly with those given by the flame of a Bunsen gas-burner, presumably due to a hydrocarbon of some sort.

On Saturday evening the nucleus looked much like a star-fish, having five projecting points formed by jets of light protruding from the central globe to a distance of from four to ten seconds of arc. These jets were not equal in length or brightness, and were not symmetrically disposed with reference to the axis of the comet's tail. Two of them were somewhat curved, they were all diffuse and blunt at the extremity, rather than pointed.

On Saturday, instead of jets, the nucleus had a nearly circular envelope surrounding it, sharply defined from the coma. Its diameter was perhaps 20″, but the fog came on before any measures could be made. This disc of light, surrounding the nucleus, was not uniformly bright:—it was more brilliant on the side next the Sun, and there was a curious dark opening in it of oval form, some 20° one side of the axes of the tail. We were preparing to study the spectrum of this envelope critically, when we were cut off by the mist.

Although the Comet is now receding from both Sun and Earth, it is rising so much higher in the Northern Sky each night, that if the weather becomes favorable, it may yet be possible to get something more satisfactory; but just at present the rain is pouring and the prospect is rather dreary. C. A. YOUNG.

PRINCETON, N. J., *June* 27, 1881.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. No notice is taken of anonymous communications.*]

LOCUSTS AND SUN SPOTS.

To the Editor of "SCIENCE:"

SIR: Perhaps you will permit me to explain one inapposite word occurring in my communication on the above subject.

When I stated that European migrants come north and east, I should rather have said *north and west,* the set of the migrations, as far as known, is on European areas north and west; and in this direction, butterflies, sphinx moths and locusts, whose point of departure has been traced to Southern Asia or Northern Africa, travel periodically; the occurrence being made known to us by their vanguard, so to speak, sweeping over the eastern shore of Great Britain. That this track is not voluntarily chosen by instinct, but rather due to a prevailing south-easterly direction of the winds, rests now-a-days on a great amount of experience. A. H. SWINTON.

GUILDFORD, ENG., *June*, 1881.

THE BLUE COLOR OF THE SKY.

Prof. Cornu having established the fact that the atmosphere of the earth exercises an energetic absorption upon the ultra-violet rays of the spectrum, whose limit varies according to the statement of the atmosphere and the altitude of the sun. Prof. Hartley sought to attribute this limitation to the influence of ozone. His experiments have demonstrated.

1.—That the ozone is a normal constituent of the higher atmosphere, where it is more abundant than on the earth.

2.—That this quantity of atmospheric ozone suffices to limit the spectrum in the ultra-violet region, without considering the absorption caused by the great density of the oxygen and nitrogen.

3.—That the blue tint of the atmosphere is due to the presence of ozone.

In respect of this last point, Prof. Hartley remarks that, if the ozone exists in the high regions of the atmosphere, the light reflected by clouds at a great heighth has a blue appearance because it traverses a gas of this color. It is so likewise with the light illuminating the distant portions of a landscape. Experiments have shown that 25 milligrammes of ozone for every square centimeter of a layer of 80 kilogr. thick can produce this phenomenon.

WE learn that Prof. H, S. Prichett, Director of the Glasgow Observatory, has been appointed Professor of Mathematics in Washington University, St. Louis, Missouri.

DOLBEAR'S NEW TELEPHONE SYSTEM.

Among the exhibits at the forthcoming International Electrical Exhibition at Paris, the new telephone we are about to describe will command attention as an original and important invention.

It embodies the most recent discoveries of Professor A. E. Dolbear, of Tuft's College, Massachusetts, who, as one of our most esteemed contributors, needs no introduction to the readers of "SCIENCE."

The advantages claimed by Professor Dolbear may be summarized as follows:

1. It is a *new* and independent system which has important advantages over the Bell and other Telephonic methods.
2. Its capability of transmitting speech over longer lines of wires than has been hitherto employed, and its freedom from the troubles of induction.
3. It is a silent instrument, the words coming out clear without the sputtering aud confused noises of the old system.
4. It is an absolute departure from the Bell system, and its principles of operation entirely independent.

We are enabled to place before our readers a description of this original telephone prepared by Professor Dolbear himself, illustrated by some excellent cuts loaned to us by Mr. H. C. Buck, who is leaving for Paris to represent Professor Dolbear at the forthcoming Electrical Exhibition.

Before describing Professor Dolbear's Telephone in detail, we may state that in order to receive messages by the Bell system it is necessary to use between the ear and the line wire an electrical machine, consisting of a magnet, a magneto-coil to influence the magnet, which coil is connected with the line wire and with the ground. Take out this machine, and we take out the Bell telephone system—this is substantially what Professor Dolbear claims to do—for to receive a message, he takes out the machine, and puts the end of the telegraph wire directly to the ear. For convenience of ordinary use Professor Dolbear provides the receiving end of his telegraph wire with a small handle, in which he arranges a couple of thin diaphragms, one of them attached to the wire—a contrivance that improves the vocal delivery of the line wire.

Professor Dolbear thus describes his invention:

RECEIVER.

This consists, in its simplest form, of two metallic disks about two inches in diameter, so mounted as not to be in metallic contact, and this is effected by turning a flange in a hard rubber case so they may be kept apart by it (see Fig. 1). A cap is screwed down upon each plate; one of them having a small hole in the middle of it to listen at; the other is a larger one, having a knob turned upon it for conveniently holding it in the hand. Through the middle of the knob a screw is sunk which touches the back plate and serves to adjust it to the best position relative to the front or vibrating plate. The back plate is thus fastened at both edge and middle, which prevents it from vibrating, while the front plate is only fast at its edge, leaving the middle free to vibrate.

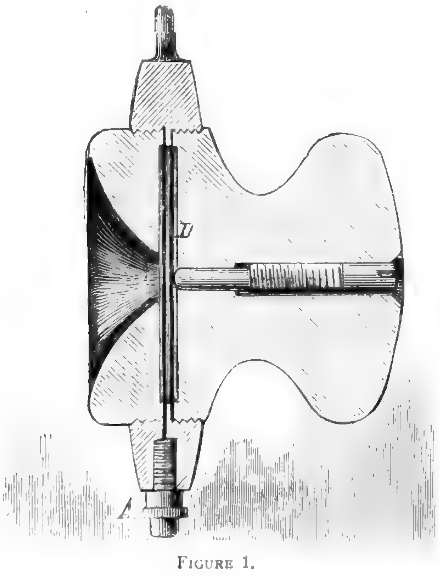

FIGURE 1.

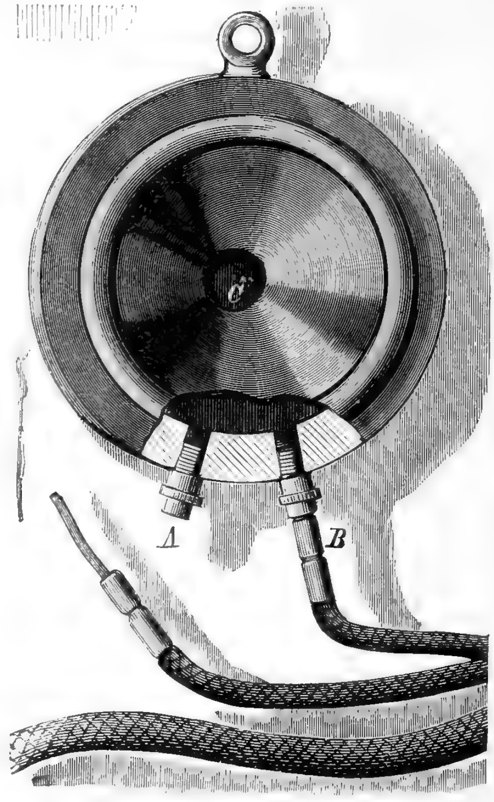

FIGURE 2.

Each of these plates, A B, Fig. 2, is in metallic connection with the induction coil so as to be its terminals. When thus connected and one makes and breaks connection in the primary circuit, a click may be heard by one holding the receiver near to the ear. If a Helmholtz interrupter be employed to make and break the primary circuit, the pitch of the fork can easily be heard, and with a *Reiss transmitter* or other suitable one in the same place, any kind of a sound will be reproduced.

The explanation of this is easily understood from the foregoing description of the conditions present. The electromotive force generated by induction in the coil changes the two terminals in the receiver, one positively, the other negatively; they therefore attract each other.

One of them is free to move, while the other is rigid. The middle of the freer plate consequently moves slightly toward the other whenever they are electrified, and *in so doing spends the energy of the electricity*, while its elasticity brings it back to its place. It is not essential, however, that both of these terminal plates should be connected to the induction coil, for if only one is connected, the recurring charges will cause the free plate to vibrate, for a charged body will attract any other body, so if the connection be to the back plate it will attract the front one and make it move, and if the connection be to the front plate it will attract the back plate and approach it. The effect will be increased by putting the finger upon

the terminal that is free ; not because it *makes a ground*, as it is termed in electrical science, or completes an electrical circuit, for if the individual listening be as perfectly insulated as glass or hard rubber can make him, the sound is as loud as if he stood on the ground ; but the individual becomes electrified by induction, it is the same as enlarging the terminal would be. Consequently receivers are

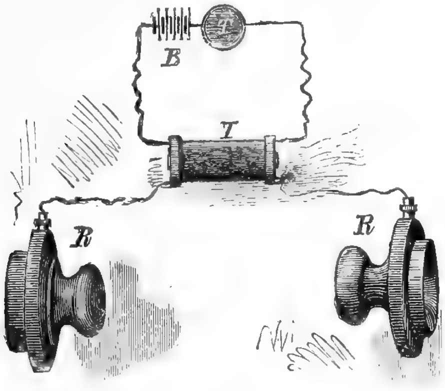

FIGURE 3.

made having only one wire terminal (see Fig. 3), the other plate being connected by a conductor to a metallic ring upon the knob, and this receiver is as efficient as the other.

Electricians will recognize in this structure what is technically known as the *air condenser*, and the mutual attraction of the two plates has been employed as a means of measuring electrical potential. In this case one of the plates is suspended from one arm of a balance, while the other is fixed underneath it at a short distance. The attraction of the plates when they are electrified requires an extra weight to keep them apart, and the weight needed is the measure of the attractive force. But the plates will attract each other when glass or mica or any other non-conducting substance is placed between them in the place of the air ; and one might expect that if such an air condenser would give sonorous results, other forms of condensers, would do so likewise, and this is so. Indeed, whoever has charged a Leyden jar has probably noticed the sounds coming from it when it is nearly saturated. In 1863 Sir Wm. Thompson had his attention directed to the sounds produced by discharge in an air condenser.*

When the two plates of Epinus's condenser are in metallic contact no sounds whatever can be produced by it, but if they are separated by a thin film of air they will

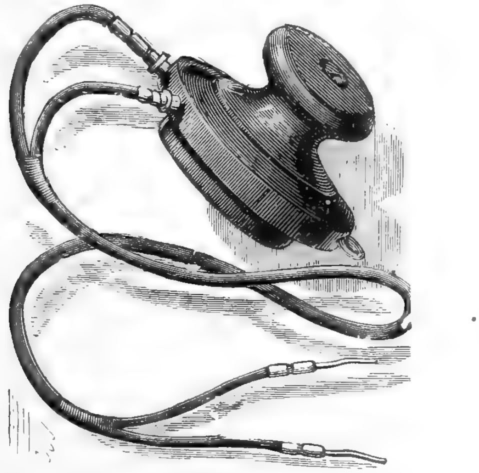

FIGURE 4.

reproduce speech (see Fig. 6, at E). In the first case the electricity passes from one plate to the other without doing work or changing its form ; while in the latter, its form is changed and work is done, and between the best conductors, such as silver and copper and the perfect non-conductor air there are all degrees of conductibility, and whenever electricity spends its energy upon an imperfect conductor it results in heating it ; that is, in molecular and atomic vibrations. Consequently an undulatory current from an ordinary transmitter, when sent through an imperfect conductor, will set up sound vibrations in it which may be appreciated by the ear. Let, then, any poor conductor, like a disk of carbon, a sheet of paper or of gelatin, or such chemical substances as ammonium chloride, be placed between the terminal plates, and an undulatory current sent through them will result in sound, and speech may be reproduced.

Now, the phenomena observed in Geissler's tubes and Crooke's tubes show that the residual gaseous molecules are violently impelled from the electrified terminals, not simply because they are electrified, but because they are heated, for the same phenomena are witnessed when the terminals are heated in other ways ; so it is probable that between the plates of the air condenser there is an actual impulsion of the air particles from one to the other, and that the phenomenon of attraction is not isolated from molecular impact. Receivers have been made in which a vacuum could be produced between the plates, but no great difference could be observed in their performance ; and when one reflects upon the immense number of

FIGURE 5.

molecules left in the best vacuum yet produced, it is not a matter for much surprise.

When a non-conductor, such as air, or vulcanite, or mica, separates the two plates, there is a complete transformation of the electricity at the limiting surfaces, and with small condensers the efficiency depends upon the electromotive force employed. For low electromotive forces, such as common batteries of a few cells can give, the effect is almost inappreciable, and for this reason such a receiver as this is quite free from the disturbance known as induction, and which is so troublesome in the magneto-telephone, such induced currents being generally of low electromotive force.

Among the earliest of my experiments, made while developing this method, was to attach one terminal wire from an induction coil to the outer coating of a Leyden jar, taking the other wire from the coil in one hand, and

* See papers on Electro-Statics and Magnetism, page 236.

applying one ear to the knob of the jar. Every word spoken at the transmitter was distinctly heard, but the prickly sensation due to the electricity was too disagreeable. Another receiver, not less curious than the Leyden jar, was found in the pair of insulating handles made for the medical application of electricity. When these were connected to the coil wires, and one held in each hand by the wooden part, while the metallic ends were placed at the ears, any kind of a sound at the transmitter was heard without any difficulty, but of course the same sensation was felt as with the jar. Many forms of condensers have been employed with capacities too small to measure up to two micro-farads, and these in all sorts of relations, charging the plates from batteries, from Holtz machines, charging the line as in cable works, etc., all of which give results that differ only in degree.

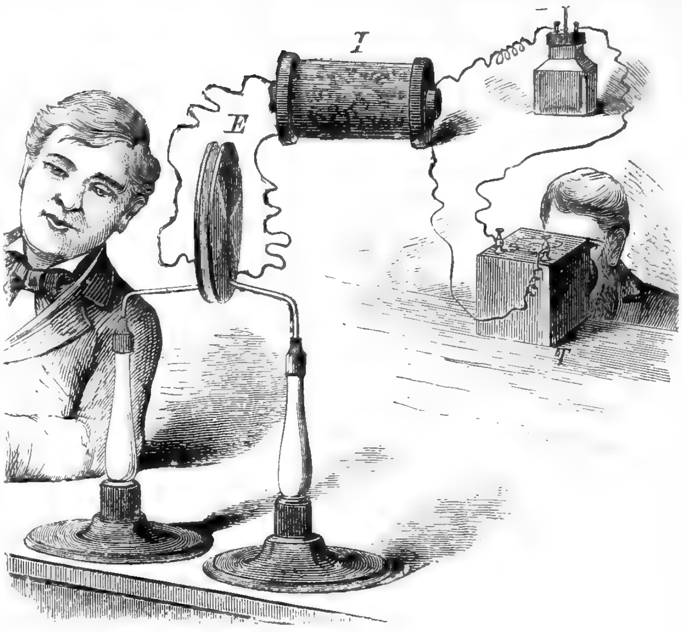

FIGURE 6.

THE TRANSMITTER.

As with other systems in common use, there is a transmitter as well as a receiver. One form of the transmitter is attached to the door of a box containing battery and coil. This transmitter is substantially the same as the one invented by Reiss in 1861. His consisted of a cubical box (see Fig. 6) about five inches on a side, having an opening on one side to talk into, and another one on top, across which the diaphragm was fastened. A pin of platinum was glued to the middle of the membrane, and connected by a wire to a binding screw. A V-shaped wire with platinum point touched upon the platinum of the membrane, and with its binding screw served to complete a galvanic circuit. This one (see Fig. 10) differs from this of Reiss only in making the chamber smaller, making the connecting wire on top T-shaped, and substituting carbon or other suitable substance for the platinum; but the platinum does very well. It is a matter of some surprise that the old transmitter is still spoken of as a *make and break* circuit, and that it can only transmit pitch, whereas, whether it breaks or not when a sound is made in it depends solely upon the intensity of that sound, just as with the Blake transmitter, if one talks gently to the original Reiss transmitter, it not only does not break, but it transmits speech with all its qualities.

Accompanying the transmitter an induction coil is shown at I, Fig. 6, and as the working of the receiver depends upon electromotive force and not upon current, it is necessary, if a coil be used to raise the electromotive force, to have one with many more turns than is needed with the magneto receiver, and the best results have been obtained with a coil having a resistance of four or five thousand ohms, but it is probable that this will be reduced.

On account of the high electromotive force a better insulation is needed than ordinary telegraph lines give, when the induction coil is at the further end of the line, but if it is at the receiving end, and a low electromotive force is employed in the primary, then ordinary insulation will answer. Again, the electromotive force being high, inserted resistances do not so markedly decrease the efficiency of the instrument, as in the case with the magneto-telphone. For instance, the articulation is perfect and loud enough with a resistance of fifty thousand ohms, a resistance equal to five thousand miles of common telegraph wire, and it may be heard through a resistance of a million ohms, practically an infinite resistance.

If one of the terminals of a receiver be charged in any way, the reaction between the two plates will be stronger than it will be without. Let, then, one terminal be attached to a knob of a Holtz machine that is kept charged by rota-

FIGURE 7.

tion. The sounds will be heard much louder, and any other source of electricity with high potential will answer the same purpose. Hence a battery of a large number of cells may be substituted for the Holtz machine, and one of the terminals of the battery may go to the ground, though this is not essential. This arrangement will keep the terminal plate charged to the potential due to the chemical relations and number of cells in the battery. If the battery be placed in the line wire it will keep both ends of the line charged. A Volta's pile may be substituted for the battery in either place, and so may a charged condenser of any capacity, the electrically

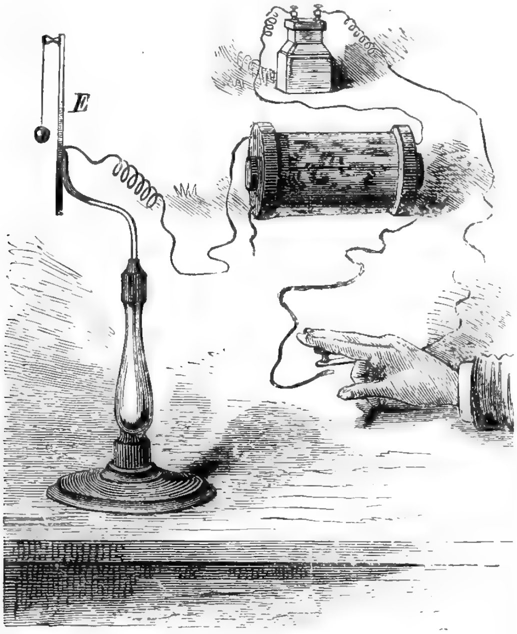

FIGURE 8.

charged terminals in this system acting in a way analogous to the permanent magnets in the magnetic system.

There are various other ways of employing condensers, and as one would infer from the preceding descriptions of the phenomena, these condensers will talk, that is, they will reproduce in sound the varying electrical conditions to which that may be subjected, as will also either a battery or a Volta's pile.

I have often heard them talk, and have made many experiments with such receivers.

By this system telephonic communication can be secured through ordinary medical electrodes.

In perfecting this new telephone Professor Dolbear has given long and constant study to the scientific problems involved, while the mechanical construction has been prosecuted by Mr. H. C. Buck, aided by skilled machinists and competent assistants. The above concise description in the inventor's own words will give our readers a clear understanding of the principles that underlie his interesting invention, and it only remains for us to describe in brief the several figures in our front page engraving.

Fig. 7 shows the telephone in actual use, the transmitter being secured to the wall, the battery and induction coil being placed in a box on the floor, or in a convenient closet. Fig. 4 is a perspective view of the new receiver; Fig. 2 a face view of the same, with a portion of the casing broken away to show the connection of the two binding posts, A B, with the diaphragms, C D, and the adjusting screws by which the distance between the diaphragms is regulated are shown in the sectional view Fig. 1.

Fig. 8 illustrates the principle of electrical attraction upon which the action of the new receiver is based; the electrostatic charge received by the plate, E, from the induction coil attracts the pith ball suspended in front of the plate.

Fig. 6 shows the two plates, E, of an Epinus condenser, placed near together and connected with the terminals of the secondary wire of the induction coil, I, and used as a telephone receiver.

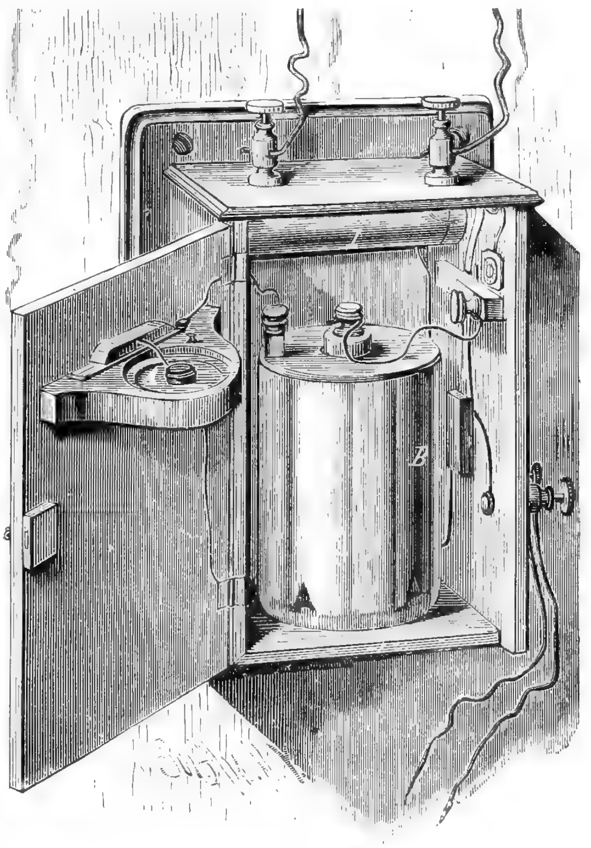

FIGURE 9.

Fig. 5 illustrates the essential features of the new telephonic system. I being the induction coil whose primary is in circuit with the battery, B, and transmitter, T, the receivers, R, are each connected with a single terminal of the secondary wire of the coil, I.

Fig. 9 shows Professor Dolbear's experimental telephone transmitter. In this instrument the diaphragm, A, is horizontal, and carries a carbon electrode, upon which rests a moveable carbon electrode connected by an arm with a delicately pivoted bar supported by the diaphragm cell. The local circuit is from the battery, B, through the carbon electrodes, and through the primary of the induction coil, I.

EXTRACTION OF SILVER.—To extract the silver from silvered objects, these should be plunged into a bath composed of a mixture of 100 grammes of finely pulverised saltpetre and 1000 grammes of sulphuric acid. If the acid is weak, the copper and the other metals except the silver will be attacked; if the acid is concentrated the silver alone will be dissolved.

UPON A MODIFICATION OF WHEATSTONE'S MICROPHONE, AND ITS ADAPTABILITY TO RADIOPHONIC RESEARCHES.*

By Alex. Graham Bell.

In August, 1880, I directed attention to the fact that thin discs or diaphragms of various materials become sonorous when exposed to the action of an intermittent beam of sunlight, and I stated my belief that the sounds were due to molecular disturbances produced in the substance composing the diaphragm.[1] Shortly afterward, Lord Raleigh undertook a mathematical investigation of the subject, and came to the conclusion that the audible effects were caused by the bending of the plates under unequal heating.[2] This explanation has recently been called in question by Mr. Preece,[3] who has expressed the opinion that, although vibrations may be produced in the discs by the intermittent beam, such vibrations are not the cause of the sonorous effects observed. According to him the aerial disturbances that produce the sound arise spontaneously in the air itself by sudden expansion due to heat communicated from the diaphragm—every increase of heat giving rise to a fresh pulse of air. Mr. Preece was led to discard the theoretical explanation of Lord Raleigh on account of the failure of experiments undertaken to test the theory.

He was thus forced, by the supposed insufficiency of the explanation, to seek in some other direction the cause of the phenomenon observed, and, as a consequence, he adopted the ingenious hypothesis alluded to above. But the experiments which had proved unsuccessful in the hands of Mr. Preece, were perfectly successful when repeated in America under better conditions of experiment, and the supposed necessity for another hypothesis at once vanished. I have shown in a recent paper read

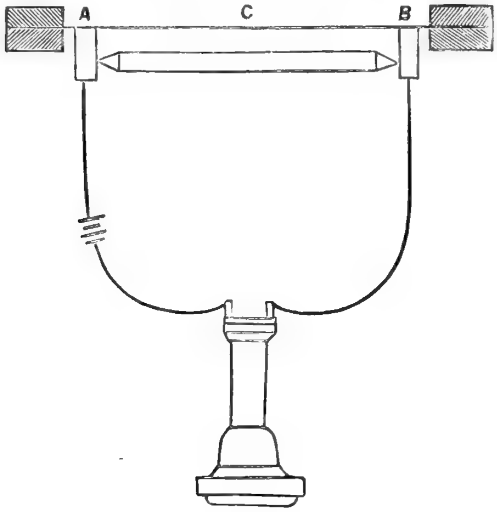

Fig. 1.

before the National Academy of Science[4] that audible sounds result from the expansion and contraction of the material exposed to the beam, and that a real to and fro vibration of the diaphragm occurs, capable of producing sonorous effects. It has occurred to me that Mr. Preece's failure to detect with a delicate microphone the sonorous vibrations, that were so easily obseerved in our experiments, might be explained upon the supposition that he had employed the ordinary form of Hughes' microphone shown in Fig. 1, and that the vibrating area was confined to the central portion of the disc. Under such circumstances it might easily happen that both the supports, *a b*, of the microphone might touch portions of the diaphragm which were practically at rest. It would, of course, be interesting to ascertain whether any such localization of the vibration as that supposed really occurred, and I have great pleasure in showing to you to-night the apparatus by means of which this point has been investigated.

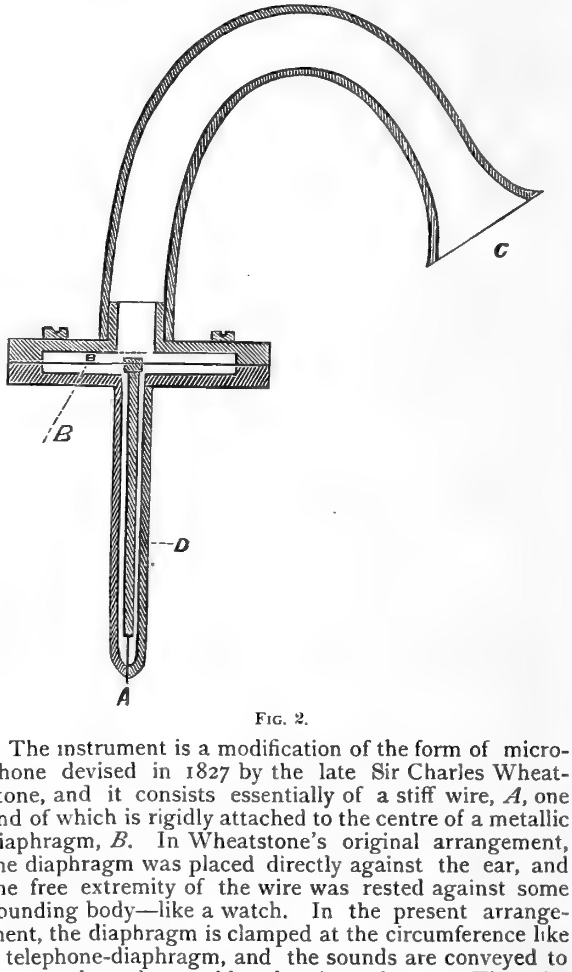

Fig. 2.

The instrument is a modification of the form of microphone devised in 1827 by the late Sir Charles Wheatstone, and it consists essentially of a stiff wire, *A*, one end of which is rigidly attached to the centre of a metallic diaphragm, *B*. In Wheatstone's original arrangement, the diaphragm was placed directly against the ear, and the free extremity of the wire was rested against some sounding body—like a watch. In the present arrangement, the diaphragm is clamped at the circumference like a telephone-diaphragm, and the sounds are conveyed to the ear through a rubber hearing-tube, *c*. The wire passes through the perforated handle, *D*, and is exposed only at the extremity. When the point *A* was rested against the centre of a diaphragm upon which was focussed an intermittent beam of sunlight, a clear, musical tone was perceived by applying the ear to the hearing-tube *c*. The surface of the diaphragm was then explored with the point of the microphone, and sounds were obtained in all parts of the illuminated area and in the corresponding area on the other side of the diaphragm. Outside of this area on both sides of the diaphragm, the sounds became weaker and weaker until, at a certain distance from the centre, they could no longer be perceived.

At the points where we would naturally place the supports of a Hughes' microphone (see Fig. 1) no sound was observed. We were also unable to detect any audible effects when the point of the microphone was rested against the support to which the diaphragm was attached. The negative results obtained in Europe by Mr. Preece may, therefore, be reconciled with the positive results obtained in America by Mr. Tainter and myself, A still more curious demonstration of localization of

* A paper read before the Philosophical Society of Washington, D. C. June 11, 1881.

[4] April 21, 1881

vibration occurred in the case of a large metallic mass. An intermittent beam of sunlight was focussed upon a brass weight (1 kilogram), and the surface of the weight was then explored with the microphone shown in Fig. 2. A feeble but distinct sound was heard upon touching the surface within the illuminated area and for a short distance outside, but not in other parts.

In this experiment, as in the case of the thin diaphragm, absolute contact between the point of the microphone and the surface explored was necessary in order to obtain audible effects. Now, I do not mean to deny that sound waves may be originated in the manner suggested by Mr. Preece, but I think that our experiments have demonstrated that the kind of action described by Lord Raleigh actually occurs, and that it is sufficient to account for the audible effects observed.

ASTRONOMY.

On the 23rd ultimo, Mr. E. L. Larkin, a subscriber and contributor to this journal, telegraphed to Professor Swift, of Rochester, the discovery of a comet in the constellation of Auriga; but as others have since made the same claim, the priority of discovery awaits confirmation by those who dispense the pecuniary reward offered by Mr. Warner for all comets discovered during the present year.

We reserve until next week our report on this interesting celestial object, by which time our correspondents will have worked out the results of their observations, which have been delayed by atmospheric and other difficulties. The comet is now plainly visible, and American astronomers are on the alert to thoroughly examine it with all the appliances which modern science has placed at their command. At the date of our writing nothing reliable has been determined by actual observations, but some interesting facts, based on preliminary and partial observations, have been communicated, which, if accepted with reserve, pending final results, may be found useful to those directing their attention to the comet.

Professor Henry Draper is said to have made several successful photographs of the erratic stranger. Professor C. A. Young, of Princeton, has examined its spectrum, and reports that that of the nucleus was continuous, while that of the coma was sensibly coincident with the spectrum of the Bunsen burner flame. As seen directly in the 9½ inch equatorial, with eye-pieces of the lowest power, on the evening of the 26th, the nucleus was small and bright, with five bright jets of unequal length projecting from it a short distance. The tail showed three maxima of brightness, of which the brightest was near the axis, and was quite convex in the direction of increasing right ascension. On the 26th he states the spectrum was about the same, but the nucleus, instead of showing jets as before, was nearly surrounded by an envelope.

Professor Boss of the Dudley Observatory determines the diameter of the nucleus to be seven seconds or 1 500 miles, at an estimated distance of 45,000,000 of miles.

Professor Asaph Hall considers it most probable that the comet is identical with that discovered by Professor B. A. Gould at Buenos Ayres of the 1st of June. On the 26th ultimo an observation was made at the naval observatory, Washington, which indicated "the position of the comet at its lowest culmination, obtained with the transit circle, was at 11 h. 27. P. M., Right ascension 5 h., 48 m., 384-100 s., North declination, 57 deg., 40 m., 52 sec.

THE LUNAR ECLIPSE.—The eclipse of the moon on June 11 was seen under favorable conditions at the Naval Observatory, Washington. The only observations of importance were observations of occultation of B. A. C. 5862, and two faint stars during the eclipse.

THE OHM.

A British Association committee has been reappointed for the remeasurement of the Ohm, and of other units. It is not to their work, however, that we wish now to draw attention, but rather to a good stroke in the right direction, done in the Cavendish laboratory by Lord Rayleigh with the assistance of Dr. Schuster and others. The old British Association apparatus has been fitted up again, with such improvements as the criticism of nearly twenty years has suggested. It will be remembered that this is the only method in which the measurement of transient currents by ballistic galvanometers is not employed. A circular coil of insulated wire forming a closed circuit rotates about a vertical axis, and the electrical current induced in it by the earth's magnetism gives a steady deflection to a magnetic needle at its centre. The manifold precautions, calculations and corrections which have to be entered into by the experimenters are given by Professor Fleeming Jenkin and others. One important correction is that which is due to the self-induction of the coil which retards the current, and a most important fact has been brought to light by Lord Rayleigh, namely, that this self-induction is considerably greater than it was thought to be by the original committee. Professor Rowland, assuming that an unknown error existed proportional to the square of the speed of the rotation, has found that the original experiments of the committee lead to the result that the Ohm is 0.74 per cent. smaller than it was intended to be, and his own experiments lead to its being 0.89 smaller. Kohlrausch found it nearly 2 per cent. too great, and Weber thought it correct. The Cavendish laboratory experiments lead to its being 1.05 per cent. too small, and the elaborate paper to the Royal Society in which this result is given promises a redetermination with new apparatus on the same principle. In making the present determination a new method of suspension of the needle, a stroboscopic method of measurement of the speed—the old governor and the tinkling bell being discarded—and driving the coil by means of a water turbine instead of by hand, are some of the improvements which have been introduced.

It is to be remembered that no re-measurement of the Ohm can ever effect our use of it as a standard. It is no longer to be regarded as exactly equal to one thousand million C. G. S. units, but this is of no more consequence than the fact that one gramme is no longer regarded as being exactly equal to the mass of a cubic centimetre of water at 4° C.—*The Electrician.*

ALCOHOL IN WATER AND AIR.

An interesting discovery has been brought before the Academy of Sciences by M. Muntz, Chief of the laboratories belonging to the Agricultural Institute. He has found that alcohol is distributed throughout the universe, in the sun, air, water of the ocean and streams. It is a known fact that fermentation is a general phenomena in air, water and earth; This fermentation gives off CO^2, and as a necessary consequence, alcohol. This is what the experiments of M. Muntz have demonstrated; he has been able to prove the presence of alcohol in water, etc., by reducing the alcohol to an *iodoform* state by means of iodate and carbonate of soda. The precipitate which is obtained even in the presence of a millionth quantity of alcohol, affects the crystalline form of the snow examined under the microscope. The alcohol is produced in earth containing organic matter in decomposition, and hence it extends into the waters of streams, and into the atmosphere. Still, the portions are so infinitesimal that a water-drinker will never feel himself "alcoholized;" the dose of alcohol contained in a cubic metre of water (1000 litres), being at the most a gramme.—

ELASTIC RESTORATION OF CAOUTCHOUC.—Objects made of this substance easily lose their elasticity. Dr. Pol, however, avers that their elasticity may be restored by plunging them for an hour into a mixture composed of 2 parts of water and 1 part of ordinary ammoniac.

THE TELEPHONIC RECEIVER.

Mr. Preece has presented to the Royal Society the result of his investigations upon radiophony. They relate to the phenomena produced by the action of intermittent rays upon discs and vases of different substances. Confirming and pursuing the investigations of Mercadier in France, and of Tyndall, he has come to the conclusion that the sounds produced under these conditions are due to calorific effects, and not to light.

Caoutchouc and ebionite (hardened caoutchouc), are absolutely opaque, but they act as diathermics or tranparencies for calorific rays; the radiating heat can act through a screen of these materials.

It has been proved by delicate experiments, that six vibrations or more can be produced during a second, by the intermittent action of the heat, producing a dilitation of the disc's mass. The phenomena, therefore, produced by Bell and Tainter are not due to an absorption of heat, changing the volume of the affected substance.

Mr. Preece made use of a specially constructed chamber and is convinced that the sounds are produced by the contained air, and not by the discs or surfaces of the chamber. In it is placed a mechanism which recalls that by which the "moulinet" of Crook's radiometre is moved under the influence of the heat.

He has proved, finally, that the absorbing for the heat of the gas, contained in the chamber experimented on, influences the production of the sounds. These experiments have been repeated upon bottles blackened with camphor smoke, both on their exterior and interior surfaces.

Mr. Preece has thus been led to think that a wire of platinum, traversed by an intermittent current, can become a source capable of producing on suitable walls calorific rays, which have the power to cause sounds through the heating of the gas on contact with these walls.

The experiment was crowned with success; it was made at first by sending currents into a spiral of platinum by means of a stop-wheel turned with the hand, and when a good microphone was substituted a reproduction of the wood was effected.

Thus has been realized a receptive telephone founded upon an entirely new principle.—(*La Nature*).

ALTERATION OF MILK.

M. Fauvel, in the capacity of chemist to the municipal laboratory of Paris, has discovered that the milk employed for babes often undergoes an alteration which has hitherto been unsuspected. In his investigations he has noted the presence of cryptogamic vegetations. These are found in the tubes of glass and caoutchouc, which enter into the construction of the small feeding apparatus, especially so in the swelling of the rubber which the infant sucks. The new microphite can be easily cultivated in whey, and the author has thus observed the various stages of its development. This, however, is but the first of M. Fauvel's intended investigations. This discovery is important from a hygienic point of view. These observations were confirmed by the fact that twenty-eight out of thirty-one cases presented these symptoms. (*La Nature*.)

NOTES.

FIRE BALLS.—There are many persons who persist in their statement that fire-balls exist only in imagination; but here is the authentic statement of Henry O. Forbes, who, in a letter to *Nature* thus describes the phenomenon.

"I was standing in a window on the second floor of the Hôtel Braganza (in Lisbon), which stands close to and high above the Tagus, and had an unbroken view of the river. There occurred a flash followed by an instantaneous crash, but the tail of the flash, however, gave origin to two balls, which descended separately and not far apart, towards the river, and when quite close to, or in contact with the water, burst in rapid sequence, with explosions which might have been the crack of doom."

PHOSPHORESCENCE.—Mr. W. Crookes, after submitting the action of precipitated aluminum to the action of electric discharges in a Geissler tube, announces that a phosphorescence similar to that obtained from the ruby was developed. This is, evidently, the reproduction of the phenomena obtained, a long while ago, by M. Edw. Becquerel by means of the solar light. Mr. Crookes, indeed, adds that the aluminum, if sufficiently electrified, passes from an amorphous state into a crystalline structure, a fact quite credible, and that it assumes at the same time a rose shade kindred to that of the natural ruby, a tint very difficult to understand.

EFFECTS OF TEMPERATURE UPON MAGNETISM.—Mr. John Trowbridge has just completed the following experiment in the physical laboratory of Harvard University. He submitted a bar of iron to a great cold of 60° cent. below zero, obtained by evaporating CO^2. He proved that the decrease of magnetism, suspected by Wiedeman, if the bar be at a lower temperature than that allowing magnetic impregnation, is indeed a demonstrated physical fact. The bar, which had been magnetized at 20° C. below zero, had lost almost ⅔ of its magnetism after 47 minutes of exposure to this cold. He also observed that, by keeping a bar of steel for a certain time at a temperature of 20° cent., 50 per cent of its primitive magnetism was restored.

PREECE ON FAURE'S BATTERY.—Mr. Preece, the electrician, is not favorable to Mr. Faure's battery. He remarks that although it possessed considerable force its resistance was very feeble and it could therefore give a powerful current. He dwells especially upon "time" as a factor in electric experiments. A strong current of one minute duration can be readily obtained, but for purposes of lighting, something more durable is needed. It is a pretty thing, but for to-day it is not practical.

THE AURORA BOREALIS.—The idea that the Aurora Borealis gave forth a distinctly audible sound was hitherto regarded as absurd. Physicists, however, are beginning to acknowledge it as a fact. "*Nature*," of London has a few letters on the subject. There seems to be two opinions as regards the nature of the sound produced. One party pretends that the noise is analogous to the rustling of silk, the other party compares it to the sound of crackling flames. The question however will shortly be solved by means of baloon ascensions that are now being made.

ACTION of Light upon Phosphorescent Bodies.—M. Clémandot.—The author maintains that phosphorescence is a purely physical phenomenon, due to a vibratory action exercised chiefly by the blue ray of light. He connects these phenomena of vibration in phosphorescent bodies with those which light occasions in organized bodies.

NOTE.

I wish some one would begin with the start given by the paper on polarization of sound, in "SCIENCE" for May 14, and thoroughly go through the subject of Etherial Physics.

The mechanics and elementary laws of action of the Ether substance are needed.

The seemingly rotary or spiral course pursued by the particles conveying light and electricity, as shown in the polarization of light and in that of magnetism, are especial subjects of choatic conception. And there is more beyond! SAMUEL J. WALLACE.

NOTICE TO CORRESPONDENTS.

The writer of a paper "*On Ether*" received by us, will much oblige by forwarding his name and address.

SATURDAY, JULY 9, 1881.

OBSERVATIONS UPON THE COMET AT PRINCETON.

The comet has been seen and observed every night since June 25, except on June 30th. Every night, however, except July 2d and 3d, the observations have been interfered with by clouds, so that very little continuous thoroughly satisfactory work has been possible.

The light has fallen off rapidly. On the 26th, the comet was for half an hour better seen than at any other time, and the nucleus was judged to be just about equal to Arcturus in brilliancy. On July 2d, it was compared pretty carefully with the Pole Star and with α Urs. Majoris by *squinting*, so that the blurred images of star and comet were brought close alongside. I judged it just equal to Polaris and about $\frac{1}{4}$ to $\frac{1}{3}$ of a magnitude fainter than Dubhe.

The nucleus and coma have presented a very interesting series of telescopic phenomena, in the main such as have been seen in all other large comets. It is noteworthy, however, that immediately behind the nucleus no strongly marked dark shadow-like stripe has been developed, nor, what is perhaps just as common on the contrary, any bright central streamer. On the whole, the central portion of the tail has been a little less brilliant than the edges, even close to the head, but the difference has been slight. On the 25th, the nucleus about 10 P. M. showed 5 projecting jets, much like the pseudopodia of some low animal organism—not well formed, nor distinct, nor symmetrical,—their length from two to six times the diameter of the nucleus, those on the front of the nucleus being the longer.

On the 26th, the nucleus was almost entirely surrounded with a nearly complete, well defined, circular envelope about 1′ in diameter. In this envelope was a curious oval vacuole, behind the nucleus, but on the preceding side of the axis of the tail.

On subsequent evenings no envelopes nearly so complete were noted—only jets of varying length and position, those on the side of the sun being apparently blown back, like flowing hair, by some solar repulsion.

On the 29th there was but one jet on the sunward side, and this was curiously curved toward the preceding side, making the whole look like a comma. (We use preceding rather than Western, because below the the pole where the comet was, the terms Eastern and Western might lead to misapprehension.)

On July 1st the head was curiously unsymmetrical. The coma was extended out in the South following direction like a great liberty cap, the axis of the principal jet which divided both ways, in front like hair parted in the middle, being inclined some 50° to the line of this extension.

With the spectroscope a number of observations have been made.

The nucleus has generally given a simply continuous spectrum, extending from below C well above G; but on June 25th and July 1st, it showed distinct banding at points where the bands of the spectrum of the coma crossed it.

This was seen by several observers on the 25th, and by both Mr. McNeill and myself on the 1st.

The spectra of some of the brighter jets had been caught and isolated several times. They were in all cases continuous, without detectable bands of any kind.

The spectrum of the tail was found to be continuous, with a faint superposed band-spectrum, the same as that of the coma. On July 1st and 2d this band-spectrum was distinctly traceable to at least 15′ distance from the head of the comet, the continuous spectrum perhaps 5′ or 10′ further.

The spectrum of the coma consisted of the usual three bands; but both the upper and lower bands, though pretty bright, were very ill defined; so much so, that I could obtain no satisfactory measurements of wave length, farther than to observe on June 25th and 26th, that the lower edges of the upper and lower bands of the so-called 'first' spectrum of Carbon, (λ, 5635 and 4740) given by a Bunsen burner, fell apparently near the lower limit of these two bands in the comet spectrum as seen with a one prism spectrum. But these comet-bands did not look at all like the flame bands, the difference of appearance being so great, as somewhat to shake my belief for the time being, in the identity of the two spectra.

The middle band, on the contrary, was perfectly defined at its lower edge, and with the one prism spectroscope distinctly showed three fine lines in the band, and these, so far as could be judged, coincided exactly

with the three lines in the middle band of the carbon spectrum.

This resolution into lines was seen by Professor Brackett, as well as by Mr. McNeill and myself, on June 29th; it was still evident on July 2d, but no longer on July 3d.

The coincidence with the middle band of the flame spectrum, has always appeared to be precise; but to obtain further evidence as to the exact position of the band a careful comparison was made on July 2 with the *b* lines of the magnesium spectrum, using the Grubb spectroscope with a dispersive power of *four* sixty-degree-dense flint prisms and a magnifying power of about 25. The slit was opened until the well defined upper edge of *b* just touched the lower edge of b_2. Then, the spark producing the magnesium spectrum being suppressed, the bright wire of the micrometer was set upon the lower edge of the comet band; finally, the spark being restored, the distance was measured from the edges of b_2. In this way twelve readings were obtained by Mr. McNeill and myself, all giving results ranging between 5160.0 and 5169.5, the mean being 5164.8 ±.0.7. I do not think the possible error can exceed 2 divisions, or three times the probable error. If so, the Comet spectrum cannot possibly be identified with the *second* Carbon spectrum, (the spark spectrum of a Geissler tube containing C O). Since the corresponding band of that spectrum has a wave-length of 5198.4. The wave-length of the band in the flame spectrum is 5165.3—both according to the figures of Dr. Marshall Watts, given in *Nature*, vol. 20, page 28.

As a further test, on July 3d, the suggestion of Dr Watts, made in the paper referred to, was followed out by confronting the comet-spectrum by means of an occulting bar, directly with Geissler tubes containing CO and CO_2, and with the Bunsen-burner flame. The bands on this night were more distinctly defined than on previous occasions, though the nucleus spectrum was less brilliant, and the result of the confrontal was very satisfactory and decisive. The upper and middle bands were found undoubtedly coincident, so far as the power used could show, with the flame spectrum, and *not* with the bands of the tube spectra. In the case of the lower band, the evidence was less conclusive, because the edge was ill defined and faint, making pointing difficult, and because bands of the flame and tube spectra are nearly coincident here. Still, even with this band, the evidence of about half a dozen pointings turned in the same direction.

On the whole, I consider it now absolutely certain, that the comet-spectrum is not the *second* spectrum of Carbon, whether it be the *first* or not. As to this latter point I do not feel quite sure, but the coincidences are certainly very remarkable and close, hough the peculiar appearance of the upper and lower bands when the comet was brightest requires explanation. C. A. YOUNG.

PRINCETON, *July* 4, 1881

PRIMORDIAL COSMIC RINGS.

III.

By EDGAR L. LARKIN.

The doctrine that a sphere of atoms, abandoned rings, or any other shaped masses can develop into planets is a physical error. It is impossible that the ball revolved. Face the south, hold the plane of the page of "SCIENCE" horizontally, call the paper the centre of the sphere, and it will be seen that to cause rotation force must be applied, if above the centre, from west to east; below, from east to west; to the right, from below, upward; and to the left, from above, downward. The gas was of excessive tenuity, and external force instead of causing rotary motion would displace the atoms in front of it. The mildest, or most violent force alike, would be unable to cause revolution in a globe of atoms of such extreme mobility. But there was no external force; energy is a property of matter, and the nearest matter was 20 trillions of miles away. If the sphere rotated the motion came from internal causes, none of which could have at that time existed. There were no vortices, currents, tides or whirlwinds in matter of such rarity; no force outside, and none within save the slowest possible radial descent. The sphere was at rest. No point in the experiment of M. Plateau had analogy to the generation of rings on the gaseous globe. He placed a globule of oil in a fluid having like specific gravity, passed a wire through it, and turned it as an axis until the sphere of oil partook of the rotation, flattened and detached a ring. The cosmical mass was of rare gas, and existed in a void, with no external power to turn it. If Plateau had suspended a ball of hydrogen in a vacuum, annihilated the attraction of the earth, and then made it revolve without applying force, the cases would be similar.

Neglecting the laws of Nature we will assume that the primitive sphere was in rotation. Admitting it, a demonstration will be made that if by unknown law it cast off a ring or any other form of mass, said portion could not have been abandoned anywhere in the vicinity of the orbit of Neptune.

First proposition:—If the sphere by rotary motion, or other mode of force cast off its equator, matter which condensing made Neptune, then that planet formed, and now moves on a line that coincided with the *Centre of Gravity* of the discarded mass, no matter what was its shape, size or density.

This statement we deem self-evident, incapable of argument, and an absolute truth.

Second proposition:—If the ring that contained the matter now existing in Neptune, was thrown off the equator of a sphere, a section of the ring perpendicular to its length would be either a circle, or a segment of a circle. That is, the ring would be either cylindrical, or flat inside and curved outside, the curvature being the arc of a great circle, a meridian bisecting the poles of the sphere. We can conceive of no form of mass capable of being detached from the circumference of a sphere. other than cylindric or segmental.

Third proposition:—If the Neptunian ring was not cast off when the mass was a sphere, it was abandoned after the ball had depressed at the poles, and elongated at the equator. And a perpendicular section of such detached protuberance would be some one of the Conic Sections.

Draw a chord of an arc from north to south any distance below the orbit of Neptune, so that it does not de-

scend farther than half way to Uranus, or 500,000,000 miles; then all the matter alluded to in this paper will be above the chord. So long as the mass remains spherical the chord will cut out a segment of a circle. Now let the cosmic sphere receive some unknown impulse that will accelerate its velocity of rotation, and the mass will change to a spheroidal form. The chord of the arc will shorten, matter at the equator will become elevated and sections of the protuberance will change curvature. Make both ends of the chord points of tangency, and produce tangents to the curve to infinite space. Then if rotation accelerates, the curve bounding the ascending equatorial protuberance must continually change form, and the tangents, direction; while sectional curves will pass all varieties of the hyperbola, parabola and ellipse. Thus let the mass become very oblate, pass a cutting plane down to the chord, and the curve cut out will be hyperbolic. Increase rotation; the equator will become higher, the chord shorter and the sections parabolic. Let the velocity be still accelerated, the equatorial matter will be lifted to greater altitudes, the chord will be shorter than ever, and the sections elliptical. To this reasoning the objection may be raised by some that no matter how flattened the mass might become, sections cut to the chord of the arc would in every case be elliptical. We do not insist that they would be hyperbolas or parabolas; but will prove if ellipses, that elliptical segments are more fatal to the theory of ring formation than are segments of any other form of curve. Two factors engaged in the evolution of cosmic rings—gravity and an opposing force generated by rotary motion. We attack the whole Nebular Hypothesis with the fact that if the revolving gaseous mass abandoned matter at present existing in Neptune, the planet is now in the position of the centre of gravity of the detached portion. This being true, Neptune never became a member of the solar family by displacement of its material from the original mass, because no mass could have been cast off whose centre of gravity coincided with the orbit of that world. Let us see if the Neptunian ring was abandoned when the cosmic mass was a sphere. If so, the ring was either cylindrical or a segment of a circle. But the centre of gravity of a section of a cylindric ring is in the centre of the section. Since Neptune now traverses a path once the centre of gravity of the ring, it follows that when detached the spere of gas was larger than a ball bounded by the Neptunian orbit, as there must have been as much matter above the centre of a section of the ring as below. The larger the sphere the slower the rotation, hence it did not rotate as rapidly as it would, had it been equal in size to a globe having the diameter of Neptune's track. But it had to revolve faster to detach a ring because Neptune now moves on an orbit with a velocity of 3.36 miles per second; yet displays no tendency to leave it on a tangent. And greater detaching force would have been required to cause a ring to leave the equator than would now be necessary to throw Neptune off its orbit, because the force had to overcome what little cohesion the dissociated atoms had. The sphere must have been far larger than the path of Neptune, because the ring, being abandoned at the equator, had to be hundreds of millions in thickness to secure gas enough to condense into the planet, and its rate of rotation proportionately less than its present velocity.

It is certain that the ring whence Neptune was formed was *not* cylindrical. The only other possible form of ring is segmental. The distance of centres of gravity of all circular segments from the centre of the circle can be calculated. The problem resolved itself into this:—given the distance of the centre of gravity of the segment of a circle from the centre, to find the dimensions of the segment, and radius of the circle. We know that Neptune is in the position of the centre of gravity of whatever shaped mass was detached. But it lies on the circumference of a circle whose radius is the distance to the sun. Therefore the circle must have been larger than its orbit to be able to afford a segment having sufficient size to have its centre of gravity coincide with the track of Neptune. In all these computations we take the distance of Neptune from the sun to be 2,780,000,000 miles.—Elements of 1850, Newcomb's Astronomy. The ring of whatever shape is supposed to be detached, severed, straightened, and cut into an infinite number of sections perpendicular to its length. In the case in question, sections are segments of a circle, and we are in search of the radius of the circle whence the segment was cut. We have found the length of the radius to be 3,000,000,000 miles, by means of the formula, $G = \frac{C^3}{12A}$, wherein

G=the distance of the centre of gravity of the segment from the centre of the circle.

C=the chord of the arc, or base of the segment.

A=the area of the segment.

That is—"Divide the cube of the chord of the segment by twelve times the area of the segment; the quotient will be the distance of the centre of gravity required from the centre of the circle."—Vogde's Mensuration p, 237. Making approximation with a circle whose radius was 2,900,000,000 miles, with chords at different distances within the Neptunian orbit, it was found in two trials that a circle of that radius was untenable. Using a circle having a radius of 3,000,000,000 miles, and chord descending 300,000,000 miles, it was soon found that the centre of gravity of that segment was in distance from the centre equal to the distance of Neptune from the sun. But the chord was 2,600,000,000 miles long! Does anybody believe that a break took place along a line of such length, and 300,000,000 miles below the equator of the sphere? Was detachment possible when the sphere rotated slower than the orbital velocity of Neptune now is, yet shows no signs of elevating to a tangent to its path, though moving with unimpeded force? The first world was not abandoned by the cosmical mass when a sphere.

Could it have been formed from the matter contained in the segment of any other curve known to geometers?

To find the centre of gravity of a parabolic area:—"The centre of gravity is on the axis, at a distance from the vertex equal to three-fifths the altitude of the segment," Peck's Calculus p. 175. Then Neptune, as it is the centre of gravity of the parabola must be two-fifths above the base or limiting plane of the curve, We have made calculation of the altitudes of several possible parabolas, by locating the base at different distances between the orbits of Uranus and Neptune. The following table shows the distances of the limiting planes below Neptune, the altitudes of the segments, above the base,—above Neptune,—and also gives the diameter of the mass on the hypothesis, that it could have been so elongated as to make it possible that parabolas could be cut out of the equator by perpendicular planes.

TABLE I. ALTITUDES OF PARABOLAS. DISTANCES IN MILES.

Distances of Base Below Neptune.	Altitudes Above Base.	Altitudes Above Neptune.	Diameters of Mass when so Expanded.
500,000,000	1,250,000,000	750,000,000	7,060,000,000
400,000,000	1,000,000,000	600,000,000	6,760,000,000
300,000,000	750,000,000	450,000,000	6,460,000,000
200,000,000	500,000,000	300,000,000	6,160,000,000
100,000,000	250,000,000	150,000,000	5,860 000,000
50,000,000	125,000,000	75,000,000	5,710,000,000
25,000,000	62,500,000	37,500,000	5,635,000,000

Should these figures be deemed unsatisfactory, because they relate to sections or surfaces, while actually considering a solid ring, a table of *paraboloids* is inserted. The ring was 17,467,000.000 miles long, cut it in an infinite number of parabolic sections; revolve each

about its axis considered motionless, and an infinite number of paraboloids will be generated, all interlacing throughout the length of the ring. The centre of gravity of a paraboloid is two-thirds the distance, from the vertex to the limiting plane.

TABLE II. ALTITUDES OF PARABOLOIDS IN MILES.

Distances of Base Below Neptune.	Altitudes Above Base.	Altitudes Above Neptune.	Diameters of Mass when so Elongated.
500,000,000	1,500,000,000	1,000,000,000	7,560,000,000
400,000,000	1,200,000,000	800,000,000	7,160,000,000
300,000,000	900,000,000	600,000,000	6,760 000,000
200,000,000	600,000,000	400,000,000	6,360,000,000
100,000,000	300,000,000	200,000,000	5,900,000,000
50,000,000	150,000,000	100,000,000	5,760,000,000
25,000,000	75,000,000	50,000,000	5,660,000,000

No tables of altitudes of hyperbolas or hyperboloids have been inserted, as the distances of their gravitation centres differ so little from parabolic segments, that it was not thought best to fill up the columns of "SCIENCE" with useless figures. For those who think the ring could not have been left when sections were parabolic or hyperbolic, we give a table of altitudes of ellipsoids, that is when sections cut to the chord as before, were ellipses. "The centre of gravity of a semi-prolate spheroid of revolution is on its axis of revolution and at a distance from the centre equal to three-sixteenths the major axis of the generating ellipse."—Peck's Calculus, p. 175.

Therefore Neptune is 3-16 above the conjugate axis, and 13-16 below the vertex of the ancient semi-ellipsoid, all the worse for the theory of ring detachment. Consider the ring cut by perpendicular planes descending to the chord, into an infinite number of semi-ellipses. The chord becomes the conjugate; revolve each curve about its semi-transverse axis regarded as stationary, then the ring will be made up of an infinite number of semi-prolate spheroids of revolution, each so nearly coincident with the next as to have the surfaces fail to coincide only by infinitesimal space. The table is computed by calling the conjugate diameter, the chord of the arc, and the semi-axis major, the line reaching from its centre up to the equator, Neptune being in the centre of gravity of the solids of revolution.

TABLE III. ALTITUDES OF SEMI-PROLATE SPHEROIDS.

Distances of Conjugate Axes Below Neptune.	Altitudes Above Base.	Elevations Above Neptune.	Diameters of Cosmic Sphere When so Elongated.
500,000,000	2,667,000,000	2,167,000,000	9,894,000,000
400,000,000	2,134,000.000	1,734,000,000	9,028,000.000
300,000,000	1,600 000,000	1,300,000,000	8,160,000,000
200,000,000	1,066,000,000	866,000,000	7,292,000,000
100,000,000	533,000,000	433,000,000	6,426,000,000
50,000,000	266,000,000	216,500,000	5,592,000,000
25,000,000	133,000,000	108,250,000	5,778,000,000

These tables of absurd figures are inserted to show the hypothesis irrational. No such extension of the mass was possible, and no protuberance could have arisen above the equator able to afford perpendicular sections, hyperbolic, parabolic or elliptic. Nor could the chord become the limiting plane of any parabola, hyperbola or conjugate axis of any ellipse. Yet, the tables are logical deductions from the doctrine of ring detachment, for if the mass depressed at the poles, and elongated at the equator, curvature of radial sections must have assumed all varieties of conics. Since the centres of gravity of all these curves, and solids generated by their revolution are known, the figures are correct if the theory is true. It will be shown in a paper on mass, volume and density, that most of these equatorial elevations could not have contained matter enough to form Neptune.

Is it credible that the primeval mass ever detached rings or any other shaped portions? From the altitudes of these conoids it is seen that to cast off the Neptunian material the rupture in every case took place at depths of hundreds of millions of miles, where cohesion was greatest and rotary velocity least! In all these computations the abandoned masses were considered as homogeneous, as difference in density in a gas of such excessive rarity cannot enter as a factor at depths of a few hundred million miles. It may be said that cohesion in a gas so rare, was not a factor. Granted, then *rotation* was not, since a ball of gas of such tenuity as to have no cohesion, could not possibly be set in revolution. The equatorial edge of the mass could not have become angular, for sections cut to the base would be triangles, whose centres of gravity are two-thirds the distance from the angle to the base, and nowhere near where Neptune exists. Neither could sections have been cissoidal, conchoidal, cycloidal or sectoral, nor of any other similar curvature known to geometry. The surface was not irregular; loose masses did not float above the periphery; the matter was all of the same specific gravity, hence *buoyancy* did not obtain on a mass of dissociated atoms. The mass existed in a void, else external matter by friction would have induced currents from east to west. No modes of energy save rotary force, existed to detach a ring, no internal repulsion, as that had vanished in dissociation. The dogma is beset on all sides with difficulties. When the mass was spherical, matter enough to form Neptune was unable to leave the equator; when elongated, segments of enormous depth had to be left by the shrinking mass, to afford material sufficient to condense into the oldest planet; and the break occurred where it was most difficult to be made, and where the power necessary to make it was the least.

Not only the most complex, but the simplest laws of nature dispute the Nebular Hypothesis. Even primary schools have text books wherein laws are laid down that subvert it! Primers of natural philosophy teach that if a revolving sphere diminishes in diameter, its velocity of rotation becomes accelerated, and the same primers teach that if the diameter increases the velocity diminishes. Therefore, if the primeval gaseous sphere ever revolved, said rotation caused the equatorial diameter to increase in length; but as soon as lengthened the velocity of rotation diminished and the mass again became a sphere, the oscillation always remaining within small limits. The diameter of the mass when spherical was 5,560,000,000 miles; can it be believed that rotation so far gained mastery over retardation as to allow the mass to attain diameters ranging between 6,000,000,000 and 7,000,000,000 miles to detach parabolic segments; and between 6,000,000,000 and 9,000,000,000 miles to abandon semi-prolate spheroidal sections to make up a ring? We are unable to conceive that valid argument can be made in favor of the detachment of matter in any form or volume from the mass. This theory, opposed by every known law of nature has actually been entertained by eminent physicists, geometers and astronomers, fully conversant with these same laws that destroy the doctrine; a thing long noted by psychologists, wherein delusions hold sway over fine minds with greater tenacity than ideas known to be true.

SEISMOLOGY IN JAPAN.—The labors of the Seismological Society of Japan have established the fact that there is a chronic center of disturbance within a radius of a few miles from Yokohama. We are glad we do not reside in the said Yokohama; at the same time, we congratulate the society on the success attending its researches.

THE USE OF WATER AS A FUEL.

By Dr. George W. Rachel.

The results of certain experiments, made with what has been called the Holland Hydrogen Locomotive, have lately been published in several city papers. They are not only of the highest practical importance, but of great scientific interest, so that it appears entirely proper to discuss them from that aspect in this journal.

The fuel used is naphtha and water; the manner in which combustion is accomplished by a peculiar unique apparatus may be shortly described thus:

The principal feature of this new invention is an iron retort having two compartments, one for naphtha and the other for water. The two fluids are conducted into the two chambers by induct-pipes at one end of the retort, while at the opposite side there are two escape-pipes, through which the vapors of the two substances escape from their respective chambers, where gasification has taken place. The two gases are being mixed by passing into a common receptacle, the manifold, and from there they are distributed through three main pipes to the 352 burners. Of these 44 are placed directly under the (four) retorts, while the balance is arranged under the boiler.

The astonishing results obtained by this ingenious apparatus have been the subject of many discussions in various scientific and industrial journals on both sides of the Atlantic. The attacks have usually been directed against the possibility of making an advantageous use of the hydrogen for the purpose of combustion. The explanation that in the Holland retort the principal source of the tremendous heat produced, is due to the combustion of hydrogen derived from the dissociation of the water vapor, has been supposed to be met by the following statement:

The dissociation of the steam must consume as much heat, as is afterward developed by the combustion of the hydrogen.

It was contended that the principle of the Holland method was entirely wrong, implying an error against the law of the conservation of energy which is the fundamental law of the Universe, and therefore this whole matter must be a delusion.

This objection, which looks plausible enough can be shown to be erroneous, as it is based on a misconception, or rather a misinterpretation of this great law of Nature. The error consists in the wrong application of the word heat; the sentence containing the objection to be correct, must read thus:

The dissociation of the steam must require as much *energy*, as is afterward developed by the combustion of the hydrogen thus obtained. Now, it is a fact, that the energy developed by the combustion of the hydrogen invariably takes the form of heat, but the principle of the correlation of forces which forms the basis of this very law, teaches us that it must not necessarily do so during the process of dissociation. In order to fully expose the misinterpretation of Nature's fundamental law contained in the objection above quoted, we may be allowed a few words on the subject of dissociation.

Prof. H. St. Clair Deville, who first succeeded in an ingeniously contrived apparatus to dissociate water vapor into its elements, hydrogen and oxygen, estimates the temperature required for the purpose at 6000°C, probably even somewhere near 8000°C. Prof. Schroeder van der Kolk even places it at a still higher figure, viz.: about 10,000°C. But these figures, it must be well understood, refer to the dissociation of water vapor in the absence of any other element. If, on the contrary, the dissociation is induced to take place in the presence of other elements —notably metals—the dissociation temperature is lowered considerably. Thus, for instance, the dissociation is effected in the presence of platinum, at 1700°C; iron filings, 1400°C; silver, 1000°C, instead of 8000°C.

The question is now: How are we account for this? Prof. Deville in a controversy now going on between Prof. Ad. Wurtz and his school, and Berthelot and himself, on this very subject of dissociation, replies to some objections of his adversaries, as follows:*

It is a well-established fact that the dissociation of water-vapor takes place at much lower temperatures in the presence of certain elements. . . . . These and other examples . . . . prove that the development of heat during the formation of a compound body, does not hold any known relation to its dissociation temperature. Evidently the error is very frequently committed in regard to these processes to confound actual and kinetic energy, actual and latent heat."

The relation referred to in this passage, must, however, in the light of the law of "Conservation of Energy" be one of absolute equivalency; the energy expended on one process—dissociation—must under all circumstances be equivalent to the energy developed during the other process—formation of the compound body, *i. e.* in our case water-vapor.

If, therefore, our experiments show that the temperature of dissociation is lowered in the presence of certain elements, we must look for some other form of energy which supplants the amount of heat saved. What force is it that steps in here and plays the role of a dissociating agent in place of the tremendous heat? The answer is obvious, it is *chemical affinity*, for chemical affinity is the only form of energy capable of such intensity of action. Furthermore, chemical affinity is to a certain extent not directly discernible and measurable, as Friedrich Mohr has shown.†

The irrefutable proof for our assertion lies in the fact that there is in the case under consideration, always formed an oxide of the metal employed. We find the molten silver and platinum covered with thin films of their respective oxides while the iron filings show an amount of oxidation which is—as it is in the two former cases—in direct proportion to the quantity of vapor dissociated. The chemical affinity of the glowing and molten metals to the oxygen of the water-vapor being greater than the chemical affinity of hydrogen to oxygen, they appropriate the oxygen of the steam, and, combining with it, form their respective oxides—thus liberating the hydrogen and accomplishing dissociation.

Deville's above-quoted statement, that there is no known relation betweenthe formation—and dissociation-temperatures of compound bodies must be modified, therefore, in the light of the foregoing observations. What he is pleased to call "Kinetic energy" and "latent heat" is actually nothing else than chemical affinity. The position of Wurtz and his followers, by the way, is untenable; they contend that the two temperatures should be equal,(in accordance with the law of the conservation of energy) and meet the often observed fact that these temperatures differ considerably with the assertion that, as theoretically they should not do so, the observations are wrong. Their interpretation of the great principle contains the same error which the objections to the Holland process are suffering from; they insist that the energy which produces dissociation must take the form of heat and heat only, because heat is the only form of energy met with during formation. They forget that such limited application of this great principle is entirely arbitrary and that the only requirement of the law is that of absolute equivalency, while there is no rule as to the kind of energy required.

I have been somewhat elaborate in my remarks on the subject of dissociation, because the conditions under which the dissociation of steam takes place in the Holland process are the exact counterpart to those which have just been dwelled upon. Instead of the metals, the

*Comptes rendus, 1879.

† Science Vol. I, pg. 244.

carbon of the Naptha-gas reduces the dissociation-temperature.

The fact that under certain conditions carbon has a dissociating action on steam, or—as some put it—carbon may be burned up with watery-vapor, has been known for a long time; the presence of free hydrogen in furnace and generator-gases is due to this circumstance. The difference between the dissociating action of carbon on water-vapor as compared with that of the metals abovementioned is only one of degree. *The temperature at which it takes place is much lower.*

After a prolonged and careful observation of the phenomena connected with the Naphtha and water-process under consideration, the writer was firmly convinced that the carbon in them plays the role of a dissociating agent, and that the temperature at which its dissociating property asserts itself must be a low one, comparatively speaking. For, in this way only was it possible to account for remarkable results of the HOLLAND heating method.

Unhappily, we were not then acquainted with the experiments presently to be discussed, although the fact privately communicated to us that MR. MOSES FARMER, of Hartford, the well-known philosopher, had found experimentally the temperature at which carbon will dissociate water-vapor to be not much above 900° C., seemed to confirm the position taken.

While our proposal to entrust some able chemist with this investigation was under consideration, we became aware of the fact that the desired experiments had already been made in another quarter of the globe more than a year ago. Thus, fortunately, a doubt of their genuineness, which otherwise might perhaps have been entertained by the opponents of the HOLLAND method, is out of the question.

PROFESSOR ACKERMAN, who is superintendent of the chemical labratory at the *Stockholm School of Mines*, requested one of his assistants, MR. C. G. DAHLERUS, to make some experiments with the view of determining the temperature and other circumstances required for the combustion of carbon with watery vapor. The real aim was to explain the occurrence of free hydrogen in both furnace and generator gases; this fact is, as we said before, well-known to mining engineers.

The apparatus used by DAHLERUS consisted of a tube filled with charcoal, which was heated in a combustion furnace, while steam, generated in a separate boiler, was allowed to pass through it. The temperature was determined by trays of steatite containing pieces of Mayerhofer alloys, with various melting points being introduced into the tube. The gases generated were collected, after having passed through a spiral gas tube in order to condense the steam they contained, and were then analyzed. Every experiment lasted at least two hours before a sample of the gas was taken, the pressure of the steam in the induct pipe being kept as uniform as possible.

The results of these experiments have confirmed the correctness of our position, and have shown that dissociation of watery vapor in the presence of carbon takes place at much lower temperatures than has hitherto been admitted.

MR. DAHLERUS, in giving a table of his results, sums up as follows:

"On examining this table it appears that watery vapor is decomposed at a temperature which is indicated by the alloys as from 450° to 500° C.; *but the temperature may, in fact, not have been higher than* 400° *C., because zinc in the interior of the tube was not fused in any of the first five experiments.*"

It is evident that in the Naphtha and water process the conditions, under which the dissociating action of carbon on water vapor takes place, are much more favorable to it than those obtained in the apparatus used by DALHERUS for his experiments.

In the first place the action of carbon in the latter gentleman's apparatus could not but be of a very slow nature, the surface only of the glowing charcoal in the tube being enabled to gasify and act chemically on the steam surrounding the pieces of it. In the process under consideration, however, the whole of the carbon of the naphtha is in gaseous condition and by diffusion the vapor is acted upon simultaneously at every point. Furthermore, this very gasification of the carbon requires a definite, not inconsiderable, amount of heat which in DAHLERUS' apparatus has to be supplied by the steam itself, this being the only substance admitted into the presence of the charcoal in the tube. In the new process, on the contrary, this gasification is effected before the carbon-compounds of the naphtha are mingled with the steam and no loss is therefore experienced in in this direction. But, aside from these details—for the combustion-furnace will probably furnish the wanting heat—the highly important fact is established by these experiments that chemical affinity does, in this dissociation process, supplant heat for the greater part. And, considering the great advantages, above detailed, of the HOLLAND process over these experiments, we are justified in assuming the lowest temperature, found sufficient by DAHLERUS in five of his experiments, as entirely sufficient in the HOLLAND process also. *Instead of* 8000° C., *therefore being required for the dissociation of water, it will here take place at* 400° C.

A gain therefore of, say for convenience's sake, nineteen twentieths is effected; for every particle of hydrogen thus dissociated and liberated, at 400° C., will develope its full 8000° C., on combustion with oxygen, *i. e.*, on being burned up by the draft air. And this saving is accomplished by the supplanting of heat with chemical affinity, the latter performing the greatest part of the work of dissociation.

Nor is this all!

It is necessary to state here that DAHLERUS in pursuing his work had in view also, the preparation of *water gas*, which has been introduced into Sweden by PROF. TORREL, who was one of the commissioners from that country to the Centennial Exhibition at Philadelphia. He therefore endeavored to find the most favorable condition for the production of *water gas*, a mixture of hydrogen and carbonic oxide which is known in this country under various names (*e.g.* STRONG, LOWE and others.)

This explains the following sentence in the conclusions he draws from his results:

"Further we see that the greater the excess of watery vapor the richer in carbonic acid are the gases; or, in other words, *that carbonic oxide is very easily burned to carbonic acid by means of watery vapor*, and that the content of carbonic oxide is increased both by a lessened excess of watery vapor and by the raising of the temperature. The best gas is thus obtained by raising the temperature as high as possible and by a moderate supply of steam."

What DAHLERUS refers to as *the best gas* must be understood to be *water gas* in the accepted sense of the word, viz.: A mixture of carbonic oxide with hydrogen. It is for this reason that he advises the use of a limited supply of steam only; for, if there is an unlimited supply of steam, the dissociation of the same continues and the carbon, instead of being confined to its first stage of oxidation (to carbonic oxide), completes this process and is burned up to carbonic acid. Although the result is by these means a gas much richer in hydrogen—in fact twice as rich—this is not what the manufacturer of water-gas wants. He wants a product that may be used for illumination as well as for heating purposes and, therefore, he does not want an almost pure hydrogen-flame—which is non-luminous, as is well known. But with the HOLLAND process this is quite different; here the manufacture of illuminating gas is effected in a separate automatic arrangement which does not concern us here now. In the process under consideration, therefore, the heating quality of the gases is the only consideration. This, the more so, since there is here no separate gener-

ator from which the gases therein manufactured are led away in pipes to the heating-place. The generator, *i. e.* the HOLLAND retort is at the heating-place, in the fire-box of the locomotive, and the full effect of the carbon combustion is therefore obtained in both cases, whether the dissociation of the steam takes place to furnish oxygen for the first stage of this combustion only or whether the dissociation is accomplished so as to burn up the carbon completely with oxygen derived from the dissociated water-vapor. But there is this great difference: If the carbon derives all the oxygen necessary for its complete conversion into carbonic acid from the dissociation of the steam, there will be twice as much hydrogen liberated as against its conversion into carbonic oxide only, as will be seen from the following statement of the two cases by DAHLERUS:

"When watery vapor burns carbon to carbonic oxide, there are formed from two volumes of watery vapor and one volume of carbon two volumes of carbonic oxide and two volumes of hydrogen; further, when carbon is burned by watery vapor to carbonic acid, there are formed from one volume of carbon and four volumes of watery vapor, two volumes of carbonic acid and four volumes of hydrogen. Consequently the volume of hydrogen in the gases is equal to the volume of carbonic oxide and double that of the volume of carbonic acid."

In connection with these important relations I must, in conclusion, refer to the results of numerous experiments, made with the HOLLAND process, which can only be fully and satisfactorily explained in the light of the previous discussion. They are certainly a most remarkable series of experiments, never before equalled or excelled; the results accomplished by the Naphtha and water process have startled all experts and scientists who have witnessed them, while those who have not seen their actual performance reluctantly admit their genuineness. Yet they are absolute facts, and the possibilities which they have in store are greater than anything that has as yet been reported.

In starting the fire under the boiler of this locomotive, it must be stated, there is first lighted a small tank filled with naphtha, which is placed under one of the retorts in the fire-box. As soon as this retort is thereby sufficiently heated to gasify the naphtha, naphtha-gas is burned under all the retorts, and water admitted into them to be converted into steam. When both naphtha and water are thus gasified, their gases are jointly admitted to all the burners under the whole length of the boiler, and the generation of steam now begins in earnest. As soon as feasible, steam from the boiler is introduced into the retorts instead of water, so that after this period the naphtha only has to be gasified in the retorts.

I now give one of Mr. CONANT'S tables in full, containing the results of an experiment he witnessed on April 29th:

LIGHTED AT 10:05 A. M. GAS STARTED AT 10:35.

Steam, Pounds.	Time, M.	Naptha, Gall.	Naptha, Per Lb. Gall.	Naptha, Per Min Gall.	Totals. Gall.	Totals. H. M.
10	69½	5.62	.56	.08	5.62	1 09½
20	15	3.83	.40	.27	9.45	1 24½
30	18½	2.7	.29	.15	12.35	1 43
40	9	2.41	.24	.27	14.76	1 52
50	8	2.14	.21	.27	16.9	2 00
60	7	2.14	.21	.30	19.04	2 07
70	5	1.61	.16	.32	20.65	2 12
80	3½	1.07	.10	.30	21.72	2 15½
90	4½	1.07	.10	.24	22.79	2 20
100	4	1.07	.10	.27	23.86	2 24
110	4	1.07	.10	.27	24.93	2 28
120	4	1.07	.10	.27	26.00	2 32
Engine started out—safety valve blowing—oil disturbed and no record.						
133	5	----	----	----	----	----

Pop valve blowing av. 33 sec., with 32 sec. intervals. No right of way and no run.

The puzzling fact that the higher the temperature and the steam-pressure rise, the less naphtha is burned, would be absolutely inexplicable if it was not for the relations alluded to in the foregoing observations. Up to 60 or 70 pounds of steam-pressure in the boiler the consumption of naphtha averages 2.14 gals. for every ten pounds of pressure added, while above these figures, it averages only 1.07 gals.—just one-half of the former quantity—for every additional 10 pounds. We know what that means. It means that there is an evident supplanting of the naphtha by some other much more powerful heating agent; the naphtha in this process unmistakably plays a subordinate role, as far as the heating is concerned. We know its task. It dissociates the water and thereby liberates its hydrogen; it is the latter that furnishes the bulk of the caloric energy developed. During the earlier stages, when the steam-pressure is yet comparatively low, the quantity of steam introduced into the retorts is limited and the carbon therefore is burned up to carbonic oxide only by dissociated oxygen; as soon, however, as the steam-pressure rises above a certain point the quantity of steam introduced is very soon sufficient to furnish all the oxygen necessary for the complete combustion of the carbon of the naphtha to carbonic acid. Thus, we are enabled by a correct interpretation of Nature's laws to explain fully and satisfactorily the paradoxical fact that the greater the heat, the less the consumption of oil. We know that instead of two volumes of hydrogen in the first, we must have four in the second case.

There is one other point which I may probably feel called upon to treat of, viz.: the utter invisibility of this tremendous fire. For the present the above will suffice.

DR. GÜNTHERS ICHTHYOLOGY.*

Less than a century ago the last edition of the Systema Naturæ of Linnæus, published in 1766, was taken as the basis and text of essentially a new compilation by Johann Friedrich Gmelin, and among the species admitted by Linnæus were intercalated those subsequently added by others to the system. There were very many duplications arising from the imperfect acquaintance of the compiler with his subject, but nevertheless, all told, only 826 species of fishes were named. There are now known, in round numbers, nearly ten thousand species. In the interval between the compilations of Gmelin and the present were published works of a like nature, by Walbaum, Lacépède, Bloch, Schneider, and Shaw. These were all finished before 1804, and were all of very little value. For considerably more than half a century no other descriptive general enumeration of fishes was completed. Meanwhile, from 1828 to 1849, Cuvier and Valenciennes gave to Ichthyology 22 volumes of a work designed to be a general natural history of fishes, but this was never finished. At last, in 1859, was commenced and in 1870 brought to an end, a work purporting to enumerate all the species of fishes known to the dates of publication, by Dr. Albert Günther, under the auspices of the British Museum. For this contribution the scientific world was laid under great obligations to the author as well as publisher. It was a compilation requiring considerable skill and acquaintance with the literature, and the work may be said to have been moderately well performed. Its author followed the outlines of classification proposed many years before by the illustrious Johannes Müller. On the whole this was the best course, perhaps, to be taken at the time. In 1861, however, he gave a systematic re-arrangement of the Acanthopterygian families, which was above all characterized by an excessive valuation placed on very trivial charac-

* An introduction to the study of fishes. By Albert C. L. G. Günther. Edinburgh: Adam and Charles Black. 1880.

ters, and was, in some respects, a step backwards, although of not very much moment.

Another and most radical modification—the next stage—may be fitly noticed in the author's own words. [1.] "The discovery (in the year 1871) of a living representative of a genus hitherto believed to be long extinct, *Ceratodus*, threw a new light on the affinities of fishes. [2.] The author who had the good fortune of examining this fish, was enabled to show that, on the one hand, [3] it was a form most closely allied to *Lepidosiren;* on the other, that it could not be separated from the Ganoid fishes, and therefore that also [4] *Lepidosiren* was a Ganoid: a relation pointed out already by Huxley in a previous paper on 'Devonian Fishes,' [5] This discovery led to further considerations of the relative characters of Müller's sub-classes, and to the system which followed in the present work" (pp. 25-26). In regard to this claim there are several noteworthy and characteristic features.

(1) In 1870, in Dr. Günther's Cat. Fishes Brit. Mus., vol. 8, p. 323, it is expressly admitted that "after [the 'sheet' descriptive of *Protopterus* and *Lepidosiren*] had passed through the press, Mr. Krefft informed me of the most interesting discovery that a living representative of *Ceratodus* had been found in Queensland. Nothing of this genus was hitherto known beyond teeth, as those described and figured by Agassiz in Poiss Foss. iii, p. 129, pls. 18-20." (2) Dr. Günther knew nothing whatever of *Ceratodus* till he received a communication respecting it from Mr. Krefft. (3) As indicated by Dr. Günther himself (Trans. Royal Soc., v. 161, for 1871), Mr. Krefft, in even the title of his paper, published April 28, 1870, and before Dr. Günther's "reply had time to reach Mr. Krefft," recognized the affinity of the genus to *Lepidosiren.* (4) As early as 1860, Gill (as Brandt, Peters, Lütken and others subsequently recognized) showed that "*Lepidosiren* was a Ganoid," and that *Polypterus* was a type intermediate between the ordinary Ganoids and the Dipnoi. (5) Consequently the only novelty in Dr. Günther's work was "the system which is followed in the present volume," which has been pronounced by an eminently competent judge to be "a triumph of systematic *gaucherie.*" Whatever is true in the statements examined had been appreciated before Dr. Günther labored and only what is untrue to nature and to science was original with him. The co-ordination of the facts enumerated was the necessary logical result of the successive steps.

But what is "the system which is followed in the present work?" Only the salient features may be noticed, and these will sufficiently appear from the enumeration of the sub-ordinal, ordinal and super-ordinal groups. These are:

I. SUB-CLASS—PALÆICHTHYES.
- I. Order—Chondropterygii.
  - I. Sub-order—Plagiostomata [Sharks and Rays].
  - II. Sub-order—Holocephala [Chimæroids].
- II. Order—Ganoidei.
  - I. Sub-order—Placodermi [Extinct].
  - II. " —Acanthodini [Extinct].
  - III. " —Dipnoi.
  - IV. " —Chondrostei.
  - V. " —Polypteroidei.
  - VI. " —Pycnodontoidei [Extinct].
  - VII. " —Lepidosteoidei.
  - VIII. " —Amioidei.

II. SUB-CLASS—TELEOSTEI.
- I. Order—Acanthopterygii.
- II. " —Acanthopterygii Pharyngognathi.
- III. " —Anacanthini.
- IV. " —Physostomi.
- V. " —Lophobranchii.
- VI. " —Plectognathi.

III. Sub-Class—Cyclostomata.

IV. Sub-Class—Leptocardii.

To those familiar with the facts and details of the anatomy of fishes and the inferior vertebrates, this enumeration will be its own best commentary. Suffice it for the present at least to affirm that it involves more contradictions and inconsistencies than have been manifested in any recent taxonomical exposition of any class of animals emanating from a respectable source.

Almost equally in disaccord with the cultivators of the other branches of Vertebrate Zoology is Dr. Günther in his treatment of GENERA.

The extreme of differentiation is practiced by ornithologists, (provided the differences are obvious and external), and a course is pursued in mammalogy which has received the sanction of the greatest number of students of that class, during at least the last quarter of a century. American ichthyologists have endeavored to comply with the principles on which genera in the latter class have been recognized as much as the differences of facts will permit, and although, of course, there are many disagreements as to detail, there is an essential congruity between them. The principles, if any, applied by Dr. Günther are undiscernable from his work. His methods indeed, seem to have varied with the whim of the moment and to have been modified for each case: the results then happening appear for him to have crystallized and not to have been subject to review or further consideration afterwards. Strange contrasts constantly occur in the extension or limitation of the groups. In the genus *Tetrodon*, for example, is discoverable a very considerable range of variation, not only in external features but still more markedly in the details of structure, and especially in the bones of the head. So great are these that there are three well defined major groups and a number of minor ones entitled to generic distinction, but, nevertheless, our author has refused to admit more than one "genus" for all the representatives of the type, whereas, in the related group of Diodontines, he has recognized a number of genera upon characters of very much less moment, such as the development of the spines, nostrils, &c. Under the genus *Gasterosteus* are confounded all the representatives of the family of Gasterosteids, and yet upon differences of the same kind as those which distinguish, for example, the "*Gasterosteus spinachia*" from the other species of *Gasterosteus*, are elsewhere constituted distinct *families.*

These examples might be extended indefinitely. Heterogeneous combinations of forms on one hand chance in strange contrast with isolated generic types on the other.

Comprehensiveness of genera *per se* is not a great evil, provided there is consistency in the treatment of the subject, and that all share as nearly alike as the nature of the case allows. It is to the assignment of inordinate value to a few superficial characters, and the subordination, to the manifestation of such, of other characters whose coincidence demonstrates them to be of greater importance, that we object. It is true that the acceptance of such comprehensive groups isolates in a measure the class in which they are recognized from others and tends to constantly mislead the inquirer who would compare the constituents of the several classes, *e.g.*, as to their geographical or geological relations. Even this, however, is of minor importance. It is the utter disregard of the gradations of structural differences exhibited by Dr. Günther in his constitution of genera that detracts so much from the value of his work. To enter into detail would necessitate space equal to the portion considered, and some instances must suffice.

Serranus (p. 381) is distinguished among its allies by the "small scales," presence of "very distinct canines in both jaws," and the absence of serratures from the lower margin of the preoperculum. Under the genus thus defined, there are not only species which disagree with the principal characters, but the *typical Serrani (S. cabrilla, S. scriba,* etc.) are more nearly related to the species of *Centropristis* than to the rest of their associates. A

natural arrangement—*i.e.* one based on their anatomical details—would require, first, the fusion of the Güntherian genera *Centropristis*, *Anthias*, *Callanthias*, *Serranus*, *Anyperodon*, *Prionodes*, *Plectropoma*, and *Trachypoma*; then the wide removal of certain forms, and finally the disintegration of the conglomeration on an entirely different basis from that accepted by Günther.

The instances wherein genera are referred to families with the diagnoses of which they diametrically disagree are numerous. Leaving out of consideration cases of conflict of genera or species with the characters assigned as *ordinal* to the including group (e. g., *Pogonias*, *Sciæna*, *Gerres*) the following are examples:

The genus *Dactyloscopus* is referred to the family Blenniidæ, in which the spinous portion of the dorsal fin is said to be "as much developed as the soft, or more." *Dactyloscopus* has in the most evident manner, notwithstanding the erroneous definition of Günther (Catalogue of the Fishes in the British Museum, Vol. III., p. 279), only the first ten to twelve dorsal rays spinous, all the others being articulated. In fact, *Dactyloscopus* has nothing whatever to do with the Blenniidæ, but is very closely related to *Leptoscopus*, and belongs unquestionably to the same group; in other words to an entirely different division of fishes in the Güntherian system. (See Trachinidæ p. 462.)

The genus *Zoarces*, (p. 497) also referred to the family of Blenniidæ, still more disagrees with the true representatives of that family in the structure of the dorsal fin and, as he himself admits, has "no other fin spines" than a few near the caudal; it shows, in fact, an organization similar to that manifested in the family Lycodidæ of Günther, (p. 537) placed by him in a different *order* of fishes—the Anacanthini.

Siphonognathus is a remarkable genus referred to the family of Labridæ. This family is defined as having, in addition to other characters, "the soft anal similar to the soft dorsal, ventral fins thoracic, with one spine and five soft rays," and "branchiostegals five or six." Nothing whatever is said respecting the anal, ventrals, or branchiostegals of *Siphonognathus* and as the necessary data are thus entirely suppressed, it would naturally be assumed that the genus would have the characters attributed to the family. In fact, however, *Siphonognathus* has not the "soft anal similar to the soft dorsal," there are *no* ventral fins, and there are only *four* branchiostegal rays. It will be thus apparent that it would be impossible to identify this fish from Dr. Günther's Introductiou, unless it were assumed that great blunders had been made. This is indeed the case, but it is not safe to assume that the author is an habitual blunderer, and to proceed on that basis, even in the case of Dr. Günther. We are somewhat prepared, however, for the idiosyncrasy exhibited by Dr. Günther, when he compares the relationship of *Siphonognathus* to *Odax* as being similar to that of *Babirussa* to *Sus* (see Catalogue of Fishes in B. M., v. 4, p. 243). Any one who can really entertain such views, and consider the differences between the mammalian genera to be of the same kind or degree as those between the fish genera is unfit to institute comparisons.

Numerous genera are adapted, which, although they may be good, consistency would require Dr. Günther to merge with others. Thus we have *Ptyonotus* (which he has unnecessarily substituted for *Triglopsis* of Girard) retained for a form in the family of Cottidæ (p. 480); this is, however, far more closely related to the "*Cottus quadricornis*" of Günther than are any of his other species of that heterogeneous group. *Pammelas* is still retained as the name of a distinct genus which is allied to *Trachynotus*, although it had been named before Dr. Günther applied his, and its affinities have been well-known for many years to be with *Centrolophus*: it is indeed to a species of that genus (the *C. ovalis*), that the *P. perciformis* is most closely related, and yet in spite of the concurrent testimony of previous ichthyologists we find it injected, in the "Introduction to the Study of Fishes," into a family remote from that to which *Centrolophus* has been referred. As examples of other forms unnaturally separated we may instance (1) *Chætopterus* (p. 390) and *Aprion* (p. 397); (2) *Grystes* (p. 392) and *Huro* (p. 393), and (3) *Auliscops* and *Aulorhynchus* (p. 508). The last type, it may be remarked, is more nearly related to the so-called *Gasterosteus spinachia* than to the Fistulariidæ and should be either referred to the same family or differentiated as a distinct one.

Changes of the names of established genera on trivial pretexts are also indulged in. The name of *Triglopsis* was abandoned for *Ptyonotus* because there was a *Triglops* previously established. Although they are unquestionably much alike, they are sufficiently different, and Steindachner has even lately named a genus *Atherinops*, knowing well that *Atherinopsis* had already been proposed for another genus of the same family. *Dactylopus* is discarded for *Vulsus* because, forsooth, the term DACTYLOPODA had previously been applied by Meyer to a group (not genus) of extinct reptiles. And yet our author himself retains both *Chondrosteus* and Chondrostei etc., without the slightest demur. *Xiphasia* is rejected with an exclamation mark (!) and the yet more objectionable name *Xiphogadus* proposed because the author was dissatisfied with the name, and—we strongly suspect—still more with the namer (Swainson). Why expect any better reason?

The idea is conveyed in the work—and that it has been extensively claimed elsewise by our author is no secret—that all the established genera are admitted in this volume. Without counting the scores of genera that Dr. Günther refuses to recognize, but which every one applying the canons observed by mammalogists and ornithologists would adopt, there are many which even that author could scarcely neglect unless through ignorance. Among those omitted, and which are especially interesting, on account of representing previously unknown types of high value (families or sub-families), or because they throw light on the relations of families in which they belong are: *Elassoma*, *Xenichthys*, *Hoplopagrus*, *Gnathanacanthus*, *Nematistius*, *Grammicolepis*, *Bathymaster*, *Cottunculus*, *Oxylebius*, *Anoplopoma*, *Dactylagnus*, *Myxodagnus*, *Anarrhichthys*, *Plagiotremus*, *Chænopsis*, *Nematocentris* and *Protistius*. If he had really known *Hoplopagrus* (referred to incidentally on page 279, but not otherwise noticed), he, *perhaps*, would not have so far separated his "*Percidæ*" (pp. 375-379) and "*Sparidæ*" (405-410), as he has done: if he had known *Cottunculus* he would, *perhaps*, have recognized the affinity of *Psychrolutes* to the *Cottidæ*, and not isolated it as the type of a remote family—at least no scientific ichthyologist would have failed to so profit by the knowledge. The work of Bleeker, Steindachner, Klunzinger, Lütken, Vaillant, Sauvage, Giglioli and Collett in Europe, and that of all American ichthyologists has, however, been almost of nought so far as Dr. Günther is concerned. It need be only remarked, in connection with the latter, that of the numerous genera of Etheostomine fishes only *Pileoma* (*Percina*) and *Boleosoma* (p. 379) are recognized. The reason therefore is no secret—they are too small, and as they have not been able to grow larger, they do not deserve to be considered. The interesting relations, physiological and morphological, that they present are not sufficient to outweigh this cogent objection. Among American fishes there is no group that has been so much written about and that is better known than the genus *Micropterus*, but notwithstanding Dr. Günther has not yet learned that he has distributed its well defined representatives under three genera, nor that *Huro* was based on a mistake and is not a valid genus, nor that there are two, and only two, well-determined species, and those two can not be generically distinguished. When it is further remarked that only three genera are recognized

for the Centrarchines and Lepomines, and that these are diagnosed by the least important and most fallacious characters, and that thereby the species are thrown into almost inexplicable confusion, some idea may be formed of the unreliability of the work.

The general anatomical portion of the work is, on the whole, really a tolerably good *résumé* of facts respecting the structure and organization of fishes, for the author has wisely followed Gegenbaur, Huxley and Parker without sufficient deviation to fall into much error. One great objection to it, however, is the undue prominence given to the peculiarities of the teleostean types and the exhibition of them in such a manner as to prevent the reader's conception of the range of variation in the forms treated of, and especially as to the taxonomic value of such variations. In this connection too, we may notice the reproduction of some rather strange views. Thus, it is said that "the numbers of the dorsal and anal rays give good specific, generic, or even family characters," except when greatly increased, while "the taxinomic [taxonomic] value of this character becomes uncertain. The numbers of the pectoral and caudal rays are rarely of any account" (p. 44). The last remark embodies a striking illustration of the length to which Dr. Günther's neglect carries him in contempt of the facts. Far from the number of the completely developed caudal rays being of no account, there are rarely deviations in the number in related forms, and when such prevail they generally accompany other decided modifications of structure and are available for major diagnostic purposes, as Bleeker has observed. Again, it is claimed of the pectoral limb that the structure of that of *Ceratodus* "*evidently*" represents one of its first and lowest conditions" (p. 74). So far is this from being "evident" that it is difficult to understand how any one familiar with the stucture and development of the limb in the Selachians and related types, and conversant with the logic of science could entertain for one moment such an opinion and, on the contrary, not look upon the Ceratodontoid limb as an extreme deviation from the primitive type. But the very climax of absurdity and unscientific comparison is exemplified in the case of *Ceratodus* by the homologisation of the basal segment of the axis of the pectoral *fin* (not that which supports it) with the basal cartilage of the Sturgeon, and which itself is the source of several other errors (pp. 74, 76). A comparison of the pectoral limbs of *Ceratodus* and *Polypterus* would be sufficient to prevent any scientific naturalist from making such a blunder. We need not dwell further on such defects but in connection with the systematic portion, we cannot omit to notice that Dr. Günther recognizes that in the Chondropterygians there are no bones representing the membrane bones of the skull of the Ganoid and higher fishes; that at the most there are simply "rudimentary maxillary elements" (p. 69); that the scapular arch "is formed by a single coracoid cartilage" (p. 69); that "the same type of branchial organs [as in the Cyclostomes] persists in *Chondropterygians*, which possess five, rarely six or seven, flattened pouches with transversely plaited walls," each pouch opening "outwards, and by an aperture into the pharynx, without intervening ducts" (p. 137); and that an "air bladder is absent but occurs in all Ganoids," etc. (p. 141), and that the generative organs are very peculiar (p. 166). Yet in spite of all these differences, in face of the recognized similarity between the teleosteoid Ganoids (*Amia*, &c.) and certain Physostomes, and in ignorance of the evanescence of the characters designed to differentiate the Teleosts, he adheres to the combination of the Ganoids with the Chondropterygians in one sub-class—the Palæichthyes. It is indeed a "singular concurrence" of characters (p. 312)—but not of important ones—that is employed to segregate this group, for not one is common to all the members included in it, and at the same time exclusive of other types. A knowledge of the anatomical labors of recent biologists would have instructed him as to this fact. The "Sub-class Palæichthyes" is indeed, as has been said by a recent well qualified judge, "a triumph of systematic *gaucherie*." The group in fact is the outcome of a confusion of ideas respecting generalized characters and extravagant valuation of certain facts entitled to consideration but by no means to anything like the extent admitted.

Quite as inscrutable as his Morphology is Dr. Günther's Physiology. As we turn the pages of the Introduction we come across strange assertions respecting the functions connected with structural peculiarities. Several of these may be taken as examples.

The power of ejecting from the mouth drops of water to some distance, and with such force as to dislodge insects and precipitate them into the water, has been attributed to more than one Javanese fish, but whether the real shooter was a *Chelmo*, a *Toxotes*, or an *Epibulus*, or each one, (or even whether any actually had such power), seems to have become doubtful. Skepticism as to any case might have been legitimate, but Dr. Günther unqualifiedly asserts that as to *Chelmo* "*this statement is erroneous*," and that the feat "*is practised* by another fish of this family (*Toxotes*). The long slender bill of *Chelmo* (which is a true salt-water fish) rather enables it to draw from holes and crevices animals which otherwise could not be reached by it" (p. 399). *Toxotes* has an unusually deeply cleft mouth, and one less fitted to perform such a feat as that in question could scarcely be found. The inaptness of the structure to the alleged function might well evoke skepticism in anyone, and this being once excited, the literature respecting the several fishes which have been named ejaculators will demonstrate that (1) there is no *observational* basis for the attribution of blowing drops of water to the *Toxotes*, and (2) there have been observations (by Hommel, Reinwardt and Mitchell), of a certain kind, of ejaculatory feats by *Chelmo*. In fact, if it is conceded that the feat is performed by a fish, in the sentences repeated from Dr. Günther, there are concentrated seven distinct errors: (1) denial in spite of evidence, (2) affirmation without sufficient basis, (3) denial in face of (comparative) adaptation of structure to function, (4) credulity in spite of inaptness of structure to function, (5) gratuitous assumption of a function—"to draw from holes and crevices animals which could not otherwise be reached by it," (6) the assumption, by implication, that the Archer was not a salt-water type, although the first observer (Hommel) especially stated that it was a sea-fish, and (7) erroneous taxonomy in the association of *Toxotes* in the same family with *Chelmo*. Almost all possible kinds of errors have thus culminated in this single case.

An instance of another gratuitous assumption respecting a function, refers to a Sciænoid fish.

The genus "*Collichthys* Günther" (previously named *Sciænoides* by Blyth) is distinguished by a "great development of the muciferous system on the head and the small eye," and this characteristic "leads one [and but one—Dr. Günther alone] to suppose that these fishes live in muddy water near the mouths of large rivers" (p. 430). What teleological relation there is between muciferous channels and small eyes and the muddy water of large (or any kind of) rivers, Dr. Günther has not vouchsafed to inform us. That such characteristics do not usually indicate the conditions suggested, is admitted by Dr. Günther himself, for he has recognized that "the muciferous system of many deep-sea fishes is developed in an extraordinary degree" (p. 300), and that a large portion of the deep-sea forms are characterized by small eyes (pp. 300-301). The fact is that instead of the inference in question being the outcome of a consideration of the structure indicated, it is the result of data concerning the habitat of one species of the genus and the desire to connect the structure with some function, however irrelevant. It is recorded in the "Catalogue of the Acanthop-

terygian Fishes in the British Museum" (v. 2, p. 316)—a work which has served as the basis of the "Introduction to the Study of Fishes"—that the "*Collichthys pama*" inhabits the "Bay of Bengal, entering rivers." The statement given as a deduction is therefore really a co-ordination—and an entirely sophistical one—of the ascertained structural peculiarity and the habitat of that species.

One other characteristic deduction, also relating to a Sciænoid type, may be noticed because of its interest to American students.

The "Drum" of the Atlantic (*Pogonias chromis*) is especially mentioned in connection with "the extraordinary sounds which are produced by it and other allied Sciænoids." "It is [says Dr. Günther] still a matter of uncertainty by what means the "Drum" produces the sounds. Some naturalists believe that it is caused by the clapping together of the pharyngeal teeth, which are very large molar teeth. However, if it be true [sage proviso!] that the sounds are accompanied by a tremulous motion of the vessel, it seems more probable that they are produced by the fishes beating their tails against the bottom of the vessel in order to get rid of the parasites with which that part of their body is infested." In this paragraph are several illegitimate assumptions and inferences which a slight knowledge of the literature respecting the subject would have prevented. (1) The sounds are entirely independent of "vessels." (2) There was no reason to suppose that the fish in question was more infested with parasites in the tail than any other. (3) The statement that "allied Sciænoids" (and this is especially true of the closely related fresh-water sheepshead, or *Haploidonotus*, referred by Günther to a genus with which it has not the slightest affinity!) produce similar sounds was for the moment forgotten. (4) The co-ordination of facts and phenomena rendered it unnecessary to look to such source for solution. (5) The source indicated was one of the most improbable that could be conceived. There is, indeed, ample cause for surprise that any educated ichthyologist could suppose that a fish would agitate its tail in the manner suggested to relieve a spasmodic pain, such as is postulated by the explanation given. Our author's credence in the allegation that the sounds produced are "accompanied by a tremulous motion of the vessel," was, as we have seen, sufficient to impel him to substitute a most improbable for at least a probable hypothesis.

A mistake of another kind is made respecting the Rays. It is said that "the majority are *oviparous*" (p. 336). As was long ago recognized by Müller and Henle, the Raiidæ are the only oviparous rays; Gunther includes them all in one family and four genera, and admits about 35 species. All the others recorded by him, so far as known, are viviparous; they number, in his opinion, five families, twenty genera and more than 100 species, consequently the majority are *viviparous!*

Whether a work so abounding in errors that we are only able to specify a few as examples and hint at some kinds of others is worth acquiring must be left to the reader to judge. As a curiosity in taxonomical literature it certainly *is*, but for such purposes as are most desirable —correct information and identification of genera—it as certainly *is not*. THEO. GILL.

DESCARTES AND THE BAROMETRIC THEORY.—At one of the late sittings of the Academy of Moral and Political Science, M. Nourisson made an extremely interesting communication relative to a letter of Descartes, in which the great philosopher clearly indicates the principal of atmospheric pressure, twelve years before Toricelli's experiments on the barometer. Toricelli constructed the fast barometric tube in 1643; in 1647 Pascal accomplishes his celebrated experiments of Puy-de-Dôme and of the "Tour Saint Jaques." It would appear that Descartes had suggested to the author of *Pensées* the idea of this mode of experiment.

CORRESPONDENCE.

To the Editor of SCIENCE:

ON ETHER.

There are two theories in regard to ether, one of which assumes that it is a discontinuous medium, that is, a medium composed of particles at enormous distances apart, as compared with their diameters.

In this theory ether is spoken of or defined as an "imponderable elastic medium." If we examine the above definition we find several inconsistencies. To begin with, an imponderable body is a body without weight. Now the weight of a body, is the result of the mutual attraction, exerted between it and some other body; in other words, weight is the effect of gravitation. Now as every particle attracts every other particle with a force, that is directly as the mass, and inversely as the square of the distance between them, an imponderable body must be one in which the mass is zero, or that is at such a distance from every other body that the reciprocal of the square of this distance is zero. The last supposition is of course absurd.

Now the mass of a body is equal to the product of its volume and density, or $M=d\ V$ and if M is equal to zero, either d or V must be zero and as it would be impossible to conceive of a body that occupies no space, we must think of d as equal to zero, or in other words an imponderable body is simply a portion of space. This same theory assumes that radiant energy is transmitted by means of the moving particles of ether, *i. e.*, one particle moving with a certain velocity, strikes another and imparts some of its energy to it and this flying off strikes another and so on. But the momentum of a body is expressed by $M\ V$ and its energy by $\frac{M V^2}{2}$ (V=Velocity), making M equal to zero, as we must if the particles are imponderable, we have $O\ V=M_0=o$ and $\frac{O\ V^2}{2}=E=o$, hence the transmission of radiant energy by an imponderable substance, composed of particles is an impossibility. If we assume that the particles are effected by gravitation, then at once it is evident that the ether could not be of equal density throughout the universe, for around each celestial body there would be an atmosphere of ether which would gradually decrease in density from the surface of the body outwards.

By elasticity in the above definition, is meant that property of matter, possessed by gases in the highest degree, of having its volume or density changed by some force and regaining its former state when the original condition are again imposed. When a gas is compressed, the mean free path of the molecules is shortened and the compressibility is dependent upon the length of the mean free path. When the pressure is removed, the gas expands, the expansion being due to a conversion of the energy of vibratory motion of the molecules or heat into energy of translation. If the ether is elastic, then of course with a change from less to greater density the particles must be moved nearer together, and the compressibility will be dependent upon the average distance between the particles. When a change from greater to less density takes place, the particles must be moved farther apart and the explanatory reason given for this expansion is that the energy of the moving particles causes the expansion.

From what has been said in regard to imponderability, it is evident that a discontinuous imponderable elastic substance is an impossibility according to the present ideas of dynamics. The transmission of radiant energy by a discontinuous ether, if the particles are ponderable, is possible in two ways, 1st, By an alternate rarefaction, and condensation of the ether, similar to the manner in which sound is transmitted through air. 2d, By the

movements of individual particles. If the first is true, the same conditions must apply to the transmission of radiant energy, as to the propagation of sound. Sound travels through air with a velocity of 330 miles per second, at 0° cent.

Taking for an example a sound produced by a body vibrating 20,000 times per second and dividing the velocity of sound by this number, we have as the wave length 16.5 mm. Clausius has shown that the mean free path of an oxygen molecule is 5000 times its diameter. Taking $\frac{1}{5 \times 10^7}$ mm. as the diameter, we have 10^4 mm. as the mean free path of an oxygen molecule, and dividing the length of the sound wave calculated above, by this number we have 1665×10^4, or the length of the wave of this extremely high note, is 1665×10^4 times longer than the mean free path of an oxygen molecule, hence it is evident that the propagation of sound is dependent primarily upon the movement of aggregates of molecules.

The elasticity of the ether is assured to be many times greater than that of the most perfect gas. Assuming that it is 1000 times more elastic than oxygen gas, the average distance between the surfaces of the particles must be 1000 times greater than the average distance between the surfaces of the oxygen molecules.

Taking as the mean free path of an oxygen molecule, 10^4 mm., the distance between the particles of ether would be .1 mm. Now the wave length of a certain ray of red light is .000,609 mm., hence the average distance between the particles is 164 times as great as this particular wave length. It follows from this, that the transmission of radiant energy, through such an elastic medium as the ether, cannot be in any way comparable with the propagation of sound through air. If the energy is not transmitted in this manner, then it must be transmitted in the second way, *i. e.*, by the movements of individual particles. But with an ether as elastic as generally assumed, this is impossible, since the average distance between the particles is 164 times as great as the length of a comparatively long undulation, and it would be absurd to say that a vibrating molecule could, by impact with a particle of ether, send the particle 5000 times the diameter of the molecule, and further, that the particle would return from this long journey in time for the next vibration. Even assuming that the particles of ether could move fast enough to accomplish this movement in each vibration, then if the molecules are circular, the particle would have to return in a line that was normal to the surface of the molecule at the point of contact, or it would fly off in another direction after impact with the molecule, and as the particles are so far apart, as compared with the diameters of the molecules, if one particle was driven off there would be no other to take its place. There would also be required a series of particles in a straight line between the body receiving and the body radiating energy.

But it is needless to enlarge upon this method of transmitting radiant energy, for the constant length of undulation and undulatory motion itself, would be impossible in a medium, in which the average distance between the particles was 164 times as long as an undulation.

The only discontinuous medium through which radiant energy *could* be transmitted, would be one in which the average distance between the particles was a small fraction of an undulation. But in a medium of this sort there would be hardly any chance for compression, much less than in oxygen gas, and to assume that ether is less elastic than a gas, is contrary to the theory of discontinuous ether. As a discontinuous ether will not answer the requirements, we must, if we assume *any* ether, assume a continuous one. By means of a continuous ether all the phenomena of light can be explained. One is inclined, however, to apply to a continuous ether the same reasoning as is applied to matter. But as ether is not matter, we cannot with justice attribute to it any of the properties of matter except extension and elasticity, and till we are much farther advanced in our knowledge of the universe, it will be impossible to say anything about ether, except to assume its existence and its continuity. B.

THE COMET.

The comet was seen from this Observatory at 14h. 30m., June 22, 1881. The latitude of the place is 41° 13′; longitude from Washington in time, 53m. 48s. This longitude is approximate, as we have no transit, and being without a correct astronomical clock, are continually annoyed for want of true time. The latitude is somewhat indeterminate, as the declination circle has no Vernier, reading seconds. The telescope (a fine 6 inch Alvan Clark & Sons), is not precisely in the meridian, and we are unable to place it there with accuracy, having no micrometer. With all these hindrances, the adjustment is such that catalogued stars are always in field with power of 60, but in many cases fail to come to the centre or line of collimation. When observation was first made the declination was 43° 10′, then make δ=the declination = 43° 10′, and λ = the latitude of New Windsor = 41° 13′, and take:

log. tan. δ = - - - -	9.972,188
log. tan. λ = - - - -	9.942,478
log. sin. 55° 15′= - -	9.914,666

which being converted into time = 3h. 41m.; and 6h. — 3h. 41m. = 2h. 19m., A. M., June 23, mean local time in New Windsor, or time of comet's rising, that is, of the nucleus. The tail being several degrees long and direected towards Polaris, was above the horizon some time before.

Had the horizon been water, the nucleus would have come in sight at 2.19, as it was, an interval of 11m. was required to bring it above undulations of the earth. We thought best not to telegraph before seeing the nucleus, but as soon as we positively knew the apparition to be a comet, haste was made to send dispatch. The village is on a branch railroad and telegraph offices are not open nights, so we had to send to the residence of the operator, arouse and engage him to go to the office and send telegram. This took time, and it was not until after 3 A. M. that message was sent. Meanwhile we endeavored to place telescope on nucleus but were unable to, as there was a tree in range, causing another delay until 3.30, when observation was made—the nucleus being an hour above horizon and in apparent

R. A. - - - - - -	5h. 34m,
δ - - - - - - -	43° 10′

a rough position, as no corrections were made for refraction or parallax.

The telegram read: "Vast comet in northeastern heavens." After mature consideration we regret using so many words, one only—"Comet,"—was all that was necessary, when the acute observer, Swift, would have been on the alert at once. Before sunrise we were favored with 30 minutes good definition, when two envelopes were seen, the nucleus extending a bridge to the external surface of the inner one. Since, the nucleus has changed form, is no longer round, but has prolonged into a beak-shaped mass, and looks like Comet III., 1862, August 29, as drawn by Challis (Chambers' Astronomy, p. 322). The cometary matter is of great tenuity, as it was seen to run over a sixth magnitude star at 10h. June 28, which passed about 15″ from nucleus, yet it was visible through the immense volume of gas.

The comet was seen from many points in the Western States twenty-four hours before noticed at this place, by steamboat hands, street-car drivers, railroad conductors, night-watchmen, policemen and many others whose business required them to be out all night.

NEW WINDSOR, ILL., *July 1st*, 1881. EDGAR L. LARKIN.

SCIENCE:

A WEEKLY RECORD OF SCIENTIFIC PROGRESS.

JOHN MICHELS, Editor.

PUBLISHED AT
TRIBUNE BUILDING, NEW YORK.

P. O. Box 3838.

SATURDAY, JULY 16, 1881.

We are indebted to Professor Edward S. Holden for a series of seven interesting drawings of the recently discovered Comet; they are now being engraved and will appear in "SCIENCE" next week.

These drawings were made by Professor Holden from observations made with the 15-inch equatorial of the Washburn Observatory.

We have received a copy of the instructions furnished to the officers in command of the expeditionary force to Lady Franklin Bay, which appear to have given general satisfaction, and probably suffice for all the purposes of the expedition. Still we regret to find that the services of a naturalist have not been considered requisite, and that no provision appears to have been made for collecting specimens and information respecting the Fauna and Flora of the Polar regions. A microscope is not even added to the list of apparatus provided for the use of the expedition.

Mr. Alfred Russell Wallace in his last work, "Island Life," observes that there is an enormous waste of labor and money with comparatively scanty and unimportant results to natural history, of most of the great scientific voyages of the various civilized governments during the present century. All these expeditions combined have done far less than private collectors in making known the products of remote lands and islands. They have brought home, he asserts, fragmentary collections, made in widely scattered localities and these have been usually described in huge folios, whose value is often in inverse proportion to their bulk and cost. The same species have been collected again and again, often described several times, and, not infrequently stated to be from places they never inhabited. The result of this wretched system, says Mr. Wallace, is, that the productions of some of the most frequently visited and most interesting islands on the globe are still very imperfectly known, while their native plants and animals are being yearly exterminated. The remedy suggested by Mr. Wallace, is that resident naturalists at a very small annual expense, should be appointed, who, he considers, would do more for the advancement of knowledge in this direction, than all the expensive expeditions which have again and again circumnavigated the globe.

We are of course aware that most of the many recent expeditions to the polar regions have been specially organized for the promotion of the physical sciences, but the value of an expert naturalist on such occasions should not be neglected, and wherever permanent stations are established the naturalist may be expected to do good work, and even occasionally interpret natural phenomena which are sometimes inexplicable to the physicist.

The comet has been observed here (with the exception of June 27) on every night since June 23, although clouds have often considerably hindered the work.

In addition to the measurements of position, the light of different parts of the comet has been photometrically determined. This work, very probably, has been undertaken only at this Observatory. The instrument employed for the purpose is one which has already been extensively used here for measuring the light of nebulæ. The results of these observations are expressed in stellar magnitudes on Pogson's logarithmic scale, regarding the light of a star of the given magnitude as diffused over a circle 1′ in diameter, the brightness of which would then be equal to that of the observed portion of the nebula or comet. On the first five nights of the present month, various parts of the coma and tail have thus been observed. The result, from a provisional reduction, is as follows:

Coma,	0.′5	south of nucleus,	magnitude	6.9
"	0.′5	north of "	"	7.8
Tail,	0.°5	" "	"	9.6
"	1.°0	" "	"	10.3
"	2.°0	" "	"	11.0
"	3.°0	" "	"	11.2
"	4.°0	" "	"	11.6

I add the corresponding results, also from provisional reductions, for some other comets and nebulæ:

Palisa's Comet, 1879 *d*.	magnitude	8
Comet, 1880 *d*.	"	7
Webb's Planetary Nebula, DM. + 41°4004	"	4.7
Brightest part of great nebula in Orion (20 points in which have been observed), ...	"	8.0
Nebula G. C. 4487, ...	"	11.2
" G. C. 4802, ...	"	11.3

On June 28th, and on July 1, 3, 5 and 6, the coordinates of a number of points in the border of the comet's tail were observed for the purpose of determining its form.

Cambridge, U. S., *July 6th*, 1881.

THE UNITY OF NATURE.

By the Duke of Argyll.

IX.

THE ORIGIN OF RELIGION CONSIDERED IN THE LIGHT OF THE UNITY OF NATURE.

(*Continued.*)

The considerations set forth in the previous chapter indicate the fallacies which lie in our way when we endeavor to collect from the worship of savage nations any secure conclusions as to the origin of Religion. Upon these fallacies, and upon no more safe foundation, Comte built up his famous generalization of the four necessary stages in the history of Religion. First came Fetishism, then Polytheism, and then Monotheism, and last and latest, the heir of all ages, Comtism itself, or the Religion of Humanity which is to be the worship of the future.

Professor Max Müller has done admirable service in the analysis and in the exposure which he has given us of the origin and use of the word "Fetishism," and of the theory which represents it as a necessary stage in the development of Religion.[1] It turns out that the word itself and the fundamental idea it embodies, is a word and an idea derived from one of those popular superstitions which are so common in connection with Latin Christianity. The Portuguese sailors who first explored the West Coast of Africa were themselves accustomed to attach superstitious value to beads, or crosses, or images, or charms and amulets of their own. These were called "fetiços." They saw the negroes attaching some similar value to various objects of a similar kind, and these Portuguese sailors therefore described the negro worship as the worship of "fetiços." President de Brosses, a French philosopher of the Voltairean epoch in literature, then extended the term Fetish so as to include not only artificial articles, but also such great natural features as trees, mountains, rivers and animals. In this way he was enabled to classify together under one indiscriminate appellation many different kinds of worship and many different stages in the history of religious development or decay. This is an excellent example of the crude theories and false generalizations which have been prevalent on the subject of the origin of Religion. First, there is the assumption that whatever is lowest in savagery must have been primeval—an assumption which, as we have seen, is in all cases improbable, and in many cases must necessarily be false. Next there is great carelessness in ascertaining what is really true even of existing savages in respect to their religious beliefs. It has now been clearly ascertained, that those very African negroes whose superstitious worship of material articles supposed to have some mysterious powers or virtues, is most degraded, do nevertheless retain behind and above this worship certain beliefs as to the nature of the Godhead, which are almost as far above their own abject superstitions as the theology of a Fénélon is above the superstitions of an ignorant Roman Catholic peasant. It is found that some African tribes have retained their belief in one Supreme Being, the Creator of the world, and the circumstance that nevertheless no worship may be addressed to Him has received from Professor Max Müller an explanation which is ample. "It may arise from an excess of reverence quite as much as from negligence. Thus the Odjis or Cohantis call the Supreme Being by the same name as the sky; but they mean by it a Personal God, who, as they say, created all things and is the Giver of all good things. But though He is omnipresent and omniscient, knowing even the thoughts of men, and pitying them in their distress, the government of the world is, as they believe, deputed by Him to inferior spirits, and among these, again, it is the malevolent spirits only who require worship and sacrifice from man."[2] And this is by no means a solitary case. There are many others in which the investigations of missionaries respecting the religious conceptions of savage nations have revealed the fact that they have a much higher theology than is indicated in their worship.

The truth is, that nowhere is the evidence of development in a wrong direction so strong as in the many customs of savage and barbarous nations which are more or less directly connected with Religion. The idea has long been abandoned that the savage lives in a condition of freedom as compared with the complicated obligations imposed by civilization. Savages, on the contrary, are under the tyranny of innumerable customs which render their whole life a slavery from the cradle to the grave. And what is most remarkable is the irrational character of most of these customs, and the difficulty of even imagining how they can have become established. They bear all the marks of an origin far distant in time—of a connection with doctrines which have been forgotten, and of conceptions which have run, as it were, to seed. They bear, in short, all the marks of long attrition, like the remnants of a bed of rock which has been broken up at a distant epoch of geological time, and has left no other record of itself than a few worn and incoherent fragments in some far-off conglomerate. Just as these fragments are now held together by common materials which are universally distributed, such as sand or lime, so the worn and broken fragments of old religions are held together, in the shape of barbarous customs, by those common instincts and aspirations of the human mind which follow it in all its stages, whether of growth or of decay.

The rapidity of the processes of degradation in Religion, and the extent to which they may go, depends on a great variety of conditions. It has gone very far indeed, and has led to the evolution of customs and beliefs of the most destructive kind among races which, so far as we know, have never been exposed to external conditions necessarily degrading. The innate character of this tendency to corruption, arising out of causes inherent in the nature of Man, becomes indeed all all the more striking when we find that some of the most terrible practices connected with religious superstition, are practices which have become established among tribes which are by no means in the lowest physical condition, and which inhabit countries highly blest by Nature. Perhaps there is no example of this phenomenon more remarkable than the "customs" of Dahomey, a country naturally rich in products, and affording every facility for the pursuits of a settled and civilized life. Yet here we have those terrible beliefs which demand the constant, the almost daily sacrifice of human life, with no other aim or purpose than to satisfy some imaginary Being with the sight of clotted gore, and with the smell of putrefying human flesh. This is only an extreme and a peculiarly terrible example of a general law, the operation of which is more or less clearly seen in every one of the religions of the heathen world, whether of the past or of the present time. In the very earliest ages in which we become acquainted with the customs of their worship, we find these in many respects strange and unaccountable, except on the supposition that even then they had come from far, and had been subject to endless deviations and corruptions through ages of a long descent.

Of no Religion is this more true than of that which was associated with the oldest civilization known to us—the civilization of Egypt. So strange is the combination here of simple and grand conceptions with grotesque symbols and with degrading objects of immediate wor-

[1] Hibbert Lectures, 1878.

[2] Hibbert Lectures, pp. 107, 108.

ship, that it has been the inexhaustible theme of curious explanations. Why a Snake or why a Dung-beetle should have been taken to represent the Divine Being, and why in the holiest recess of some glorious temple we find enshrined as the object of adoration the image or the coffin of some beast, or bird, or reptile, is a question on which much learned ingenuity has been spent. It has been suggested, for example, that a conquering race, bringing with it a higher and a purer faith, suffered itself to adopt or to embody in its system the lower symbolism of a local worship. But this explanation only removes the difficulty—if it be one—a step further back. Why did such sufferance arise? why was such an adoption possible? It was possible simply because there is an universal tendency in the human mind to developments in the wrong direction, and especially in its spiritual conceptions to become more and more gross and carnal.

Nor is it difficult to follow some, at least, of the steps of consequence—that is to say, the associations of thought —by which worship may become degraded when once any serious error has been admitted. Animal worship, for example, may possibly have begun with very high and very profound conceptions. We are accustomed to regard it as a very grotesque and degraded worship, and so no doubt it was in its results. But if we once allow ourselves to identify the Divine Power in Nature with any of its operations, if we seek for the visible presence of the Creator in any one of His creations, I do not know that we could choose any in which that presence seems so immanent as in the wonderful instincts of the lower animals. In a previous chapter we have seen what knowledge and what foreknowledge there is involved in some of these. We have seen how it often seems like direct inspiration that creatures without the gift of reason should be able to do more than the highest human reason could enable us to do—how wonderful it is, for example, that their prevision and provision for the nurture and development of their young should cover the whole cycle of operations in the second work of creation which is involved in the metamorphoses of insects—all this, when we come to think of it, may well seem like the direct working of the Godhead. We have seen in a former chapter that men of the highest genius in philosophical speculation, like Descartes, and men of the highest skill in the popular exposition of scientific ideas, like Professor Huxley, have been led by these marvels of instinct to represent the lower animals as automata or machines. The whole force and meaning of this analogy lies in the conception that the work done by animals is like the work done by the mechanical contrivances of men. We look always upon such work as done not by the machine but by the contriving mind which is outside the machine, and from whom its adjustments are derived. Fundamentally, however little it may be confessed or acknowledged, this is the same conception which, in a less scientific age, would take another form. What is seen in the action of an automaton is not the mechanism but the result. That result is the work of mind, which seems as if it were indwelling in the machine. In like manner, what is seen in animals is the wonderful things they do; and what is not seen, and is indeed wholly incomprehensible, is the machinery by which they are made to do it. Moreover, it is a machinery having this essential distinction from all human machines, that it is endowed with life, which in itself also is the greatest mystery of all. It is, therefore, no superficial observation of animals, but, on the contrary, a deep pondering on the wonders of their economy, which may have first suggested them to religious men as at once the type and the abode of that Agency which is supreme in Nature. I do not affirm as an historical fact that this was really the origin of animal worship, because that origin is not historically known, and, like the origin of Religion itself, it must be more or less a matter of speculation. Some animals may have become objects of worship from having originally been the subjects of sacrifice. The victim may have been so associated with the god to whom it was devoted as to become his accepted symbol. The Ox and the Bull may well have been consecrated through this process of substitution. But no such explanation can be given in respect to many animals which have been worshipped as divine. Perhaps no further explanation need be sought than that which would be equally required to account for the choice of particular plants, or particular birds and fishes, as the badges of particular tribes and families of men. Such badges were almost universal in early times, and many of them are still perpetuated in armorial bearings. The selection of particular animals in connection with worship would be determined in different localities by a great variety of conditions. Circumstances purely accidental might determine it. The occurrence, for example, in some particular region of any animal with habits which are at once curious and conspicuous, would sufficiently account for the choice of it as the symbol of whatever idea these habits might most readily suggest or symbolize. It is remarkable, accordingly, that in some cases, at least, we can see the probable causes which have led to the choice of certain creatures. The Egyptian beetle, the Scarabæus, for example, represents one of those forms of insect life in which the marvels of instinct are at once very conspicuous and very curious. The characteristic habit of the Scarabæus beetle is one which involves all that mystery of prevision for the development of the species which is common among insects, coupled with a patient and laborious perseverance in the work required, which does not seem directly associated with any mere appetite or with any immediate source of pleasure. The instinct by which this beetle chooses the material which is the proper nidus for its egg, the skill with which it works that material into a form suitable for the purpose, and the industry with which it then rolls it along the ground till a suitable position is attained—all these are a striking combination of the wonders of animal instinct, and conspicuous indication of the Spirit of wisdom and of knowledge which may well be conceived to be present in their work.

But although it is in this way easy to imagine how some forms of animal-worship may have had their origin in the first perception of what is really wonderful, and in the first admiration of what is really admirable, it is also very easy to see how, when once established, it would tend to rapid degradation. Wonder and reverence are not the only emotions which impel to worship. Fear, and even horror, especially when accompanied with any mystery in the objects of alarm, are emotions suggesting, perhaps, more than any, that low kind of worship which consists essentially in the idea of deprecation. Some hideous and destructive animals, such as the crocodile, may have become sacred objects neither on account of anything admirable in their instincts, nor on account of their destructiveness; but, on the contrary, because of being identified with an agency which is beneficent. To those who live in Egypt the Nile is the perennial source of every blessing necessary to life. An animal so characteristic of that great river may well have been chosen simply as the symbol of all that it was, and of all that it gave to men. There is no mystery, therefore, in the crocodile being held sacred in the worship of the God of Inundation. But there are other animals which have been widely invested with a sacred character, in respect to which no such explanation can be given. The worship of serpents has been attributed to conceptions of a very abstract character—with the circle, for example, into which they coil themselves, considered as an emblem of Eternity. But this is a conception far too transcendental and far-fetched to account either for the origin of this worship or for its wide extension in the world. Serpents are not the only natural objects which present circular forms. Nor is this attitude of their repose,

curious and remarkable though it be, the most striking peculiarity they present. They have been chosen, beyond any reasonable doubt, because of the horror and terror they inspire. For this, above all other creatures, they are prominent in Nature. For their deceptive coloring, for their insidious approach, for their deadly virus, they have been taken as the type of spiritual poison in the Jewish narrative of the Fall. The power of inflicting almost immediate death, which is possessed by the most venomous snakes, and that not by violence but by the infliction of a wound which in itself may be hardly visible, is a power which is indeed full of mystery even to the most cultivated scientific mind, and may well have inspired among men in early ages a desire to pacify the powers of evil. The moment this becomes the great aim and end of worship, a principle is established which is fertile in the development of every foul imagination. Whenever it is the absorbing motive and desire of men to do that which may most gratify or pacify malevolence, then it ceases to be at all wonderful that men should be driven by their religion to sacrifices the most horrid, and to practices the most unnatural.

But if we wish to see an illustration and an example of the power of all conceptions of a religious nature in the rapid evolution of unexpected consequences, we have such an example in the case of one man who has lived in our own time, and who still lives in the school which he has founded. I refer to Auguste Comte. It is well known that he denied the existence, or at least denied that we can have any knowledge of the existence, of such a Being as other men mean by God. Mr. John Stuart Mill has insisted with much earnestness and with much force that, in spite of this denial, Auguste Comte had a religion. He says it was a religion without a God. But the truth is, that it was a religion having both a creed and an ideal object of worship. That ideal object of worship was an abstract conception of the mind so definitely invested with personality that Comte himself gave to it the title of The Great Being (*Grand Etre*). The abstract conception thus personified was the abstract conception of Humanity—Man considered in his past, his present, and his future. Clearly this is an intellectual Fetish. It is not the worship of a Being known or believed to have any real existence; it is the worship of an idea shaped and molded by the mind, and then artificially clothed with the attributes of personality. It is the worship of an article manufactured by the imagination, just as Fetishism, in its strictest meaning is the worship of an article manufactured by the hand. Nor is it difficult to assign to it a place in the classification of religions in which a loose signification has been assigned to the term Fetishism. The worship of Humanity is merely one form of animal-worship. Indeed, Comte himself specially included the whole animal creation. It is the worship of the creature Man as the consummation of all other creatures, with all the marvels and all the unexhausted possibilities of his moral and intellectual nature. The worship of this creature may certainly be in the nature of a religion, as much higher than other forms of animal worship as Man is higher than a beetle, or an ibis, or a crocodile, or a serpent. But so also, on the other hand, it may be a religion as much lower than the worship of other animals, in proportion as man can be wicked and vicious in a sense in which the beasts cannot. Obviously, therefore, such a worship would be liable to special causes of degradation. We have seen it to be one of the great peculiarities of Man, as distinguished from the lower animals, that whilst they always obey and fulfill the highest law of their being, there is no similar perfect obedience in the case of Man. On the contrary, he often uses his special powers with such perverted ingenuity that they reduce him to a condition more miserable and more degraded than the condition of any beast. It follows that the worship of Humanity must, as a religion, be liable to corresponding degradation. The philosopher, or the teacher, or the prophet who may first personify this abstract conception, and enshrine it as an object of worship, may have before him nothing but the highest aspects of human nature, and its highest aspirations. Mill has seen and has well expressed the limitations under which alone such a worship could have any good effect. "That the ennobling power of this grand conception may have its full efficacy, he should, with Comte, regard the *Grand Etre*, Humanity or Mankind, as composed in the past solely of those who, in every age and variety of position, have played their part worthily in life. It is only as thus restricted that the aggregate of our species becomes an object worthy our veneration."[3] This, no doubt, was Comte's own idea. But how are his disciples and followers to be kept up to the same high standard of conception? Comte seems to have been personally a very high-minded and a very pure-minded man. His morality was austere, almost ascetic, and his spirit of devotion found delight in the spirit of the Christian Mystics. Yet even in his hands the development of his conceptions led him to results eminently irrational, although it cannot be said that they were ever degrading or impure. But we have only to consider how comparatively rare are the examples of the the highest human excellence, and how common and prevailing are the vices and weakness of Humanity, to see how terrible would be the possibilities and the probabilities of corruption in a religion which had Man for the highest object of its worship. Nor is this all that is to be said on the inevitable tendency to degradation which must attend any worship of Humanity. Not only are the highest forms of human virtue rare, but even when they do occur, they are very apt to be rejected and despised of men. Power and strength, however vicious in its exercise, almost always receives the homage of the world. The human idols, therefore, who would be chosen as symbols in the worship of humanity, would often be those who set the very worst examples to their kind. Perhaps no better illustration of this could be found than the history of Napoleon Buonaparte. I think it is impossible to follow that history, as it is now known, without coming to the conclusion that in every sense of the word he was a bad man—unscrupulous, false, and mean. But his intellect was powerful, whilst his force and energy of character were tremendous. These qualities alone, exhibited in almost unexampled military success, were sufficient to make him the idol of many minds. And as mere success secured for him this place, so nothing but failure deprived him of it. Not a few of the chosen heroes of Humanity have been chosen for reasons but little better. Comte himself, seeing this danger, and with an exalted estimate and ideal of the character of womanhood, had laid it down that it would be best to select some woman as the symbol, if not the object, of private adoration in the worship of Humanity. The French Revolutionists selected a woman, too, and we know the kind of woman that they chose. It may be wise, perhaps, to set aside this famous episode in a fit of national insanity as nothing more than a profane joke; but the developments of anthropomorphism in the mythology of the Pagan world are a sufficient indication of the kind of worship which the worship of Humanity would certainly tend to be.

The result, then, of this analysis of that in which all Religion essentially consists, and of the objects which it selects, or imagines, or creates for worship, is to show that in Religion, above all other things, the processes of evolution are especially liable to work in the direction of degradation. That analysis shows how it is that in the domain of religious conceptions, even more than in any domain of thought, the work of development must be rapid, because, in the absence of revelation or the teachings of Authority, fancy and imagination have no guide and are under no restraint.

---

[3] Mill's "Comte and Positivism," p. 136.

When, now, we pass from the phenomena which Religion presents in the present day to what we know of its phenomena in the earliest historic times, the conclusions we have reached receive abundant confirmation. Of the Origin of Religion, indeed, as we have already seen, history can tell us nothing, because, unless the Mosaic narrative be accepted, there is no history of the origin of Man. But the origin of particular systems of Religion does come within the domain of history, and the testimony it affords is always to the same effect. In regard to them we have the most positive evidence that they have been uniformly subject to degradation. All the great religions of the world which can be traced to the teaching or influence of individual men have steadily declined from the teaching of their founders. In India it has been one great business of Christian missionaries and of Christian governors, in their endeavors to put an end to cruel and barbarous customs, to prove to the corrupt disciples of an ancient creed that its first prophets or teachers had never held the doctrines from which such customs arise, or that these customs are a gross misconception and abuse of the doctrine which had been really taught. Whether we study what is now held by the disciples of Buddha, of Confucius, or of Zoroaster, it is the same result. Wherever we can arrive at the original teaching of the known founders of religious systems, we find that teaching uniformly higher, more spiritual than the teaching now. The same law has effected Christianity, with this difference only, that alone of all the historical religions of the world it has hitherto shown an unmistakable power of perennial revival and reform. But we know that the processes of corruption had begun their work even in the lifetime of the Apostles; and every church in Christendom will equally admit the general fact, although each of them will give a different illustration of it. Mohammedanism, which is the last and latest of the great historical religions of the world, shows a still more remarkable phenomena. The corruption in this case began not only in the lifetime but in the life of the prophet and founder of that religion. Mahomet was himself his own most corrupt disciple. In the earliest days of his mission he was best as a man and greatest as a teacher. His life was purer and his doctrine more spiritual when his voice was a solitary voice crying in the wilderness, than when it was joined in chorus by the voice of many millions. In his case the progress of development in a wrong direction was singularly distinct snd very rapid. Nor is the cause obscure. The spirit of Mahomet may well have been in close communion with the Spirit of all truth, when, like St. Paul at Athens, his heart was stirred within him as he saw his Arabian countrymen wholly given to idolatry. Such deep impressions on some everlasting truth—such overpowering convictions—are in the nature of inspiration. The intimations it gives and the impulses it communicates are true in thought and righteous in motive, in exact proportion as the reflecting surfaces of the human mind are accurately set to the lights which stream from Nature. This is the adjustment which gives all their truthfulness to the intimations of the senses; which gives all its wisdom and foresight to the wonderful work of instinct; which gives all their validity to the processes of reason, which is the real source of all the achievements of genius; and which, on the highest level of all, has made some men the inspired mouthpiece of the oracles of God. But it is the tenderest of all adjustments—the most delicate, the most easily disturbed. When this adjustment is, as it were, mechanical, as it is in the lower animals, then we have the limited, but, within its own sphere, the perfect wisdom of the beasts. But when this adjustment is liable to distortion by the action of a Will which is to some extent self-determined and is also to a large extent degraded, then the real inspiration is not from without, but from within—then the reflecting surfaces of mind are so longer set true to the light of Nature; and then "if the light within us be darkness, how great is that darkness!" Hence it is that one single mistake or misconception as to the nature and work of inspiration is, and must be a mistake of tremendous consequence. And this was Mahomet's mistake. He thought that the source of his inspiration was direct, immediate, and personal. He thought that even the very words in which his own impulses were embodied were dictated by the Angel Gabriel. He thought that the Supreme Authority which spoke through him when he proclaimed that "the Lord God Almighty was one God, the Merciful, the Compassionate," was the same which also spoke to him when he proclaimed that it was lawful for him to take his neighbor's wife. From such an abounding well-spring of delusion the most bitter waters were sure to come. How different this idea of the methods in which the Divine Spirit operates upon the minds of men from the idea held on the same subject by that great Apostle of our Lord whose work it was to spread among the Gentile world those religious conceptions which had so long been the special heritage of one peculiar people! How cautious St. Paul is when expressing an opinion not directly sanctioned by an authority higher than his own! "I think also that I have the Spirit of God." The injunction, "Try the spirits whether they be of God," is one which never seems to have occurred to Mahomet. The consequences were what might have been expected. The utterances of his inspiration when he was hiding in the caves of Mecca were better, purer, higher than those which he continued to pour forth when, after his flight to Medina, he became a great conqueror and a great ruler. From the very first indeed he breathed the spirit of personal anger and malediction on all who disbelieved his message. This root of bitterness was present from the beginning. But its developments were indeed prodigious. It was the animating spirit of precepts without number which, in the minds and in the hands of his ruthless followers, have inflicted untold miseries for twelve hundred years on some of the fairest regions of the globe.

Passing now from the evidence of the law of corruption and decline which is afforded by this last and latest of the great historical religions of the world, we find the same evidence in those of a much older date. In the first place, all the founders of those religions were themselves nothing but reformers. In the second place the reforms they instituted have themselves all more or less again yielded to new developments of decay. The great prophets of the world have been men of inspiration or of genius who were revolted by the corruptions of some pre-existing system, and who desired to restore some older and purer faith. The form which their reformation took was generally determined, as all strong revolts are sure to be, by violent reaction against some prominent conception or some system of practice which seemed, as it were, an embodiment of its corruption. In this way only can we account for the peculiar direction taken by the teaching of that one great historical Religion which is said to have more disciples than any other in the world. Buddhism was in its origin a reform of Brahminism. In that system the beliefs of a much older and simpler age had become hid under the rubbish-heaps of a most corrupt development. Nowhere perhaps in the world had the work of evolution been richer in the growth of briers and thorns. It had forged the iron bonds of caste, one of the very worst inventions of an evil imagination; and it had degraded worship into a complicated system of sacrifice and of ceremonial observances. There seems to be no doubt that the teaching of the reformer Sakya Muni (Buddha) was a revolt and a reform. It was a reassertion of the paramount value of a life of righteousness. But the intellectual conceptions which are associated wiih this great ethical and spiritual reform had within themselves the germs of another cycle of decay.

(To be continued.)

THE COMET.

The comet is daily becoming a fainter object, and astronomers are now employed in making investigations based on their observations.

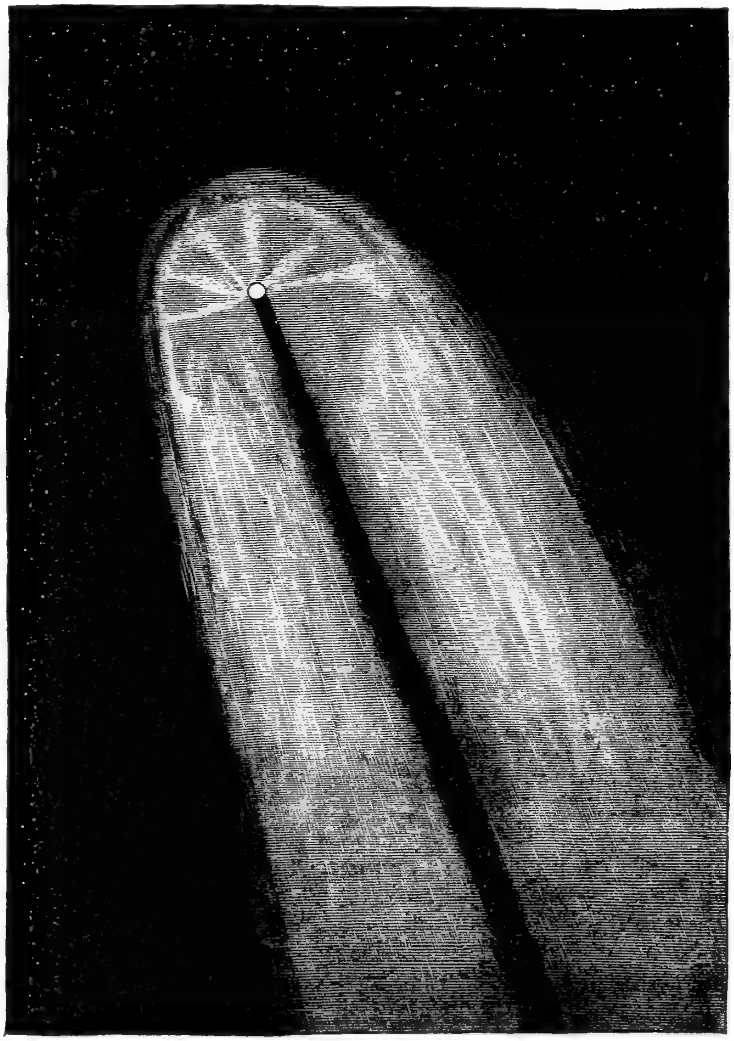
We understand that Professor O. Stone, of Cincinnati, has published a statement that he saw the nucleus of the comet divide into two parts. Professor Stone is not one likely to be mistaken in an observation of this nature, but we understand he has not been confirmed in this discovery, as observations since made with the large equatorial at Washington have failed to show any division. A disturbance, however, has been observed in the nucleus, which Professor Skinner considers might be mistaken for a division as described by Professor Stone.

On the 6th of July the comet was observed by Mr. Rock of the Naval Observatory, who thus describes what he saw:

"A bright tongue of light about one revolution long in direction of tail, with a slight node near end and curved."

In explanation of this Mr. Rock said: "I observed the comet at the time of its lower culmination about twenty minutes after midnight. The nucleus did not appear to be divided, but a bright band streamed out in the direction of the tail. This band was about fifteen seconds of the arc in length. Near the end of it was a bright spot, and that portion of the band extending beyond it was curved in the same general direction as the tail, but in a somewhat shorter arc. It is possible that the observer at Cincinnati was not able to distinguish the band of light which I saw uniting the nucleus and the node, and so concluded that he saw two nuclei. When I first observed the comet, on June 28, the coma was apparently homogeneous as it also was on July 2. On June 28, however, there were two spurs of light spreading away from the opposite sides of the head like angel's wings. On July 2, I did not observe these at all or they were very faint. On July 6 I observed the appearance that I have described. It may be that this was the same thing that I saw on June 28, observed from a different point of view. It is not improbable, however, that the nucleus has really divided. Comets appear to have a tendency to do that.

Head of Donati's Comet, After Bond.



Comet of 1881. After Prof. Henry Draper's Photograph.

To a correspondent of the N. Y. *Tribune*, Professor Harkness said:

"We think that the November meteors are the debris of a comet which first made its appearance about the year 900. This debris, to all appearance, continues to trail along the whole orbit of the comet of which it formed a part and which has disappeared. The August meteors are assigned a similar origin. Biela's comet reappeared once after its nucleus had separated into two parts; it has never been observed since. All comets appear to diminish in brightness, and it is probable that they become gradually disintegrated. I have undertaken spectroscopic investigation of this comet, sufficient to convince me that the spectrum is the same as that of all comets. I made observations on June 28 and July 1 and 2. On June 28, I found a bright continuous spectrum with three bands very hazy, the whole indistinct. Evidence of polarization was not trustworthy, and I concluded there was no polarization. On July 1 the spectrum of the nucleus was right, showing two bands; wave lengths approximately 550.29 and 611.5. On July 2, I found a bright, continuous spectrum extending from about wave length 577 to 428; the coma gave three bright bands; wave lengths

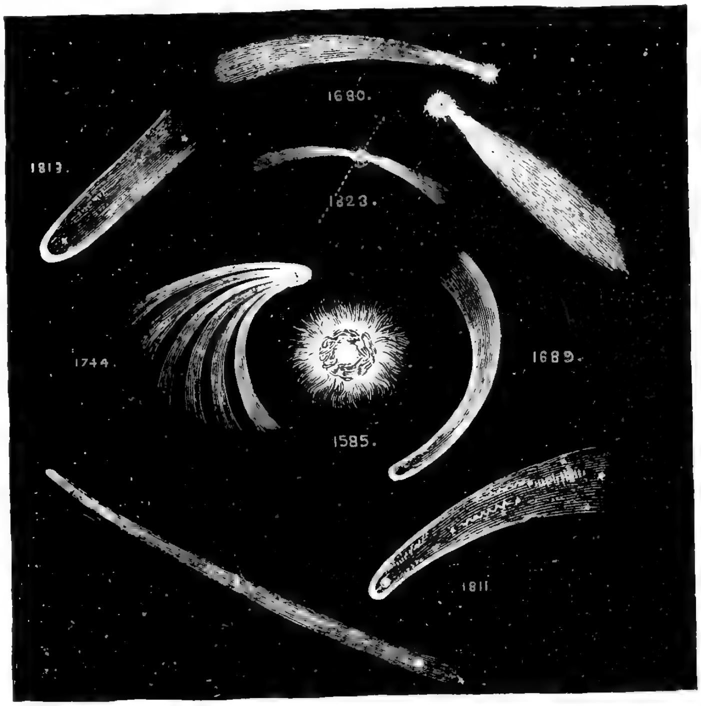
approximately 548.4, 513.3, 467.2. The tail gave no continuous spectrum. The mean of eighteen comets observed gives us wave lengths as follows: 556.4, 512.7 and 470.6; the mean of two nights' work on this comet gave me 549.3, 512.4 and 467.2. These two sets of figures agree as nearly as could be expected, considering that I used in my observations a single 60° prism, and there can be no doubt whatever that this is the usual comet spectrum."

Professor A. Hall also observed that he had received from Baron Struve, of the Imperial Observatory at Palkova, an ephemeris of Encke's comet extending from July 29 to November 14, and preparations are making at the Naval Observatory for careful observations of that body, which is considered of great scientific interest.

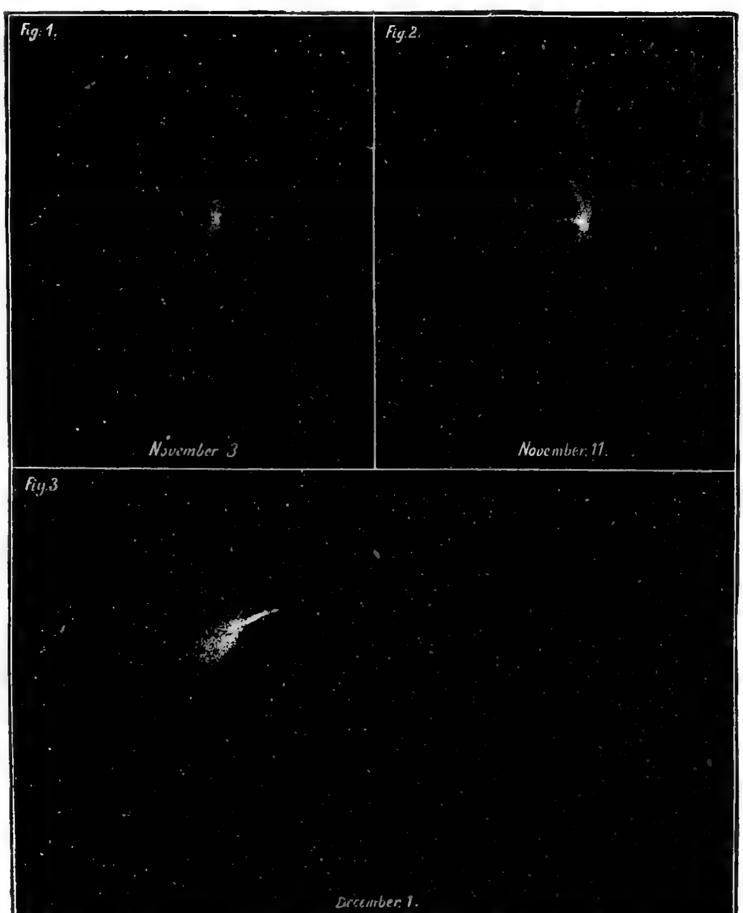
We present our readers with an illustration showing the appearance of the comet in one of Professor Henry Draper's photographs for which we are indebted to Messrs. Harper Brothers, and we hope to shortly publish Professor Draper's mature views based on his observations and photographs, both of the comet and its spectrum.

To a correspondent Prof. Draper gave the following particulars:

"In the spectrum of the comet there is one great band in the ultra-violet region beyond the line H. This morning I brought the spectroscope with me to the city, and have taken photographs of the spectrum of the electric arc with it. The electric arc



Group of Various Comets.



Views of Encke's Comet, 1871

contains carbon; not, in all probability, the pure element of carbon volatilized, but some compound of carbon—most likely a hydrocarbon. The spectrum of the electric or voltaic arc shows a strong band at the ultra-violet region, due to the presence of this carbon or carbon-compound. This spectrum I mean to compare with that of the comet, to see whether the bands in the ultra-violet region correspond in the two. If they do, the presence of some form of carbon in the comet will be demonstrated. My impression at present is that the ultra-violet spectrum of the comet does prove that it contains carbon, but I cannot speak with certainty until after I have made more careful measurements of the photographs. At all events, my experiments must settle the question.

We are indebted to Professor Pickering, of Harvard University, for some valuable observations which will be found in another column.

ON THE TAILS OF COMETS.

One of the most important articles in the June number of *Urania* is that by M. Th. Bredichin, on the Tails of Comets. After a series of investigations he arrives at the conclusion that the position, curvature and structure of a tail are explained by the repulsive force of the sun and by the effluvia of cometary matter from the nucleus towards the sun with a certain initial velocity or repulsion.

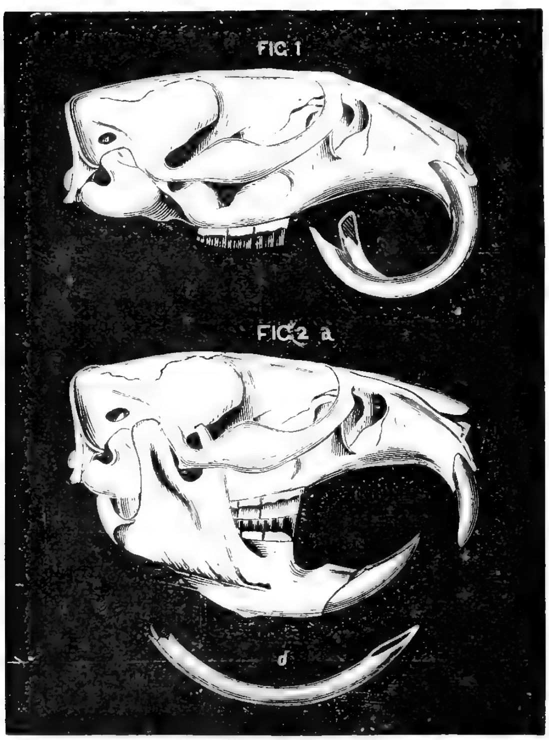
ON THE OVERGROWN TEETH OF FIBER WIBETHICUS.

By Herman L. Fairchild.

No group of animals is more clearly marked by a single feature than the *Rodentia* by their peculiar incisor teeth. Except in the Rabbits which have a supplementary pair in the upper jaw, the number is always four. The enamel is mostly, sometimes wholly, on the anterior surface; where also the dentine is harder. The constant abrasion consequently preserves a keen chisel edge which admirably adapts them for gnawing. This purpose requires them to be of a certain length. To keep that length, the loss from wear is compensated by continual outward growth from the base, the growth being supplied from permanent pulp. The outward growth and the terminal wear are nicely balanced.

It is evident that a loss of one incisor prevents abrasion of the opposing tooth, which, continuing to push outward, may become so long as to interfere with the proper use of the jaws and the remaining teeth. Such cases, while not unknown, are sufficiently rare to be of great interest to the naturalist, and of wonderment to the unscientific.

* Fig. 1, represents a striking example of such malformation in the case of a muskrat, *Fiber Wibethicus.* The figure is three-fourths the size of the specimen. This skull was found on the bank of Sacandaga River, town of Edinburgh, Saratoga Co., N. Y. Unfortunately no other portion of the skeleton was collected; but the most unobserving could not fail to notice such remarkable teeth. It was naturally supposed that some strange creature had been discovered. Falling into the hands of the writer its character was discovered and a normal specimen was procured for accurate comparison. The latter is shown in figure 2.



When removed from their sockets the overgrown incisors show a growth nearly to a complet circle, although the curvature is somewhat spiral. Their terminations exhibit the normal form produced by abrasion at a time when the teeth were of the proper length, and are naturally discolored with foreign matter on account of long disuse. The yellow color of the front surface of these incisors is fainter towards the ends, but still marked.

As the mandible is missing it is impossible to know what was the difficulty with the lower incisors. They might have been broken by severe usage or carried away by a gun-shot. But that the animal once possessed them is shown by the naturally abraded ends of the remaining ones. The trouble seems to have been of a character which prevented the after growth of the lower incisors. For if they had grown out again after an injury, they would have been forced to take a position in front of the lengthened upper incisors. This would have prevented the forward and backward motion necessary for mastication, and so prominent in Rodents, and moreover would undoubtedly have worn the anterior surfaces of the overgrown upper teeth. But the latter do not show the least unnatural abrasion, while the molars do show that they were used. Probably the breaking of the teeth near the bone would have so exposed the pulp as to destroy it and the implanted part of the injured teeth.

The fairly clean fresh surfaces of all the upper molars would indicate that the lower molars were quite intact and that the greatly lengthened teeth did not interfere with mastication, however much they interfered with prehension. The accumulation of foreign matter upon the sides of the molars is greater than on those of the normal skull. Perhaps this is due to less discrimination in choice of food, and possibly to somewhat greater age.

That the animal lived some considerable time after its misfortune, is proven by the great length of the teeth. The time required for this growth is unknown. It is, however, a very interesting point and should be determined. The rate of growth of the incisors may vary, possibly in the same individual, according to the kind of food and consequent wear; at least it would not be right to assume that the rate of growth is always the same. Observation upon a Rabbit or other rodent would be valuable but not conclusive, as the rabbit is entirely vegetarian in diet while the Muskrat is quite omnivorous. To answer the question before us, the observation should be made upon a Muskrat having the lower incisors removed or rendered useless, in order to repeat as nearly as possible the conditions under which we imagine our specimen existed.

As the ends of the overgrown incisors had long passed the point of greatest interference they did not prevent the taking of food with the mouth; and the creature probably did not die from starvation.

If the readers of "SCIENCE" can give any facts bearing on this matter from their personal knowledge and observation they will confer a favor by sending them to these columns.

In *Forest and Stream* of April 4, 1878, there is a sketch of a Woodchuck's skull showing an abnormal lengthening of both pairs of incisors, which, according to the description, did not prevent the animal from procuring sufficient food to keep it in good condition. And Owen's "Odontography" briefly describes (page 411, old ed.) the abnormal elongation of the incisors of rodents; and notices the skull of a beaver, of which a lower incisor formed a complete circle. Plate 104, Fig. 7, of the above work, also shows the abnormal upper incisors of a rabbit.

* This illustration was used, without comment, in an article by the writer in the *Popular Science Monthly* for June, 1880.

Absorbing Power of the Atmosphere.—M. Laight had long ago shown that the radiating light of the sun is largely absorbed by the layer of atmosphere. But penetrating more deeply into the question, he has successively and separately studied the absorption undergone by each ray of the spectrum. He concludes that these diverse rays are from being equally absorbed, and that the radiation is modified according to the degree of absorption. One of the results of this interesting fact is that the color of the sun is different from that which we attribute to him.

BOOKS RECEIVED.

ANTHROPOLOGY: An Introduction to the Study of Man and Civilization, by EDWARD B. TYLOR, D. C. L., F. R. S. With Illustrations. D. Appleton & Co., New York, 1881.

The present volume is one which will be very acceptable to a large class of scientific readers, for it places before them within the compass of a book of three hundred pages, the principles on which the science of Anthropology is based, and a synopsis of the mass of facts collected and arranged by Anthropologists, which are scattered in some fifty standard works and hundreds of independent papers on the subject.

As an introduction to the science of Anthropology, Dr. Tylor's work is a great success, and if carefully studied will save a vast amount of desultory reading on the part of the student, and as strictly technical details are carefully avoided, the author has succeeded in bringing the subject within reach of readers who have received or are receiving the ordinary higher English education.

The work opens with a brief but sufficiently comprehensive survey of the varieties of men, their language, their civilization and their ancient relics, thus showing by vestiges of man's early existence, what proofs we have of his first appearance and ultimate development.

The most common observer cannot fail to notice the broad distinction among races of men, but it is only within modern times that these distinctions have been worked out by scientific methods. One of the first questions which arise in tracing the history of mankind, is, did man originate from one stock in some primitive centre, and afterwards spread far and wide, or are the Negroes, Mongolians, Whites and other races distinct species, each sprung from a separate origin.

Dr. Tylor favors the views propounded by modern zoologists, which is against the several origins of mankind, for two principal reasons. First, that all tribes of men, from the blackest to the whitest, the most savage to the most cultured, have such general likeness in the structure of their bodies and the working of their minds,—as is easiest and best accounted for by their being descended from a common ancestry, however distant,—and secondly, that all the human races, notwithstanding their form and color, appear capable of freely intermarrying and forming cross races of every combination, which appears to point to a common ancestry. The author therefore advises the acceptance of this theory of the unity of mankind as best agreeing with ordinary experience and scientific research.

Any decision on this subject, however, must be considered provisional only, as our means of judging what man's progenitors were like, both in mind and body, before the forefathers of the present negroes and Tartars and Australians were separated into distinct stocks, is at the best most imperfect. Nor is it yet clear by what causes these stocks or races passed into their different types of skull and limbs, of complexion and hair.

We find no aid from the study of ancient inscriptions and figures, as to the condition of races at the beginning of historic times.

Figures of Egyptians drawn more than 4000 years ago, describe features very similar to those found in Egypt at the present day. The celebrated inscription of Prince Una, dating back 2000 years B. C., makes mention of the *Nahsi* or Negroes who were levied and drilled by ten thousands for the Egyptian army; and on the tomb of Knumkept of the 12th dynasty there is represented a procession of *Amu*, who are seen by their features to be of the race to which Syrians and Hebrews belonged. In fact all the evidences derived from ancient monuments, geography and history, prove that the great race-divisions of mankind are of no recent growth, but were already settled before the beginning of the historical period. We must then look to the prehistoric period as the time when the chief work was done of forming and spreading over the world the races of mankind.

We might expect that "language" would tell of man's age on the earth, but the reader of this work will find that although there is evidence that all recent language was derived from one primitive language, the most patient research shows that all trace of that primitive language is lost.

The first chapter of Dr. Tylor's work includes a history of the civilization of man and his gradual development in the appreciation of Art. The first traces of man in the stone age is described, dating back from twenty to a hundred thousand years, presenting evidence that, even at that remote period, man possessed all the attributes of humanity in a savage and rude condition.

In the second chapter man is compared with the brute creation. To show how man may have advanced from savagery to civilization is a reasonable task and is worked out to some extent by the author. But the evidence is wanting for crossing that mental gulf that divides the lowest savage from the highest ape.

The general conclusion advanced by the author in this branch of the subject is expressed by Dr. Tylor as follows: "On the whole the safest conclusion warranted by facts is that the mental machinery of the lower animals is roughly similar to our own, up to a limit. Beyond this limit the human mind opens out into a wide range of thought and feeling which the beast mind shows no sign of approaching. If we consider man's course of life from birth to death, we see that it is, so to speak, founded on functions which he has in common with lower beings. Man, endowed with instinct and capable of learning by experience, drawn by pleasure and driven by pain, must like the beast, maintain his life by food and sleep, must save himself by flight, or fight it out with his foes, must propagate his species and care for the next generation. Upon this lower framework of animal life is raised the wondrous edifice of human language, science, art and order."

To the many who have yet to master the principles of this, the latest of sciences, "*Anthropology*," we commend this book as one which will be read with much satisfaction and profit, for the study of man and civilization is not a matter of scientific interest only, but at once passes into the practical business of life. We have in it the means of understanding our own lives and our place in the world, vaguely and imperfectly, it is true, but at any rate more clearly than any former generation.

The knowledge of man's course of life from the remotest past to the present, will not only help us to forecast the future, but, says the author, guide us in our duty of leaving the world better than we found it.

CORRESPONDENCE.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. No notice is taken of anonymous communications.*]

FIRE BALLS.

To the Editor of "SCIENCE":—

The interesting instance, narrated in a recent number of "SCIENCE," of the descent of fire balls as observed by Henry O. Forbes, calls to mind two occurrences which I have witnessed under circumstances favorable for accurate observation.

One sultry summer day, at sea, I was lying on the deck of a small schooner, watching in the sky the gathering clouds of a sudden and violent thunder shower. I was looking over the main mast, whose top was in the centre of my field of view. As the first scattered drops of rain began to fall, and in advance of any lightning or thunder, there appeared upon the top of the mast a brush of fire

remarkably like that which is often produced on a small scale in electrical experiments. This brush shone very distinctly against the heavily overcast and darkened sky; and it looked about as large as the hand of a half-grown child, with the fingers spread moderately apart. After one or two seconds it seemed to change into a ball of fire, of smaller size but greater intensity, and distinctly round in outline, which glided smoothly down the surface of the mast and across the wooden deck, until it passed over the stern of the boat and entered the water with an explosion not unlike the report of a large pistol. There was no lightning-rod upon the vessel, but the wood of the mast and of the deck was quite wet by the time the ball passed over it. The electrical disturbance did not approach the mast with a visible flash, and the sound of the explosion, the only sound noticed, was decidedly from the direction where the ball entered the water. The ball left the mast in a line at right angles to a tangent at the point of departure, while the nearest course to the sea would have been in the direction of the tangent; but having once commenced to cross the deck it took a perfectly straight course. The wood over which it passed was slightly discolored in several places, but not at all charred.

On another occasion I was standing, with several companions, in a carriage-house, in the country, having taken refuge there from a sudden shower. Through an open door we were gazing intently upon a large barn near by, discussing the safety of occupying that more commodious retreat, when a flash of lightning, in the usual zigzag form, passed obliquely from the clouds to the barn, striking the ridge at the very summit of the roof. Thence it passed, as a distinct ball of fire, over the wet shingles down the surface of the roof to the eaves and there entered the barn. We thought there was a report as the ball entered the barn, which had been recently filled with freshly gathered hay, but were not certain, owing to the nearly, if not practically, simultaneous arrival of the thunder sound. The nearest door of the barn was opened within a very few seconds, and the interior was found filled with fire and smoke; although the roof over which the ball had passed remained unaffected until destroyed by fire breaking out from within the building. Although I had been the only one in the party to insist in taking refuge in the carriage-house instead of the barn, there seemed to arise on the part of the majority a considerable unwillingness to further dwell upon the reasons for preferring the latter place of safety.

R. H. WARD, M. D.

To the Editor of "SCIENCE."

Allow me in reply to R. C. S. again to tell him, most emphatically, that I have never entertained, for a moment, the idea of "reviving" or advocating the theory that motor cells can be distinguished from sensory ones by their size. In order to "revive" a theory it must be restated in some form. In the "transactions" of the American Neurological Association, published in the *Journal for Nervous and Mental Disease*, July, 1880, p. 476, I am correctly reported as stating that "so far as sensation went, it had nothing to do with the subject of the paper." My theory relates exclusively to the nuclie in so-called motor cells. They are called motor not by any means on account of their size, but from their evident connection with motor filaments. In spite of my denial, R. C. S. still asserts the wrong thing, and shows none of the customary regret at having possibly misunderstood me.

Prof. Stieda is referred to by me not to "polemize" against him, but to show that, while he had measured their cells and their nuclie in the spinal cord of turtles, he had not anticipated me in attributing difference in size to difference in energy. Stieda's expression is; Physiologische Dignität, which I translate physiological importance. As neither sensation nor sensory cells are here mentioned by him, it seemed plain that he, like myself, referred solely to cells of the spinal cord which, by their close relation to motor filaments, are supposed to have a motor function.

The careful reader for whom R. C. S. so dogmatically responds, is respectfully requested to bear in mind that the three brief articles which I have published, relate throughout to Reptiles and Batrachians, and not to mammals. With this reminder he will have, I think, no difficulty in reading, in some places, between the lines.

As to the auditory nerve centres, it remains for me to state that the paragraph which R. C. S. quotes was offered as a mere suggestion to one who seemed also to think that the large cells in the vicinity of the roots of the auditory nerve, in the iguana, bore some relation to my theory. As his communication was stated to be preliminary in character, and had nothing to do with my subject, I decided to make no personal reference, suggesting that these cells (as claimed fourteen years ago by Deiters) were of doubtful function, and that the cells related to vision and olfaction were (in reptiles, etc.,) all very small. This, I believe, is true, but it revives no theory.

I leave my unknown critic to the contemplation of this clause which appears in his last publication: "Notwithstanding the construction which Dr. J. J. Mason now desires to see placed upon his words," doing him the justice to suppose that he knows what he insinuates, and that being mortal, he will hasten to admit that he may have misunderstood me.

JOHN J. MASON, M. D.

NEWPORT, R. I., July 2, 1881.

DECOMPOSITION OF WATER.—In decomposing water by discharging Leyden jars through platinum electrodes, Dr. Streintz finds that, with very small electrodes giving passage to a series of discharge currents in one direction, and then left to themselves, a remarkable reversal of E.M.F. occurs, but only when the discharges do not exceed a certain number. Dr. Streintz made use of a quadrant-electrometer in his experiments.

SIMPLE METHOD OF DETERMINING THE TEMPORARY HARDNESS OF WATER.—In order to ascertain the alkalinity of springs on the spot, with samples not exceeding 10 c.c., and with a single reagent, the author makes use of a tube of 30 to 40 c.m. long, closed at the bottom, and with a mark showing the capacity of 10 c.c. From this mark upwards the tube is graduated into 0.1 c.c. To determine the temporary hardness the tube is filled to the lowest mark with the water in question, and a little piece of filter-paper, which has been previously steeped in extract of logwood and dried, is thrown in, thus giving the water a violet color. Centinormal hydrochloric acid is then added from a dropping bottle, till the color of the liquid inclines to an orange. The tube is then closed with the thumb and well shaken. The greater part of the carbonic acid escapes, and the liquid becomes red again. Acid is again added, and the shaking repeated until the next drop of the acid turns the liquid to a pure lemon-yellow, a point which a little practice is easily reached. The amount of acid used is read off on the tube itself. The author proposes to express the alkalinity of a water by the number of c.c. of centinormal acid needed to neutralise 10 c.c. He thinks that this method will be found useful both for sanitary and geological purposes.—V. WARTHA.

CHEMISTRY OF THE PLATINUM METALS.—Contrary to the prevalent view, all the platinum metals, if precipitated by zinc in a state of very fine division, are soluble to a considerable extent in nitric acid, whether weak or strong, so that palladium cannot be separated from such a mixture by means of nitric acid. The solubility appears to depend on the relative proportion of one or other of the metals in the

mixture (mass action.) Pure palladium, even in thin leaves, is not easily soluble in nitric acid, whilst all the other platinum metals are perfectly insoluble if in a moderately compact condition. Palladium cannot be isolated by agitation with mercury from a solution which, along with the platinum metals contain base metals, such as copper, lead, &c., since the mercury precipitates, not merely the palladium, but all the other platinum metals, forming probably amalgams. From the platinum metals thus precipitated by mercury, metal free from mercury cannot be obtained by distillation and subsequent ignition, since a part of the mercury forms a stable compound with the platinoids. —THEODOR WILM.

GLYCERIN.—Notwithstanding the low price which prevails for almost every description of raw produce and manufactured goods, there are a few articles which form notable exceptions. Perhaps one of the most remarkable of these is refined glycerin, which, within the last two years, has advanced from about £30 to £130 per ton avoirdupois for 30° B. This enormous advance is due partly to increased consumption, diminished production and the influence of speculation working on a market devoid of stocks. In view of the present position of the article and the prospect of a continuance of high prices for a considerable time to come, the attention of soapmakers is now being turned to the utilization of their waste "leys," and various new processes for recovering the glycerin contained in these liquors have lately been tried with more or less successful results. Apart from minor impurities, waste soap "leys" are generally found to contain glycerin, carbonate of soda or caustic soda, chloride of sodium, gelatin and albumen. One of the processes for recovering the glycerin which promises to be the most economical and the most successful begins with concentrating the liquor until the salts contained therein begin to crystallize. The liquid is then cooled and filtered to rid it of gelatin and albumen. It is afterwards made to absorb carbonic acid, which precipitates bi-carbonate of soda, and which is separated from the liquor in the usual way. After undergoing this process the liquor is then made to absorb gaseous hydrochloric acid until what remains of carbonate of soda has been converted into chloride, and further, until all, or almost all, the chloride of sodium has been precipitated and separated from the liquor in the usual manner. Arrived at this stage, the liquor contains water, glycerin and hydrochloric acid. The acid is then evaporated entirely and absorbed in water for using afresh. The dilute glycerin remaining can be purified by filtering it through animal charcoal or by concentrating and distilling it in the usual way.

AN INDUSTRIAL AND TECHNOLOGICAL MUSEUM.—An Industrial and Technological Museum of a very comprehensive character is in course of organization at Sydney. It is to include animal, vegetable and mineral produce in the crude and in the manufactured states: waste products, of whatsoever origin, foods with their constituents, and that necessary shadow side of the picture, their adulterations; educational appliances; sanitary apparatus and systems, models, plans, machinery, etc., for mining; agricultural machinery and manures; models, drawings, and descriptions of patents; a department of economic entomology; ethnological specimens, etc. One remark in the prospectus may call up a smile. The museum is intended to occupy a similar position to the South Kensington Museum. This might be construed to mean that it is to occupy a site as far out of the way of merchants, manufacturers, patentees, etc., as possible. We need scarcely say that the project has our best wishes.

WAR DEPARTMENT REPORTS.

METEORS OBSRRVED DURING MAY, 1881.

Almota, Wash. Ty., 18th. Boise City, 3d. Ft. Stevenson, 2d, very brilliant, observed about 8 p. m. in the southern heavens; first appeared about 5° above the horizon and inclined south and downward; its flight lasted about 5 seconds, leaving a faint train; in size, it was apparently nearly equal to that of the full moon. Fredericksburg, Tex., 22d, 10.10 p. m., altitude 45°, direction from northwest to southeast; as it passed along it gave a light much brighter than the stars, leaving a trail of dark blue color and exploded apparently into three balls of fire. Davenport, 22d. Washington, D. C., 9th, 9.45 p. m., appeared 45° above south-eastern horizon, pursued a northwesterly course through zenith; extent of its visible path was about 20°. Wood's Holl, 3d, 2.10 a.m., from east to west. Woodstock, Md., 17th, 9 p. m.; 23d, 9 p. m., from southeast to northwest; 24th, 8 35 p. m., from west to east. Williamstown and Fall River, Mass., 13th. Thornville, Mich., 27th. Fayette, Miss., 1st. Atco, N. J., 22d, 24th, North Volney, N. Y., 23d. Waterburg, N. Y., 2d. Little Mountain, Ohio, 7th. Mission House, Wis., 2d.

SATURDAY, JULY 23, 1881.

Professor Lewis Swift informs us that he has been receiving letters claiming the Warner Prize, at the rate of seventy per day for some time past; it may be convenient, therefore, if we state the conditions on which Mr. Warner offers the reward for the discovery of comets during the year 1881.

In the first place the comet must be telescopic, which is a bar to all naked eye observers, and the comet must be unexpected. An exception is made to this condition in favor of the comet of 1812, the reappearance of which is expected.

The first discovery of the comet must be made in the United States or Canada. To secure the prize immediate notification must be made by telegraph to Professor Lewis Swift, of Rochester, Director of the Warner Observatory. This telegram must give the time of the discovery, the position, direction and daily rate of motion with sufficient exactness to enable at least one astronomer to find it.

A study of these conditions will prevent useless applications and many disappointments. The first condition, however, which appears to limit claimants to the class who possess telescopes, should, in our opinion, be construed to object to naked eye observations only. A good opera or field binocular glass could be used with good effect in a search for comets. Caroline Herschell used a very simple instrument, and, in the course of her life, discovered no less than eight comets. With a tube with two glasses, such as was commonly used "as a finder," she used to "sweep" for comets, writing down and describing all remarkable appearances.

We direct attention to a series of interesting drawings of comet B, 1881, made by Professor Edward S. Holden at the Washburn Observatory, with the 15-inch telescope, constructed for the late Professor Watson, which will be found on pages 346 and 347 of this issue.

Professor Holden has attempted to delineate the appearance of the comet on six consecutive nights, commencing on the 24th of June, and also on the 8th and 11th of July.

Messrs. S. E. Cassino & Co., of 299 Washington street, Boston, are about to publish an international directory of the names and addresses of all those who are engaged in any of the departments of Science. Such a work can only be arranged in a satisfactory manner with the co-operation of scientific men. We therefore cordially respond to a request from Messrs. Cassino to make known their intentions in this direction, and we call upon all scientists at once to forward their names and addresses to the publisher.

This notice is not only intended for professional scientists, but for the large class of amateurs, who may be collecting, or giving their attention to any scientific specialty.

As the directory is partly prepared, prompt attention is essential to those who would have their names included.

AMERICAN ASSOCIATION FOR THE ADVANCEMENT OF SCIENCE.

We remind our readers that the annual meeting of the American Association for the advancement of Science will be held this year at Cincinnati, commencing on the 17th of August next. The executive committee announce that the sessions of the Association will be held in the Music Hall and Exposition Buildings, on Elm street. All the meetings, general and sectional, will be under one roof. Each section will have a room regularly assigned to it, and every necessary facility in the way of tables, blackboards, etc,, will be provided. The offices of the Permanent and Local Secretaries, Reporters' Room, Post Office and Reception Rooms will all be on the first floor. Between the morning and afternoon sessions a daily lunch will be served in the wing of the Exposition Buildings known as Horticultural Hall.

On the first day of the meeting, besides the general session for organization, some of the official addresses will be delivered. In the evening there will be a citizens' reception.

On the following days the usual routine business will be transacted, papers will be read, and so on. A variety of social entertainments will be provided, and an afternoon is to be devoted to visiting the Zoological Garden.

Members of the Sub-Section of Anthropology, and others who are interested, will have an opportunity to examine the excavations at Madisonville, and to visit other localities of antiquarian interest near Cincinnati. After the adjournment of the Association, excursions will be organized on the Cincinnati Southern Railroad, and also, it is hoped, to the Mammoth Cave.

Beginning on the evening of August 16, and continuing through the meetings of the Association, there will be an exhibition of scientific apparatus, appliances, and collections. This exhibition is to be in charge of the Department of Science and Arts of the Ohio Mechanics' Institute, and a large amount of valuable material will be shown. Some of the leading dealers in chemicals, ap-

paratus, microscopes, minerals and zoological specimens have already notified the Special Committee of their intention to exhibit. The goods here displayed are to be kept over for the Ninth Cincinnati Industrial Exposition, opening September 7, the Managers of which have offered special premiums for this class of exhibits.

The local executive committee comprises the following names: A. T. Goshorn, Chairman; F. W. Clarke, Ormond Stone, Secretaries; Julius Dexter, Treasurer; J. D. Cox, William McAlpin, Herbert Jenney, George W. Jones, Archer Brown, C. W. Wendte, Robert Brown, Jr.

CONTRIBUTIONS TO COMPARATIVE PSYCHOLOGY.

By S. V. Clevenger, M. D.

II. LANGUAGE.

Excepting in Kussmaul's (1) elaborate essay, speech has had but little consideration anatomically and physiologically. The philologists and ethnologists have been trying to interpret phenomena while ignoring the mechanism directly concerned therein. As readily might the operations of a locomotive be explained by a person who had never seen one. Herbert Spencer, on the origin of language, is discursive and inconclusive. Darwin passes hastily over the subject in his "Descent of Man," but later (2) lays the foundation for a proper study. Bastian may be taken as the representative of the majority expressing opinions on language (3). He says: "Language was started by some hidden and unknown process of natural development or as a still more occult God-sent gift to man." If inquiries are to terminate in such assumptions, why not extend our conceptions of occult God-sent gifts, to the explanation of the Universe? Bastian's words mean, "I cannot fathom it, therefore, no one should try to do so."

Mivart (4) adopts the usually accepted divisions of language:

I. Sounds which are neither articulate nor rational, such as cries of pain, or the murmur of a mother to her infant.

II. Sounds which are articulate, but not rational, such as the talk of parrots, or of certain idiots, who will repeat, without comprehending, every phrase they hear.

III. Sounds which are rational, but not articulate, such as the inarticulate ejaculations by which we sometimes express assent or dissent from given propositions.

IV. Sounds which are both rational and articulate, constituting true speech.

V. Gestures which do not answer to rational conceptions, but are merely the manifestations of emotions and feelings.

VI. Gestures which do answer to rational conceptions and are, therefore, external, but not oral manifestations of the *mental* word. Such are many of the gestures of deaf mutes, who, being incapable of articulating words, have invented or acquired a language of gesture.

Analyzing these divisions, we find therein the prevailing idea to be that:

I. Language consists of speech and gesture (This essay will be directed toward proving that speech is also gesture; hence *Language is gesture accompanied, or not accompanied with sounds*).*

II. Language is voluntary or involuntary.

An impassable gulf exists between the voluntary and the involuntary in the minds of those who are disposed to reverence authority more than logic. The history of human thought proves Agnosticism to be a far better friend to man than Vaticanism or its disguises. Huxley (5) concludes that "We are conscious automata endowed with free will in the only intelligible sense of that much-abused term—inasmuch as in many respects we are able to do as we like—but none the less parts of the great series of causes and effects, which in unbroken continuity, composes that which is, and has been, and shall be—the sum of existence. As to the logical consequences of this conviction of mine, I may be permitted to remark that logical consequences are the scarecrows of fools, and the beacons of wise men. The only question which any wise man can ask himself, and which any honest man will ask himself, is whether a doctrine is true or false?" Kussmaul (6) feels justified in claiming that "each act of the will is always also the realization of a movement image previously sketched out in the recollection, or an entire chain of such movement images." * * * "*What we call the will is not only a motor, but always a sensory process.*" That which is involuntary in our actions appears, neurologically speaking, to be most evidently reflex, and those who know most about the mechanism of the will, know also that it is none the less reflex for being complex, or for having evaded the analysis of dualists and those ecclesiastically biased. It is from this automatical basis that I seek an explanation for the hitherto inexplicable. Brown-Sequard insists that speech is a reflex phenomenon (21). We find certain muscles, tendons, bones and cartilages concerned in mastication, and deglutition of food common to many vertebrates. Many of these same parts, separately or conjointly, prove useful to these animals in noise production: A woodpecker (7) finds by drumming rapidly upon a sonorous piece of wood, that he excites the admiration of his kind, and attracts attention to himself. When he repeats the operation for the distinct purpose of exciting admiration and attracting attention, he uses as much and precisely the same kind of reason, as the serenader, who pours out his rhyme to the jingle of a guitar. Wilder (8) speaks of the inharmonious feline nocturnes, and *Lieder ohne Worte*, but cats to whom that sort of music is addressed, find it quite as rational and expressive as the seranaded biped, and the greater part of both sorts of caterwauling, may be interpreted to mean the same thing, inharmonious only to those not interested.

Thus the brays, snorts, shrieks, grunts, etc., of the myriad kinds of animals are only methods for expressing their satisfaction or displeasure. Many such sounds being made use of after their accidental origination. The North American Indian uses the hoggish grunt in affirmation, and a perusal of Darwin's "Expression of the Emotions in Man and Animals" would be profitable to philologists who are not too strongly permeated by a metaphysical bias. At the outset any animal having observed that its noises, of whatever origin, attract attention of other animals would be led to the use of such noises as are serviceable. All that follows is simply an improvement upon these conceptions, and the animal that uses one noise or gesture, or a thousand, to bring itself into relation with other animals, expresses, in so doing, an idea, conveys a thought and hence speaks.

But this matter of reason and language possessed by animals has been ably worked out by observers and thinkers (9).

When water in an engine boiler is low and the alarm whistles through a simple float device; or when portions of machinery jar and scrape, the necessity for more water or oil is conveyed to the engineer's mind, and by a means comparable to the mechanism of crying. Just so the colony of beavers dive out of sight when they hear the warning slap of the sentinel's tail.

* No attempt at a perfect definition is made here. In fact the impossibility of absolute definiteness, in a world where everything is relative, seems, in this instance, not to have occurred to the metaphysicians. Language, owing to its blending of voluntary and involuntary, and consisting of gestures, used thoughtlessly, as well as those for expressing thought, is inseparable from other animal activities. One definition of Life is that it consists of Motion, but everything moves, hence everything lives, and there is no such thing as Death. Even the mathematical definition of a point is absurd and unthinkable. Who can define Health or Disease satisfactorily?

Professor Whitney, of Yale (10), thinks that "there needs to be, perhaps, a radical stirring up of the subject, a ventilation of a somewhat breezy, even gusty order, which shall make words fly high and noisily against one another before agreement shall be reached. If so, the sooner it is brought, in whatever way, the better; and they are no true promoters of the progress of Science who strive to smooth things over on the surface and act as if all were serene and accordant below." The gentleman just quoted might have made short work of his opponents had he approached the controversy physiologically.

M. Renan (11) says: "Languages have sprung forth completely formed from the very mould of the human spirit like Minerva from the head of Jupiter." Schleicher, Steinthal and Müller are guilty of similar puerilities. The latter claims that "animals cannot talk because they have no general ideas; they evidently have no general ideas because they do not talk." This sort of reasoning might be pardonable in scholars of metaphysical tendencies, but when we find Carl Vogt refusing to deal with the question, and Haeckel (12) saying, "Our ape-like progenitor very probably did not possess an articulate language of ideas," the appearance of this essay does not seem to require an apology. To deny, as Mivart (13) does, that "the cat, or any other beast or bird" has the gift of speech, and to base this denial upon man having a peculiar language of sounds and gestures to express his thoughts, is quite as sensible a proceeding as for the woodpecker to taunt man with his inability to drum in its peculiar way. "Psychology," says Mivart, "denotes the study of all the activities, both simultaneous and successive, which any living creature may exhibit." Mivart, therefore, is the grossest kind of materialist, without knowing it, for "Psyche," after this definition, consists of motion alone, and this pre-supposes a material origin. Kruse (14) mentions a deaf and dumb lad who, after having acquired a gesture language, told of years of abuse to which he had been subjected by an inhuman father and narrated other details of his previous life. Kussmaul cites this as an evidence of the speech faculty, upon its creation, finding everything prepared for it in the way of ideas to convey. The phylogenesis of speech should be studied by proper consideration of such facts. The dog only needs human speech to tell in words what he thinks and expresses in every other way beside when his master takes a gun to start on a hunt for game.

We may set aside all consideration of sound in language by remembering that persons entirely deaf may converse in the regular way, "judging of what was said by the movements of the lips and tongue, which they had learned to connect with particular syllables; and regulating their own voices in reply by their voluntary power, guided in its exercise by their muscular sensations" (15).

Speech therefore is the same as any other muscular act under the control of the will. The jaw is a limb, the parts accessory to which and concerned in its movements are as susceptible of cultivation as is the arm, and in the matter of speech acquisition, and the gradually better and better subjection to the mind of all bodily parts concerned in its expression. Herbert Spencer's words are applicable though the passages here given had no reference to the point under consideration:

"Functions, like structures, arise by progressive differentiations just as an organ is first an indefinite rudiment having nothing but some most general characteristic in common with the form it is ultimately to take; so a function begins as a kind of action, that is like the kind of action it will eventually become, only in a very vague way." (16) Thus a "lecture" by the Rev. Joseph Cook was predetermined by the bark of the primordial dog. (Vogt says "let them bark, it is their nature.")

"In animals, however, besides analogously structural changes wrought during the period of growth by subjection to circumstances unlike the ordinary circumstances, there are structural changes similarly wrought after maturity has been reached. Organs that have arrived at their full size possess a certain modifiability." (17) (This I would apply to the structural changes in the brain inevitable upon language learning as well as to those occurring through training or drilling in any art or trade involving manual dexterity or proficiency.)

"The growth of muscles exercised to an unusual degree is a matter of common observation. In the often cited blacksmith's arm, the dancer's legs, and the jockey's crural adductors we have marked examples of modifiability which almost every one has to some extent experienced. It is needless to multiply proofs. The occurrence of changes in the structure of the skin when exposed to a stress of function is also familiar. That thickening of the epidermis on a laborer's palm results from continuous pressure and friction is certain." * * * "An orchestral conductor gains by continual practice an unusually great ability to discriminate differences of sound, and in the finger reading of the blind we have evidence that the sense of touch may be brought by exercise to a far higher capability than is ordinary. The increase of power which habitual exertion gives to mental faculties needs no illustration, every person of education has personal experience of it." (18)

Language, therefore, may be regarded as pure gesticulation and its perfectibility as dependent upon the gradual evolution of the reasoning powers of animals. This being the case, it requires but a glance at the construction of the jargons of to-day (by courtesy called languages) to convince us of the very low plane to which man with his much vaunted intellect has arrived. From the teleological standpoint, certainly German with its nonsensical genders, French with its slaughter of letters for euphony sake, and English with its multitude of barbarisms, must have had more of a malign than divine origin. (But then the tower of Babel story accounts for it all.) Maudsley (19) mentions the inability of the Bosjesmen to talk in the dark, owing to their depending more upon signs than vocables for intercommunication. The North American Indians can thus converse without uttering a single sound. Laura Bridgeman may also be mentioned as expressing her thoughts, and even "muttering" in her dreams by finger motions. The necessity for such considerations as the foregoing appears in the philological bias which has crept into our physiological literature through the one-sided studies of such men as von Schlegel, and through their claims that the perfectly regular and complex construction of languages of many barbarous nations is a proof of the divine origin of language. By placing language upon an equal footing with all other voluntary gestures we see at once that speech is entitled to no more regard than any other set of complex motions performed by any animal to subserve rational purposes. We cannot deny the possession of rational language to animals when we see them conveying their thoughts and desires with and without sounds, by menaces, contortions, glarings, and a multitude of other movements. I have known mules and oxen on the arid plains of the West to acquaint a thirsty herd half a mile away that water has been discovered. All of us know of the hen's ability to talk to its chickens. The most perfect rhetoric and oratory of man can be said, therefore, to differ from these animal expressions only *in degree*, and often the most pretentious discourse conveys fewer ideas than the cluck of a hen or the growl of a dog. A pure linguist, hence, can claim but little more in an intellectual way than a pure gymnast. Different groups of muscles, nerves, bones, etc., are exercised and cultivated by each. Man can claim no more for developing adroitness in the use of his jaws, lips, tongue and larynx than any animal which, finding itself in possession of certain other limbs and groups of muscles turns them to the utmost possible advantage. The great function of the jaw was masticatory, its use

in enunciation of words was subsequently developed. The hands of our progenitors were adapted to climbing trees and by subsequent training are made dexterous in us in the use of tools. The point I desire to bring prominently into view is, that the speech faculty has for its basis nothing more important than prehensile abilities. The mechanic is entitled to the same amount of respect as the linguist; in fact, the mechanic is more apt to have acquired a respectable amount of skill in the use of his tools, as generally his labor is directed to some useful and definite end; not necessarily so with the linguist, his acquisition of a few jargons frequently causes him to be mistakenly regarded as intellectual. It is not the ability to use tools or to speak that elevates man above his fellow animals, for man is not the only animal that speaks or uses tools. The intellectual differences between men consist in the greater power of co-ordination and correlation of faculties.

Dr. M. Dax, in 1836, designated the left anterior lobe of the brain as the seat of language, because loss of speech often coexisted with disease of this part, though the labors of Bouilland previously had paved the way for this definiteness. Aubertin and Broca finally assigned this faculty as centralized in the "operculum," and Dr. Wm. A. Hammond (20), in reviewing the subject, concludes that: "The integrity of the posterior part of the third frontal convolution, and perhaps of the second, is indispensable to the normal operation of the function of speech." Hughlings Jackson, and Ferrier agree with Broca in restricting the location to the operculum, but Dr. Hammond (20) claims:

1. "That the organ of language is situated in both hemispheres, and in that part which is nourished by the middle cerebral artery.

2. "That while the more frequent occurrence of right hemiplegia, in connection with aphasia, is in great part the result of the anatomical arrangements of the arteries which favors embolism on that side, there is strong evidence to show that the left side of the brain is more intimately connected with the faculty of speech than the right."

I would like to suggest to the advocates of opercular and insular localization an idea which has probably not been previously advanced, to wit: The sinistral nature of central cerebral speech innervation has, doubtless, some relation to the azygous tendencies of the parts concerned therein; for example, the tongue, uvula, maxillæ, vocal cords, etc., though not strictly fused or impaired, present peculiarities of structure and synchronism of motion of the bi-laterally placed parts widely different from those of the extremities, which could easily influence innervation to centralize upon one side of the brain, particularly when favored by the better blood supply afforded by the left middle cerebral artery. Were the two hands of man joined so as to restrict motion mainly to a perpendicular plane, as in the case of the lower jaw, then we might expect the summit of the ascending frontal convolution on the left side to develop over the corresponding part on the right side as a centre for arm motions. But this matter of localization has not been firmly established. Dr. E. C. Spitzka, before the Medical Society of the County of New York in 1877, reviewed "The Localization of Cerebral Diseases in the Light of recent Anatomical Discoveries" (22). Spitzka acknowledged that "the fibres which ultimately abut in the hypoglossal and facial nerve nuclei can be traced into the operculum and island, giving us an anatomical basis for the aphasic symptom," but insisted that "our faculty of speech is certainly more complex than is generally supposed, and the terms amnesic and ataxic aphasia, by no means exhaust the possible pathological interferences with its delicate mechanism. The first step in the acquirement of speech is its phonetic element. We hear a word or sound, and as far as it is a mere sound impression it is registered in a sensory area of the cortex. We then experiment, as it were, with our motor appartus, until we find the combination requisite to repeat said word or sound. This motor innervation has its conscious seat in Meynert's region, while the sensory perception is located in a distant area (probably, though not certainly) the occipital lobe. Now in order that the sensory perception may control the "correctness" of the motor expression the two must be associated. It will then be indifferent, whether the sensory center, the motor center, or the associating band be destroyed, we will have aphasia in either case. And there are still more intimate relations which may be equally interfered with, causing either aphasia, agraphia, alexia, or a combination of any two of these, or all." * * * "Any intricate intellectual processes *must* involve the greater part, or the whole, of one hemisphere." This was *a posteriori* completely, and "localizers" should not fail to read the proceedings of that meeting carefully. These views are consistent with the theory I recently presented to the American Neurological Society concerning the histogenetic function of nerve cells in opposition to their being "force producers." Spitzka has shown that the Island of Reil has nothing whatever to do with the development of the speech faculty. In some aberrant forms he found this lobe largely developed. It would seem that primarily this region has, if it have any connection at all with speech innervation, only a certain convenience of situation, an accidental contiguity to certain fasciculi which was taken advantage of as the speech faculty developed.

ÆTHER.

By Pliny Earle Chase.

Professor of Philosophy in Haverford College, Pa.

The laws of æthereal action and re-action are laws of action and re-action in an elastic atmosphere.

The following well known laws have an important bearing upon photodynamics and other æthereal researches:

1. Cyclical activities may often be accurately represented by formulas which introduce mean or average ve-

locities and mean *vis viva*. This is the foundation of Maxwell's theory of the equality of mean *vis viva* in the molecular movements of different gases at equal temperatures, and of Pfaundler's discovery that in estimating the heat of dissociation, the mean should be taken between the temperatures of incipient and of complete dissociation.

2. The projectile force, which produces flight or cyclical motion against any central acceleration or retardation, is equivalent to the mean acceleration or retardation multiplied by one-half the time of flight or cyclical motion.

3. The velocities of wave motion in elastic fluids, and of cosmical and molecular orbital motion, can all be expressed by the common formula $v = \sqrt{2\,gh}$.

4. Every periodic vibrating or orbital motion can be regarded as the sum of a certain number of pendulum vibrations. (*Fourier's theorem.*)

5. The distance of the centre of oscillation from the centre of relative stability is at two thirds of the length of a linear pendulum, or at the square root of four tenths of radius in a rotating sphere.

6. The acceleration of any force, which is uniformly diffused from or towards a given centre, varies inversely as the square of the distance from the centre.

7. Times of revolution under the action of such forces, vary as the three halves power of the distance; distances vary as the two thirds power of the time.

8. Centres of inertia, or nodes, in a vibrating elastic medium, tend to produce harmonic nodes.

9. The mutual inter-actions of cosmical, molecular or atomic bodies are proportioned to the respective masses; actions which are considered with reference to a single active centre vary directly as the mass and inversely as the square of the distance.

10. In elastic atmospheres the densities decrease in geometrical progression, as the height above the surface increases in the arithmetical progression.

11. Living force, or *vis viva*, is proportional to the product of mass by the square of the velocity.

12. The distance of projection against uniform resistance is proportioned to the living force.

13. In condensing nebulæ, the velocity of circular orbital revolution is acquired by subsidence, from a state of rest, through one-half of radius.

The following additional propositions may be readily deduced from the foregoing.

14. *Mean vis viva* may be represented by the *vis viva* of centres of oscillation.

15. The force of planetary projection should be referred to perihelion; the force of incipient subsidence, to aphelion.

16. In synchronous orbits, the mean velocity of rectilinear oscillation is to the velocity of circular orbital oscillation as twice the diameter is to the circumference.

17. The acceleration or retardation of a centripetal force varies as the fourth power of the velocity of orbital revolution.

18. In cyclical motions, the resultant of all internal forces must be in equilibrium with the resultant of all external forces, at the expiration of each half cycle.

19. The modulus of cyclical motion is equal to the product of mean acceleration by the square of the time of a half cycle.

20. The sum of all external forces may, therefore, be represented by a velocity which is equivalent to the mean or resultant internal force acting for one-half of the cyclical time.

21. The influence of a central force which acts at the extremity of a linear pendulum is nine times as great upon the centre of oscillation, as its influence upon the centre of suspension.

22. The limiting *vis viva* of wave propagation is five-ninths of the mean *vis viva* of the oscillating particles.

23. In condensing nebulæ, rupturing forces which are due to central subsidence may be represented by fractions in which the denominator is one greater than the numerator.

24. In synchronous rotation and revolution, the nucleal radius varies as the three-fourths power of the limiting atmospheric radius.

25. The variation in mean *vis viva* of gaseous volume is to the variation in *vis viva* of uniform velocity as 1 is to 1.4232.

26. The mean thermal and mechanical influences of the sun must be in equilibrium.

27. The collisions of particles, in subsiding towards a centre of force, tend to form belts at the centre of linear oscillation.

28. The limiting velocity between tendencies to aggregation and tendencies to dissociation is to the velocity in a circular orbit as the ratio of the circumference of a circle to its diameter is to the square root of two.

29. In explosive, as well as in cyclical motions, equilibrium must be established between internal and external forces.

30. Apsidal and mean planetary positions must also be controlled by like tendencies to equilibrium.

31. Undulations in an elastic medium maintain the primitive velocity which is due to their place of origination.

32. When two or more cyclical motions are combined, they must all be modified by the tendency to conservation of areas.

33. In expanding or condensing nebulæ, the conservation of areas maintains a constant value for the modulus of rotation.

34. Instantaneous action between different masses or particles, by mere material intervention, is impossible.

35. In synchronous motions about different centres, the mean distances from the centres of motion vary as the cube root of the masses or other controlling forces.

36. Constant velocities, in a homogeneous elastic medium, represent constant living forces.

37. The time of acquiring orbital velocity, at Laplace's limit of possible atmosphere, is to the time of acquiring "nascent" or dissociative velocity at the nucleal limit, as the diameter of a circle is to its circumference.

These laws are applicable in all branches of radiodynamics, viz.: photodynamics, thermodynamics, electrodynamics, cosmodynamics, chemical physics, hydrodynamics and pneumatics.

COMET C, 1881.

At 3 A. M., of the 14th instant, a comet was observed at Ann Arbor by Mr. J. M. Schaeberle, an amateur astronomer, who has the privilege of the University Observatory.

Mr. Henry M. Parkhurst, of Brooklyn, whose recent calculations on comet B, 1881, proved to be very accurate, has published in the New York *Herald* the following observations on Mr. Schaeberle's comet:

"The position of the new comet on the 20th instant at 2h. 46m., Washington mean time, was:—Right ascension, 5h. 54m. 58s.; North declination, 40 degrees, 40 minutes. This shows a motion of 29 minutes per day—an increase of 7 minutes—showing that the comet is not so distant as I had hoped. I have not succeeded in reconciling my two positions with that telegraphed for the time of discovery. To satisfy the right ascension given the comet must have already passed its perihelion and be moving in such an orbit that it will pass between the earth and sun within a fortnight, and be no more seen in this hemisphere. The increased brightness this morning tends to support this idea. Yet it may not have reached its perihelion; in which case it may be visible for a month longer. I shall be compelled to wait for a third accurate observation before I can determine the orbit more exactly. In any event the comet is coming directly toward the earth, and it will become much brighter than at present, so that it will probably be visible to the naked eye as soon as the moonlight ceases to interfere. It is now about 12 degrees southeast of Capella, the bright star in the northeastern sky at 3 o'clock in the morning."

COMET B, 1881.

With the drawings of the above comet we received from Professor Edward S. Holden the following letter:

WASHBURN OBSERVATORY,
MADISON, WISCONSIN,
July 9, 1881.

To the Editor of "SCIENCE."

MY DEAR SIR—As you request, I send you with this, the drawings of the head of the bright comet which have been made here. The 15½-inch equatorial, with the zone eyepiece (field 25'.5, power 145), has been used. The drawings have all been made by me, and in them *the darker the shading, the brighter the corresponding part* of the comet.

Very sincerely yours,
EDWARD S. HOLDEN.

DESCRIPTION OF ILLUSTRATIONS.

Figure 1. June 24, 1881, 14h., m. t.

" 2. " 25, " 10h., m. t. Hazy and outlines of comet not well seen. The drawing shows only the structure of the head. The nucleus is not round, and is eccentric in the envelopes.

Figure 3. June 26, 1881., 11h., 22m., m. t. Hazy and clouds. The dark semi-circular line in upper part of nucleus represents a dark part.

Figure 4. June 27, 1881, 13h., m. t.

" 5. " 28, " 10h., m. t.

" 6. " 29, " 9h., 30m., m. t.

" 7. July 8, " 10h., 35 m.—Moonlight. The nucleus is not double. There is a dark, narrow channel between the following side of the nucleus and the envelopes, as in the figure.

Figure 8. July 11, 1881, 9h., 30m., m. t.—Strong moonlight and twilight.—In this figure, which is engraved differently to the others, the white part represents light, and the shading darker portions.

FIGURE 4.

Advices from Europe state that this comet was observed by Dr. Elkin, of the Royal Observatory, Cape of Good Hope, who states that after a week of overcast sky the comet was found there on May 31. Mr. L. A. Eddie, F.R.A.S., of Graham's Town, saw it on May 27, and others claim to have seen it two days earlier. On June 4 the tail was 6° long, coma 20 minutes, and nucleus 20 seconds in diameter; the comet was as bright as α Columbæ.

Mr. William Huggins states that "On Friday night, (June 24) I obtained, with one hour's exposure, a photograph on a gelatin plate of the more refrangible part of the spectrum of the comet which is now visible. This photograph shows a pair of bright lines a little way beyond H in the ultra-violet region, which appear to belong to the spectrum of carbon (in some form) which I observed in the visible region of the spectra of telescopic comets in 1866 and 1868. There is also in the photograph a continuous spectrum in which the Fraunhofer lines can be seen. These show that this part of the comet's light was reflected solar light.

FIGURE 3.

This photographic evidence supports the results I obtained in 1868, showing that comets shine partly by reflected solar light, and partly by their own light, the spectrum of which indicates the presence in the comet of carbon, possibly in combination with hydrogen."

The following spectroscopic notes, by W. H. M. Christie, of the Royal Observatory, Greenwich, will be read with interest:

With the Sheepshanks equatorial (6¾ inches aperture) the head showed the want of symmetry that has been remarked in some other comets. On June 24 the preceding side was much the brighter, there being a strong brush or

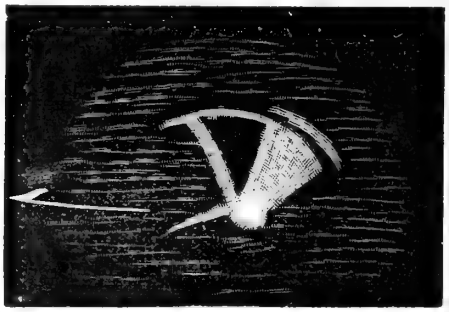

FIGURE 8.

arc of light on that side, with a bright fan close to the nucleus and a much smaller arc on the following side, the two arcs appearing to spring from the nucleus on opposite sides, and higher up to interlace. A very remarkable feature was a straight wisp of light extending from the nucleus nearly along the axis of the tail. On June 25 this had become much less striking, and the appearance of the head had entirely changed. The following side was then much the brighter, and the general appearance was that of a parabolic envelope, with a much brighter unsymmetrical parabola placed within it, the latter having its focus on the following side of the nucleus, and its axis turned round in the direction *n p s f* from that of the tail.

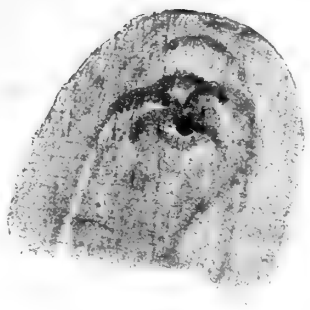

Fig. 5.

Fig. 2.

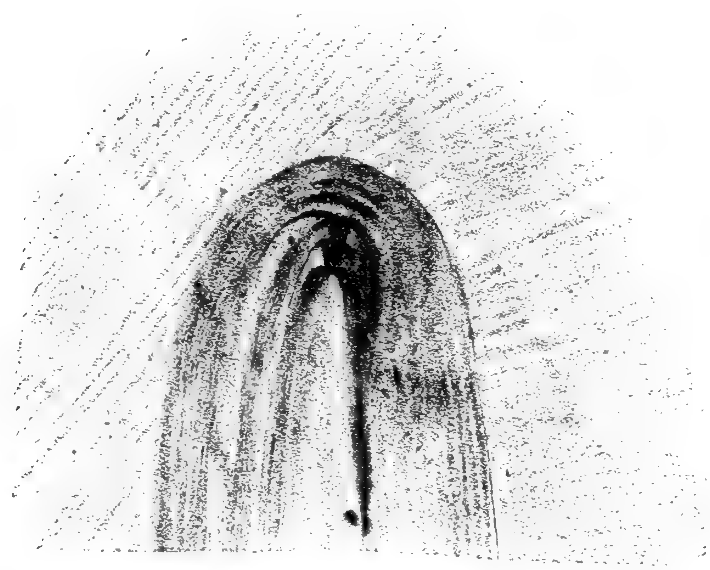

Fig. 1.

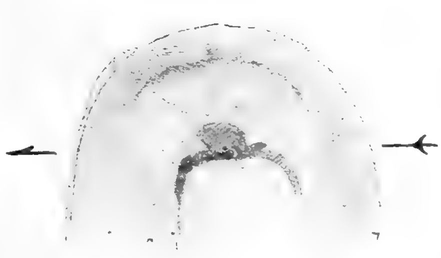

Fig. 7.

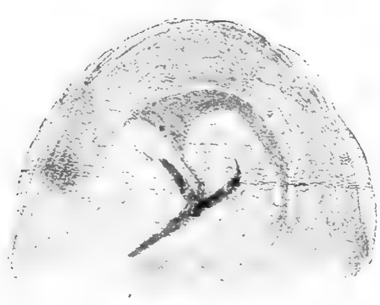

Fig. 6.

Drawings of Comet B, 1881, made by Prof. EDWARD S. HOLDEN, Washburn Observatory, Wis.

The greater part of the head gave a bright continuous spectrum, obliterating the usual cometary bands, but one portion showed three bands, in the green, blue, and violet respectively. Measures of the principal band in the green show that it coincides with the band in the first spectrum of carbon (blue base of flame) at 5165, and not with that of the second spectrum (vacuum-tube) at 5198. The bands in the blue and violet appear to correspond, as nearly as could be estimated, with bands in the first spectrum of carbon. These observations were made with the half-prism spectroscope mounted on the $12\frac{3}{4}$-inch equatorial, a dispersive power of about $18\frac{1}{2}°$ from A to H being used, with a magnifying power of 14 on the view-telescope, as in the measures of star-motions in the line of sight. No decided polarisation was detected either in the head or the tail. Cloudy weather has prevented any observation of the comet since June 25.

THE UNITY OF NATURE.

By the Duke of Argyll.

IX.

THE ORIGIN OF RELIGION CONSIDERED IN THE LIGHT OF THE UNITY OF NATURE.

(*Continued.*)

These conceptions seems to have taken their form from the very violence of the revulsion which they indicate and explain. The peculiar tenet of Buddhism, which is or has been interpreted to be a denial of any Divine Being or of personal or individual immortality, seems the strangest of all doctrines on which to recommend a life of virtue, of self-denial, and of religious contemplation. But the explanation is apparently to be found in the extreme and ridiculous developments which the doctrines of Divine Personality and of individual immortality had taken under the Brahminical system. These developments do indeed seem almost incredible, if we did not know from many other examples the incalculable wanderings of the human imagination in the domain of religious thought. The doctrine of the transmigration of souls at death into the bodies of beasts was a doctrine pushed to such extravagances of conception, and yet believed in with such intense conviction that pious Brahmins did not dare even to breathe the open air lest by accident they should destroy some invisible animalculæ in which was embodied the spirits of their ancestors. Such a notion of immortality might well oppress and afflict the spirit with a sense of intolerable fatigue. Nor is it difficult to understand how that desire of complete attainment, which is, after all, the real hope of immortality, should have been driven to look for it rather in reabsorption into some one universal Essence, and so to reach at last some final rest. Freedom from the burden of the flesh, rendered doubly burdensome by the repeated cycles of animal existence which lay before the Brahmin, was the end most naturally desired. For, indeed, complete annihilation might well be the highest aspiration of souls who had before them such conceptions of personal immortality and its gifts. A similar explanation is probably the true one of the denial of any God. A prejudice had arisen against the very idea of a Divine Being from the concomitant ideas which had become associated with personality. The original Buddhist denial of a God was probably in its heart of hearts merely a denial of the grotesque limitations which had been associated with the popular conceptions of Him. It was a devout and religious aspect of that most unphilosophical negation which in our own days had been called the "Unconditioned." In short, it was only a metaphysical, and not an irreligious, Atheism. But although this was probably the real meaning of the Buddhistic Atheism in the mind of its original teachers, and although this meaning has reappeared and has found intelligent expression among many of its subsequent expounders, it was in itself one of those fruitful germs of error which are fatal in any system of Religion. The negation of any Divine Being or Agency, at least under any aspect or condition conceivable by Man, makes a vacuum which nothing else can fill. Or rather, it may be said to make a vacuum which every conceivable imagination rushes in to occupy. Accordingly, Buddha himself seems to have taken the place of a Divine Being in the worship of his followers. His was a real personality—his was the ideal life. All history proves that no abstract system of doctrine, no mere rule of life, no dreamy aspiration however high, can serve as an object of worship for any length of time. But a great and a good man can always be deified. And so it has been with Buddha. Still, this deification was, as it were, an usurpation. The worship of himself was no part of the Religion he taught, and the vacuum which he had created in speculative belief was one which his own image, even with all the swellings of tradition, was inadequate to fill. And so Buddhism appears to have run its course through every stage of mystic madness, of gross idolatry, and of true fetish-worship, until, in India at least, it seems likely to be reabsorbed in the Brahminism from which it originally sprang.

And so we are carried back to the origin of that great Religion, Brahminism, which already in the sixth or seventh century before the Christian era had become so degraded as to give rise to the revolt of Buddha. The course of its development can be traced in an elaborate literature which may extend over a period of about 2000 years. That development is beyond all question one of the greatest interest in the history of Religion, because it concerns a region and a race which have high traditional claims to be identified with one of the most ancient homes, and one of the most ancient families of man. And surely it is a most striking result of modern inquiry that in this, one of the oldest literatures of the world, we find that the most ancient religious appellation is Heaven-Father, and that the words "Dyaus-pitar" in which this idea is expressed are the etymological origin of Jupiter Ζεύςπατήρ—the name for the supreme Deity in the mythology of the Greeks.

We must not allow any preconceived ideas to obscure the plain evidence which arises out of this simple fact. We bow to the authority of Sanskrit scholars when they tell us of it. But we shall do well to watch the philosophical explanations with which they may accompany their intimations of its import. Those who approach the subject with the assumption that the idea of a Divine Being or a Superhuman Personality must be a derivative, and cannot be a primary conception, allow all their language to be colored by the theory that vague perceptions of "The Invisible" or of "The Infinite," in rivers, or in mountains, or in sun and moon and stars, were the earliest religious conceptions of the human mind. But this theory cannot be accepted by those who remember that there is nothing in Nature so near to us as our own nature,—nothing so mysterious and yet so intelligible,—nothing so invisible, yet so suggestive of energy and of power over things that can be seen. Nothing else in Nature speaks to us so constantly or so directly. Neither the Infinite nor the Invisible contains any religious element at all, unless as conditions of a Being of whom invisibility and infinitude are attributes. There is no probability that any abstract conceptions whatever about the nature or properties of material Force can have been among the earliest conceptions of the human mind. Still less is it reasonable to suppose that such conceptions were more natural and more easy conceptions than those founded on our own personality and the personality of parents. Yet it seems as if it were in deference to this theory that Professor

Max Müller is disposed to deprecate the supposition that the "Heaven-Father" of the earliest Vedic hymns is rightly to be understood as having meant what we mean by God. Very probably indeed it may have meant something much more simple. But not the less on that account it may have meant something quite as true. I do not know, indeed, why we should set any very high estimate on the success which has attended the most learned theologians in giving anything like form or substance to our conceptions of the Godhead. Christianity solves the difficulty by presenting, as the type of all true conceptions on the subject, the image of a Divine Humanity, and the history of a perfect Life. In like manner, those methods of representing the character and attributes of the Almighty, which were employed to teach the Jewish people, were methods all founded on the same principle of a sublime Anthropomorphism. But when we come to the abstract definitions of Theology they invariably end either in self contradictions, or in words in which beauty of rhythm takes the place of intelligible meaning. Probably no body of men ever came to draw up such definitions with greater advantages than the Reformers of the English Church. They had before them the sublime imagery of the Hebrew Prophets—all the traditions of the Christian world—all the language of philosophy—all the subtleties of the Schools. Yet of the Godhead, they can only say, as a negative definition, that God is "without body, parts, or passions." But, if by "passions" we are to understand all mental affections, this definition is not only in defiance of the whole language of the Jewish Scriptures, but in defiance also of all that is conceivable of the Being who is the author of all good, the fountain of all love, who hates evil, and is angry with the wicked every day. A great master of the English tongue has given another definition in which, among other things it is affirmed that the attributes of God are "incommunicable."[4] Yet, at least, all the good attributes of all creatures must be conceived as communicated to them by their Creator, in whom all fullness dwells. I do not know, therefore, by what title we are to assume that "what we mean by God" is certainly so much nearer the truth than the simplest conceptions of a primeval age. It is at least possible that in that age there may have been intimations of the Divine Personality, and of the Divine Presence which we have not now. Moreover, there may have been developments of error in this high matter, which may well shake our confidence in the unquestionable superiority of "what we mean by God" over what may have been meant and understood by our earliest fathers in respect to the Being whom they adored. Some conceptions of the Divine Being which have been prevalent in the Christian Church, have been formed upon theological traditions so questionable that the developments of them have been among the heaviest burdens of the Faith. It is not too much to say that some of the doctrines derived from scholastic theology, and once most widely accepted in the Christian Church—such, for example, as the fate of unbaptized infants—are doctrines which present the nature and character of the Godhead in aspects as irrational as they are repulsive. One of the most remarkable schools of Christian thought which has arisen in recent times is that which has made the idea of the "Fatherhood of God" the basis of its distinctive teaching. Yet it is nothing but a reversion to the simplest of all ideas, the most rudimentary of all experiences —that which takes the functions and the authority of a father as the most natural image of the Invisible and Infinite Being to whom we owe "life and breath and all things." In the facts of Vedic literature, when we carefully separate these facts from theories about them, there is really no symptom of any time when the idea of some Living Being in the nature of God had not yet been attained. On the contrary, the earliest indications of this conception are indications of the sublimest character, and the process of evolution seems distinctly to have been a process not of an ascending but of a descending order. Thus it appears that the great appellative "Dyaus," which in the earliest Vedic literature is masculine, and stood for "The Bright or Shining One," or the Living Being whose dwelling is the Light, and in later times become a feminine, and stood for nothing but the sky.[5] It is quite evident that in the oldest times of the Aryan race, in so far as those times have left us any record, not only had the idea of a Personal God been fully conceived, but such a Being had been described, and addressed in language and under symbols which are comparable with the sublimest imagery in the Visions of Patmos. How firmly, too, and how naturally these conceptions of a God were rooted in the analogies of our own human personality, is attested by the additional fact that Paternity was the earliest Vedic idea of Creation, and Dyaus was invoked not only as the Heaven-Father, but specially as the "Dyaush pitâ ganitâ," which is the Sanskrit equivalent of the Greek Ζεὺς πατὴρ γενετήρ.

When, again, we are told by Sanskrit scholars that the earliest religious conceptions of the Aryan race, as exhibited in the Veda, were Pantheistic, and that the Gods they worshiped were "Deifications" of the Forces or Powers of Nature, we are to remember that this is an interpretation and not a fact. It is an interpretation, too, which assumes the familiarity of the human mind in the ages of its infancy with one of the most doubtful and difficult conceptions of modern science—namely, the abstract conception of Energy or Force as an inseparable attribute of Matter. The only fact, divested of all preconceptions, which these scholars have really ascertained is, that in compositions which are confessedly poetical the energies of Nature were habitually addressed as the energies of Personal or Living Beings. But this fact does not in the least involve the supposition that the energies of Nature which are thus addressed had, at some still earlier epoch, been regarded under the aspect of Material Forces, and had afterwards come to be personified, nor does it in the least involve the other supposition that, when so personified, they were really regarded as so many different beings absolutely separate and distinct from each other. Both of these suppositions may indeed be matter of argument; but neither of them can be legitimately assumed. They are, on the contrary, both of them open to the most serious, if not to insuperable objections. As regards the first of them—that the earliest human conceptions of Nature were of that most abstruse and difficult kind which consists in the idea of Material Force without any living embodiment or abode, I have already indicated the grounds on which it seems in the highest degree improbable. As regards the second supposition —viz., that when Natural Forces came to be personified each one of them was regarded as the embodiment of a separate and distinct Divinity—this is a most unsafe interpretation of the language of poetry. The purest Monotheism has a Pantheistic side. To see all things in God is very closely related to seeing God in all things. The giving of separate names to divers manifestations of one Divine Power may pass into Polytheism by insensible degrees. But it would be a most erroneous conclusion from the use of such names at a very early stage in the history of religious development, that those who so employed them had no conception of One Supreme Being. In the Philosophy of Brahminism even, in the midst of its most extravagant Polytheistic developments, not only has this idea been preserved, but it has been taught and held as the central idea of the whole system. "There is but one Being—no second." Nothing really exists but the one Universal Spirit, called Brahmin; and whatever appears to exists independently is identical with that

[4] J. H. Newman, "Idea of a University," p. 60.

[5] Hibbert Lectures, pp. 276, 277.

Spirit.[6] This is the uncompromising creed of true Brahminism. If, then, this creed can be retained amidst the extravagant Polytheism of later Hindu corruptions, much more easily could it be retained in the early Pantheism of the Vedic hymns.

There is, however, one kind of evidence remaining, which may be said to be still within the domain of history, and that is the evidence derived from language, from the structure and etymology of words. This evidence carries us a long way further back, even to the time when language was in the course of its formation, and long before it had been reduced to writing. From this evidence as we find it in the facts reported respecting the earliest forms of Aryan speech, it seems certain that the most ancient conceptions of the energies of Nature were conceptions of personality. In that dim and far-off time, when our prehistoric ancestors were speaking in a language long anterior to the formation of the oldest Sanskrit, we are told that they called the sun the Illuminator, or the Warmer, or the Nourisher; the moon, the Measurer; the dawn, the Awakener; the thunder, the Roarer; the rain, the Rainer; the fire, the Quick-Runner.[7] We are told further that in these personifications the earliest Aryans did not imagine them as possessing the material or corporeal forms of Humanity, but only that the activities they exhibited were most easily conceived as comparable with our own. Surely this is a fact which is worth volumes of speculation. What was most easy and most natural then must have been most easy and most natural from the beginning. With such a propensity in the earliest men of whom we have any authentic record to see personal agency in everything, and with the general impression of unity and subordination under one system which is suggested by all the phenomena of Nature, it does not seem very difficult to suppose that the fundamental conception of all Religion may have been in the strictest sense primeval.

But the earliest records of Aryan worship and of Aryan speech are not the only evidences we have of the comparative sublimity of the earliest known conceptions of the Divine Nature. The Egyptian records are older still; and some of the oldest are also the most sublime. A hymn to the rising and setting sun, which is contained in the 125th chapter of the "Book of the Dead," is said by Egyptian scholars to be "the most ancient piece of poetry in the literature of the world."[8] In this Hymn the Divine Deity is described as the Maker of Heaven and of Earth, as the Self-existent One; and the elementary forces of Nature, under the curious and profound expression of the "Children of inertness," are described as His instruments in the rule and government of Nature.[9] Nor is it less remarkable that these old Egyptians seem to have grasped the idea of Law and Order as a characteristic method of the Divine Government. He who alone is truly the Living One is adored as living in the Truth, and in Justice considered as the unchanging and unchangeable Rule of Right, in the moral world, and of order in the physical causation.[10] The same grand conception has been traced in the Theology of the Vedas. The result of all this historical evidence may be given in the words M. Renouf: "It is incontestably true that the sublimer portions of the Egyptian Religion are not the comparatively late result of a process of development or elimination from the grosser. The sublimer portions are demonstrably ancient; and the last stage of the Egyptian Religion, that known to the Greek end Latin writers, was by far the grossest and most corrupt."

ANCIENT PLANETARY RINGS, VOLUME, MASS AND DENSITY.

BY EDGAR L. LARKIN.

IV.

In Astronomical literature there is engrafted a venerable doctrine giving details of the processes of evolution of the solar system, from a mass of incandescent gas. The theory is a hundred years old. It says, all matter now in the sun and planets was once in a state of rare gas, extending beyond the orbit of Neptune. The gas was hot; it cooled, contracted, and rotated. When by condensation it had dwindled to the insignificant limits of the Neptunian orbit, its velocity of rotation was so great that a ring of gas was detached from the equator of the shrinking sphere. This ring in time formed Neptune. In like manner all the planets were formed, the residue of the primordial mass being the sun. This error has been taught to children, and so tenacious are the traditions of youth, that geometers have been known to cling to the illusion in mature years. It has but one rival—perpetual motion—and is known as the Nebular Hypothesis. If it is true it can be handled by arithmetic; if false, computation will detect the fallacy.

How shall it be attacked; and what can be learned of the primeval state of matter? Can we peer into the depths of primordial time when worlds were in development? The geologist penetrates strata, and writes the records of the earth. Can the history of Neptune be written? And can we trace the processes of its evolution? If so, the mass, volume and thence the density, of the ring whence it formed must be determined. We know its mass in terms of terrestrial matter, it was 102 sextillion tons, or 204 septillion pounds; because that is the amount of matter now in Neptune. By what possible means can its volume be learned? The problem seems incapable of solution, mathematics apparently being unable to furnish a method of grappling with the question. We have used diligence to find records showing that the volume and density of the ring have ever been calculated, and failed. But there is one way of learning the magnitude of the mass of gas whence Neptune condensed. It is based on the doctrine of the CENTRE OF GRAVITY, and it is a fact in nature which subverts the Nebular Hypothesis. We know that if the revolving sphere discarded equatorial matter to make Neptune, the planet formed in the line of its centre of gravity. There are formulæ for the determination of the distances of centres of gravity of segments from the centre of the circles whence they were cut. There are only three possible forms of rings that can be cut from the periphery of a sphere—segmental, cylindric and another, whose sections are in shape like sections cut by a perpendicular plane passing through a bi-convex lens. This geometrical figure is formed by the revolution of a segment of a circle about its chord held quiescent; and the solid generated is a circular spindle. This form we overlooked in the previous paper. The volumes of these rings are sought, the data being the distances of their centres of gravity from the centre of the sphere, which is the distance of Neptune from the sun—2,780,000,000 miles. It has been shown in these notes that the radius of the only sphere large enough to afford a segment of sufficient size to have its centre of gravity coincide with Neptune's orbit, was three (3) billion miles. The dimensions of this segmental ring cut off by passing the chord of the segment around the sphere, were: chord, 2,600,000,000; altitude, 300,000,000; and length, 17,500,000,000 miles, the length of the path of Neptune. Therefore its volume was nine (9) octillion cubic miles, and as this number of miles had to contain 204 septillion pounds, one cubic mile held .0224 pounds, or 157 grains, 45 cubic miles being required to contain one pound of gas.

"At 15.5° C, (60° F.), and 30 inches barometric pressure, 100 cubic inches of Hydrogen weigh 2.14 grains."

Fowne's Chemistry, p. 137. Thence one cubic mile of hydrogen weighs over five (5) trillion grains, or 777 million pounds. And as the ring was of such density as to require one cubic mile to contain 157 grains of matter, the Neptunian mass was thirty-four(34) billion times less dense than hydrogen.

The volume of the sphere, radius three (3) billion miles, whence Neptune was detached, the ring being segmental, was $\frac{4}{3}\pi R^3 = 113$ octillion cubic miles. But the ring was in volume nine octillion cubic miles, nearly $\frac{1}{12}$ the entire mass!

What unheard of convulsion took place to disrupt the mass and cause it to part with $\frac{1}{12}$ its bulk! What inconceivable power was displayed if the dogma is true, yet all the force present was gentle centrifugal tendency caused by slow rotations of 3.36 miles per second!

The mass of the first world is $\frac{1}{20000}$ of the solar system, but $\frac{1}{12}$ the volume was required to make it. The volume of a sphere bounded by the orbit of Neptune is $\frac{1}{6}\pi D^3 = 90$* octillion cubic miles, and as it contained 4 nonillion pounds of gas, each cubic mile held 44 pounds,—17,500,000 times less in density than the lightest body on earth, the mass being homogeneous. But it was not since the centre must have been compressed.

The density of the segmental ring was 34 billion times less than hydrogen, therefore, the sphere was old when it cast away its first world, having had time to acquire internal density, greater than peripheral, in the proportion of 17 millions to 34 billions. All along we have been quoting Helmholtz, where he says:—"It required several cubic miles to weigh a single grain,"—not having made calculation, but now we do not see how he arrived at these results, as one cubic mile, by following the principle of centre of gravity, is found to have contained 157 grains.

He probably alluded to the mass when expanded larger; but if extended to half the distance of the stars, a thousand cubic miles might have been required to contain one grain of matter. And we feel that we are traversing solid ground, in basing these deductions on the doctrine of the centre of Gravity. The volume of a cylindric ring to form Neptune must have been the same as the segmental, the density being nearly equal. The diameter of a section of a cylindric ring whose length was equal to that of Neptune's orbit, in order to have the required volume, was 822,000,000 miles. Since the planet coalesced in its centre of gravity, which was its geometrical centre, the material of the ring extended 411,000,000 miles above, and the same distance below the orbit. This added 822,000,000 miles to the equatorial diameter of the mass, retarded its assumed rotation, and prevented detachment of any particle of matter. The disrupting force had to be applied, not where Neptune revolves, but 411,000,000 below, at a point where force was weakest, and resistance strongest. And then such a ring was subjected to lateral pressure, and could not be severed on that account.

The ring made up of an infinite number of solids generated by revolution of circular segments about their chords, to have the same volume as segmental and cylindric, was in radial diameter 380,000,000, and in diameter north and south 2,090,000,000 miles. If this form of ring was discarded the break took place 190,000,000 below the orbit, and along a line more than two billion miles long. Rotation was slower than the orbital velocity of Neptune, and the separation was again required to be made where the force to cause it was in minimum, and its opposing powers, gravity and cohesion, at a maximum. We reassert that in no possible case could the Neptunian matter have been detached from the primeval mass when it was a *sphere*.

Neither could it have been separated when sections of the protuberance were parabolic; thus a chord, or limiting plane, the base of a parabolic segment, in order to cut out a ring in volume sufficient to contain the Neptunian gas, was in length 634,000,000, in altitude 1,250,000,000, the vertex extending 750,000,000 above, and base descending 500,000,000 miles below, the orbit, in order that Neptune might condense in its centre of gravity. This would make the equatorial diameter of the mass 7,060,-000,000 miles a physical impossibility, for rotation would have come to a dead rest ages before such elongation. Consider the curvature of sections semi-elliptical and results are still more absurd. Since the mass was unable to part with rings whose sections were hyperbolic, parabolic or semi-elliptic, we dismiss as untenable all varieties of such ring-shaped masses.

Now conceive the mass a sphere again and at rest; let rotary motion be imparted, and should the velocity become sufficient, the equatorial regions will become a swelling tide. But when a protuberance elevated motion waned, and the equator subsided. When at greatest altitude the whole mass was an ablate spheriod. Therefore, we lay down this proposition which must have obtained if the Hypothesis of ring displacement is true. If the equatorially expanding mass parted with a ring, it did so at the first opportunity.

And such fullness of time was when a segment of an ellipse could be cut away large enough to have Neptune in its centre of gravity. When the mass was an ablate spheroid, sections cut by passing planes through the entire mass, at right angles to the equator, bisecting the poles, would all be plain curves—ellipses. And a segment severed from the equator to make Neptune, was a segment of an ellipse, whose centre of gravity coincided with that planet's present track. The dimensions of this ring were, height, 319,000,000, and chord 2,350,000,000 miles, to have volume sufficient, to contain gas enough to solidify into the most remote member of the solar system. The axes of the ellipse whence this segment was cut were transverse, 5,800,000,000, and conjugate, 5,400,000,000, the diameter of the mass when spherical being 5,560,-000,000 miles. Therefore, we say that during all mutation in form of the primordial cosmical mass, admitting the hypothesis true, its equatorial diameter was never augmented more than 240,000,000 miles, as is seen in these dimensions.

Mathematical instruments of delicacy are required to measure such small deviation from a sphere. Yet, it was able to discard a ring having a volume of nine octillion cubic miles. Basing conclusions on the sure foundation of the principle of the centre of gravity, we assert that the mass never detached rings whose sections were of any form of curvature known to geometry. Then none were cast off, since every department of celestial mechanics is known to be subject to rigid mathematical laws.

The theory of cosmic evolution, which holds that planets were formed of masses detached from an aeriform sphere belongs in that list of delusions which retarded the early progress of astronomy—the "Geocentric System," the "Firmament," and "Music of the Spheres."

CORRESPONDENCE.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. No notice is taken of anonymous communications.*]

To the Editor of "SCIENCE":—

Dr. J. J. Mason in his second rejoinder to the criticism made by a reviewer in SCIENCE, leaves his unknown critic to the contemplation of the latter's clause. "Notwithstanding the construction which Dr. J. J. Mason now desires to see placed on his words," and does him "the justice" of supposing that the critic

knows what he insinuated. This the critic did indeed know! In view of the inconsistency between the text of his article, and the *dementi* of his first rejoinder, he considered himself justified in insinuating that Dr. Mason had come to recognize that one of his views was untenable, and preferred to deny having entertained that view to admitting its errors publicly. If I have misinterpreted Dr. Mason's paper, I fail to see it even now, for the doctor fails to answer my question: What other than the size of the cells and their nuclei, does Dr. Mason refer to when he speaks of a structure universally admitted to be motor?" Until he answers this, I would suggest that further correspondence on this head is a waste of the space in your periodical, and that demands for "customary regrets" are premature. I am as willing now as I have been throughout not only to withdraw my original stricture, but also the statements that have grown out of the controversy, if Dr. Mason can explain this passage and those with which it is associated, differently from my interpretation, and the meaning evident on their face.

Such an explanation should, however, avoid the incongruity existing between the text of Dr. Mason's article and the explanation he now gives of his real intention in polemicizing against Stieda, which I must confess I have not been able to assimilate. Dr. Mason might also answer this question. Why has he, if his "three brief articles" relate throughout to reptiles, and Batrachians referred to the bat as bearing out his theory, and why has he incorporated an explanation as his own, which I published two years before, without even mentioning my name, or that of some one else who may have anticipated me? My publication was certainly known to Dr. Mason, and he cannot fall back upon the flimsy excuse that it was a "preliminary" communication, and had nothing to do with his subject. If the explanation was worth while incorporating in Dr. Mason's paper, it was worth while giving its author credit for it, just as it was worth while referring to the author of the Iguana article by name, if it was worth Dr. Mason's while to offer suggestions in a patronizing way, which were altogether unnecessary as a matter of instruction, and as which they seem intended to appear.

I consider this subject closed, as far as I am concerned, until such time as the main question here repeated, is properly answered. E. C. SPITZKA.

NEW YORK, 130 E. 50th Street, July 19, 1881.

NOTES.

The *Chemiker Zeitung* states that all the English and French professors at the University of Yeddo, Japan, have been dismissed, and their places filled with Germans. The Japanese Minister of Public Instruction is a German professor. The Chinese are about establishing a German University at Pekin. These facts should be duly weighed by those who still doubt the superiority of German research over English cram and examinations!

ACCORDING to M. A. Gaudry the Permian reptiles of France diminish the vast interval which exists at present between the reptiles and the monotrematous mammals.

THE ferment which M. Béchamp supposed he had discovered in chalk has been traced, by MM. Chamberland and Roux, to an experimental error.

SATURDAY, JULY 30, 1881.

There appears to be an open question between Professor Ormond Stone, of Cincinnati, and Mr. Rock, of Washington, as to whether the nucleus of Comet b, 1881, divided on the night of the 6th instant.

Both astronomers appear to have observed the comet at the same time, but have recorded somewhat different results.

On reference to "Science," July 16th, page 334, will be found a statement of what Mr. Rock saw, as follows:

On the 6th of July the comet was observed by Mr. Rock of the Naval Observatory:

"A bright tongue of light about one revolution long in direction of tail, with a slight node near end and curved."

In explanation of this Mr. Rock said: "I observed the comet at the time of its lower culmination about twenty minutes after midnight. The nucleus did not appear to be divided, but a bright band streamed out in the direction of the tail. This band was about fifteen seconds of the arc in length. Near the end of it was a bright spot, and that portion of the band extending beyond it was curved in the same general direction as the tail, but in a somewhat shorter arc."

And then referring to Professor Stone's report of a division of the nucleus, he adds:

"It is possible that the observer at Cincinnati was not able to distinguish the band of light which I saw uniting the nucleus and the node, and so concluded that he saw two nuclei. When I first observed the comet, on June 28, the coma was apparently homogeneous as it also was on July 2. On June 28, however, there were two spurs of light spreading away from the opposite sides of the head like angel's wings. On July 2, I did not observe these at all or they were very faint. On July 6, I observed the appearance that I have described. It may be that this was the same thing that I saw on June 28, observed from a different point of view. It is not improbable, however, that the nucleus has really divided. Comets appear to have a tendency to do that."

In another part of this issue will be found a letter from Professor Stone, reiterating his former claim of having observed a division of the nucleus of this comet on the night of the 6th instant.

"He states that on the 6th of July, during observations made between 10 p. m. and 3 a. m., he saw a bright red jet projected from the nucleus into the dark region on the side of the nucleus opposite the fan, which was totally different in appearance from those usually seen. There was a dark line separating it from the nucleus. During the first few minutes a decided change took place. The jet *seemed to separate* and form a nucleus of its own, so that for a time the comet appeared double."

It may assist in a solution of this subject if our readers inspect the continuation of the interesting drawings of this comet, made by Professor Edward S. Holden, to be found on another page of this issue.*

The drawings we published last week showed the appearance of the comet on 24th, 25th, 26th, 27th, 28th and 29th of June, and the nights of the 8th and 11th of July. Those presented in this number give views of the comet for the nights of the 13th, 14th, 17th and 18th of July.

The drawing for the 11th of July is interesting as showing "a dark narrow channel between the following side of the nucleus, and the envelopes," but, added Professor Holden, "the nucleus is not double." But the drawing we offer this week for the 18th instant, is quite remarkable as showing a decided division of the nucleus, and Professor Holden remarks in his note to it, "The nucleus is double (it has not been previously)," and those who inspect this drawing will find two nuclei.

The drawings of Professor Holden and the observations of all who have watched this comet, show conclusively that the form of the nucleus changed very rapidly and continuously, and as we have the best evidence that the nucleus divided on the 18th instant, it makes it very probable that a similar phenomenon occurred on the 6th of the same month, especially as Professor Stone is an accomplished observer, and not likely to be mistaken in his description of the optical appearance of a celestial object.

An experiment illustrating "fatigue" in the sense of hearing (corresponding to fatigue of the retina) has been described by Herr Urbantschitsch. Two tubes are adapted to the ears, and adjusted, so that a given tuning-fork is heard equally on both sides. Now strike the fork strongly, and let it sound a little through one tube; then deaden it somewhat by touching. The ear on that side fails to catch the weakened sound, but on transferring the fork to the other ear, the sound is heard distinctly. If the weaker tone presented be of different pitch from the stronger, it is heard on both sides equally. The failure of sensitiveness in the other case is very transient.

* On account of delay in engraving these drawings, they are reserved until next week's issue.

LATENT SOLAR LIGHT.*

Translated from the French, by the Marchioness CLARA LANZA.

A remarkable stone, which plays quite an important role in ancient history, is the carbuncle, literally translated, glowing coal, which shines and glimmers in the dark. Lucien relates that in the Temple of Hieropolis there is the statue of a Syrian goddess in whose forehead is placed a stone called *lychins* or lamp. This stone was moderately brilliant during the day, but at night it illuminated the temple from one end to the other. Shakespeare, in Titus Andronicus, says, while speaking of Prince Bassianus' body:

> "Upon his bloody finger, he doth wear
> A precious ring, that lightens all the hole,
> Which, like a taper in some monument,
> Doth shine upon the dead man's earthy cheeks."

It is said that formerly dwarfs and gnomes wore one of these stones upon their heads as miners carried their lamps. We have likewise been told that certain birds knew where to find them and make use of them to illumine their nests. The tendency which has been remarked in birds, notably crows, to pick up brilliant objects, has naturally given rise to numerous legends and anecdotes among all people, and it is declared that in America numbers of birds light up their nests by placing therein fire-flies. The carbuncle has still another secret property, for it renders the object it adorns, invisible both to man and beast. The question may therefore properly arise, how did man happen to discover this treasure which birds alone were apparently able to distinguish? Poetic fancy, we may say, has answered this query. The invisibility is caused by a ray of light which blinds the eye. A mirror, however, does not become so easily dazzled, and if, while walking along the edge of a brook, you perceive the reflection of a nest in the water, while with your naked eye you are unable to discover it, you may be sure that the stone is there. The legend of the carbuncle first arose in India, the land of precious stones, and it was founded upon the remarkable capacity possessed by many diamonds and a few rubies of shining for a long time in the dark after being exposed a few moments to the sun or merely broad day-light. This phenomenon appears to have been studied and experimented upon for the first time in Europe somewhere about the seventeenth century, by the celebrated naturalist, Boyle. In India, however, the knowledge of it can be traced back to the furthest antiquity, as can be proved by referring to a passage in the famous drama called *Sakuntala*, whose author certainly lived long before the beginning of our era. The passage is this:

"Among the just whose souls enjoy the most complete repose, there is a hidden radiance, which illumines them with its faint glimmer. Thus shines the precious sun stone, as soon as an outward ray of light strikes it."

At Bologna, which, as we know, is a well-known scientific centre, there lived at the beginning of the seventeenth century, a shoemaker named Vincenzo Cascariolo, who like many other men of his time, determined to discover primitive matter in the shape of the philosopher's stone, and by means of it,change the vilest and most worthless metals into pure gold. He had already experimented with fire and water upon all possible substances, organic and inorganic, when in 1604, some writers say 1612, he found, one day upon Mount Paderno, close to his own dwelling, a grayish-white stone, of a fibrous structure, and whose weight being considerable, made him suspect some unusual property. He calcinated a portion of it with some coal, and night falling while he was engaged in the operation, he saw with utter stupefaction, that the entire contents of his crucible, shone with a ruddy glow, although the furnace had become quite cold. With trembling hands he seized the stone, not doubting in the least that it was the famous philosophical one, of which he had so long been in search—still less did he doubt, when he observed afterwards, that only the fragments which were exposed to the sun or broad daylight were brilliant. Alchemists in those days called the sun a golden planet. In their works they employed an identical sign to designate both the luminary and the metal, and they firmly believed that the rays of the former penetrated the latter, as water is soaked into a sponge. This mysterious connection is clearly indicated in a brief opuscule discovered during the middle ages, no one knows exactly where, and of which there exists now only a Latin translation, the original, however, doubtless having been found in some Egyptian tomb. It is called "The Emerald Table of Hermes Trismegistus," and among other things it is therein stated that "the father of the Philosopher's Stone, is the sun, its mother the moon. Separate the earth from fire, and you will obtain the wonder of the world, all shadows will flee before you." These obscure words were applied to the new luminous body called phosphorus, and the phosphorescent stone of Bologna, excited the young disciples of chemistry, to the highest pitch of interest.

Although this substance did not at once realize the great expectations set abroad concerning it, and notwithstanding the fact that it was obliged to renounce entirely the *rôle* of philosopher's stone, it nevertheless caused its discoverer to make a considerable sum of money, for men seeking knowledge and instruction came from all countries to Bologna, and purchased this natural curiosity to a great extent. Poets likewise wrote laudatory Latin verses to the now celebrated shoemaker, comparing him to Prometheus who stole fire from heaven, and placed it on the earth. Enormous enthusiasm was manifested everywhere for this remarkable stone. Volumes were written about it, and it was even stated that the sun and moon were nothing more than huge masses of Bologna phosphorus. For a long time it was thought that the stone existed nowhere but at Bologna, but later it was discovered that it was composed principally of spar or sulphate of baryta, which was to be found in numerous places.

Alchemists gathered fresh hope in 1674, when Christian Balduinus, intendant at Grosenhain in Saxony obtained an analogous luminous body by the calcination of nitrate of lime. He called it hermetic phosphorus or solar gold, and in several works he declared that this was indeed the veritable philosopher's stone whose properties he was engaged in studying. The only German Naturalistic Society at that period was the "Leopold Academy of Natural Curiosities," and this organization received the new inventor into their midst under the honored title of Hermes, which has ever remained in the chemical world. Since then, it has always been supposed that the hermetic or philosophical stone must be luminous, and Dickinson, physician to Charles II, of England, relates in his "Old Physical Truths" (1702) that Noah, whom he regarded as one of the ancestors of hermetic science, had placed a large gleaming stone of some sort, called *zohar* in Hebrew, upon the top of his ark, so that he might have perpetual light during the night, and that moreover the scientific knowledge of this same Noah had caused him to nourish every animal in the ark with an extract made from the meat or plant which the creature preferred, thus economizing space and doing away with the necessity of removing from the ark such bones, leaves, skins, etc., which might otherwise have been there.

Chemical researches advanced with singular activity; for about the same time that Balduinus was performing his experiments, Brand, of Hamburg, an obstinate investigator discovered a substance which produced luminous vapor, and condensed itself into yellow drops that shone in the dark without being exposed to the sun. Professor Kirchmayer, of Wurtemburg, announced to

* This article was originally written in German and published a short time ago in the *Gartenlaube*.

the world emphatically, that the long sought for "perpetual light" had at last been found, while another enthusiastic novice wrote a work upon the *Phosphorus mirabilis* and its marvellous brilliancy. Here again the future did not justify all the hopes which might have been expected. This substance, however, which still goes by the name of phosphorus has become one of the necessities of our age.

Phosphorus gradually entered the scientific period. In 1768 an English chemist, Canton, obtained a new kind by calcinating oyster shells with sulphur, and it was finally discovered that the best absorbents of light were combinations of sulphur, calcium, baryum and strontium. However, other metallic sulphurets and various substances are equally capable of making in the dark what is called solar, magnetic or electric light. The method of preparation, of course, has considerable influence and lights of divers colors can be obtained according to the process employed. By calcinating sulphates with organic substances, or carbonates with sulphur, a very brilliant phosphorus can be obtained, consisting principally of baryta, another of lime, less luminous and a third of strontium, which gives forth a very feeble light. Sulphate of baryta gives a phosphorescent product of an orange color. When the sulphate is prepared artificially the light is greenish.

Later, Ozarm obtained other luminous bodies by calcinating lime with sulphate of arsenic or sulphate of antimony, while another chemist, Bach, by heating sulphur with calcinated oyster shells which had probably been washed with a solution of ammoniac and realgar, procured a phosphorus so brilliant that its light was even visible during the day.

It is by this means, or others which are similar, that the luminous flowers are prepared which lately have appeared to such an extent. They are covered with some phosphorescent substance which makes them glimmer in the dark with a beautiful bluish light. The luminous matter is pulverized and applied to the object by means of a varnish or anything else that will stick. By employing phosphorus of different colors very pretty effects can be produced, bouquets of all shades, glittering butterfles, luminous inscriptions, etc. But the most interesting of all is undoubtedly luminous photography, which is made by placing a paper covered with phosphorescent powder behind the glass negative of a photograph. Heat brings out the luminous qualities as well as light, and very peculiar and beautiful effects can be obtained by writing upon such a paper as has just been described with a pointed piece of heated metal.

Unfortunately these interesting amusements are not eligible as regards trade, for as soon as it is exposed to the air sulphuric luminous matter gradually loses its properties and acquires the disagreeable odor of spoiled eggs, while the object by the end of a week or two is not phosphorescent at all. On the other hand, it can be very well preserved by putting it into air-tight glass tubes, and phosphorus of all colors thus prepared can be had from Geissler's establishment in Bonn. It has been proposed to make inscriptions of these tubes for the night bells of hotels, physicians' houses and druggists' shops, the daylight being sufficient to make them very luminous at night. Another idea, conceived by Gustave Ullig, is to make the faces of watches and clocks phosphorescent, as the glass covering them would be a protec ion against destruction.

As to the physical explanation of phosphorescence, it was thought for a long time that the light was composed of little eddies or whirlpools of subtile matter, and that sunlight became condensed and accumulated in them. Later, when it was known that light is only a vibratory movement, and that the phosphorus on the end of matches only burns because it is united with the oxide in the air, it was thought that in all the old phosphorescent substances the light was produced alone under the influence of a slight oxidation. This explanation, however, is false, and only during the last century was the true one made known by a celebrated German physician named Euler.

It is generally believed that the planets, the tops of mountains, and all celestial bodies, are visible, simply because they reflect the rays of the sun. This is also false. Brilliant surfaces alone, more or less, reflect light, others absorb it on the contrary, and cause vibration just as a musical sound makes all the objects which it strikes vibrate. Certain surfaces, however, can only reproduce certain vibrations (blue or red for example) of solar light, which is composed of the vibrations of the seven prismatic colors, and when these vibrations are repeated in our eye, the surfaces appear to us blue or red, as the case may be.

In the same way that consecutive vibrations can be determined after sound, so phosphorescence succeeds the action of light. Euler affirmed that the greater number of bodies would present these luminous vibrations if they were observed immediately after they had been exposed to the sun, and if a continued sitting in the dark had rendered the eyes of the observer very sensible. The French physician, Becquerel, constructed an instrument about twenty years ago called the phosphoroscope, by means of which he demonstrated that most substances, paper, stone, oyster shells, etc., shone for a short time after being exposed to the light, that is to say, a second or the fraction of a second, and that solar phosphorus was only distinguishable from other bodies by the persistence of this property. But whether this assertion be true, generally speaking, or not, the subject itself is not by any means simple, and there are a mass of circumstances of which we must take account.

Modern physics teach us that a number of bodies, notably colored organic matter and some metallic combinations, become phosphorescent, but only when they are lighted. This sounds like a paradox, but facts can prove the assertion. There are certain substances, both liquid and solid, which by reflected light appear to have another color than the one transmitted. A peculiar emission of rays can also be observed upon the surface. Petroleum, solutions of sulphate of quinine, decoctions of Indian bark, etc., emit bluish rays; the etherized extract of green leaves, blood red rays; uranium glass, which is pale green and used principally in the manufacture of Rhine wine glasses, emits reddish yellow rays. If any of these dichroic subtances are selected and placed in a dark room lighted only by an electric current traversing a glass tube, they will shine brilliantly, each one in its particular color, certainly with more splendor than the electric light, and yet only while the latter illumines them. How is this curious phenomenon to be explained? How can a feeble light produce such a brilliant one?

It has been said above that white light is composed of seven colors, or, more properly speaking, of an infinite number of colors, which after their dispersion from the prism separate one from the other and form a long band. The red rays are those which vibrate the slowest, and the violets those which vibrate the most rapidly. But just as there are in addition to the red rays others which vibrate slower still and are manifested not as luminous rays, but calorific ones, so there are besides the violets, ultra violet rays which vibrate so quickly that we cannot directly perceive them, although they are known by their energetic chemical action. This is notably the case in photography, and for this reason they are termed chemical rays, or invisible light. A pale, electric light, is a peculiarity of these rays, and the latter give to certain bodies that remarkable dichroic radiance which has been called fluorescence, because it was observed for the first time in fluor-spath. However, if on one side these rays produce a light which cannot be perceived by our retina owing to the extreme rapidity of their vibrations, on the other, the bodies thus illuminated should be able to

diminish the rapidity by vibrating themselves more slowly, and thus render the rays visible. Ultra violet rays could consequently be transformed into violet, blue or green; blue rays into yellow or red. What generally happens, however, is that they change red rays to purely calorific ones and thus make them invisible.

We must here make several important observations. First of all, violet rays do not only produce the greatest fluorescence, but also the greatest phosphorescence. Red rays produce neither the one nor the other. Luminous or dichroic substances give a light differing from that which they receive. It has been demonstrated, finally, that the closest relationship exists between the two phenomena—That fluorescence can be considered as an intense phosphorescence which can be seen in broad daylight, but which dies with the light which gave it birth, while phosphorescence is only a feeble but persistent fluorescence.

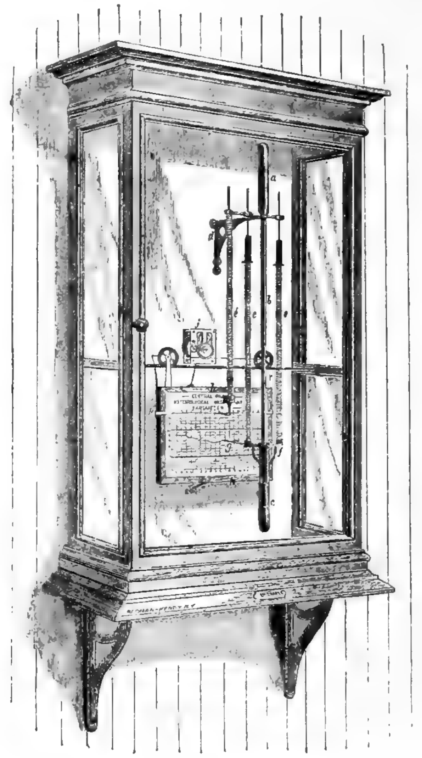
"Solar phosphorus" generally reproduces luminous vibrations even when it has ceased to receive the latter, and it can transform calorific rays into luminous ones. A diamond acts in this way, also fluor-spath, and nearly all artificial phosphorus. One of the last named gives forth a light of various colors, if it is heated to different degrees after being exposed to the light. Sulphate of strontium produces a deep purple light at 20°, a violet light at 15°, blue at 40°, bluish-green at 70°, greenish-yellow at 100°, and reddish-yellow at 200°,

Moreover, phosphorescence, like fluorescence, can be produced by means of an electric light rich in chemical rays. If you expose to such a light a flower, a butterfly or any other object covered with phosphorescent powder, it will assume a magnificent appearance. The English chemist, Crookes, prepared diamonds and rubies in this way, by enclosing them in an air-tight glass ball placed in the immediate vicinity of the negative pole, from which a luminous current issued. The effect was superb, recalling all sorts of fairy stories. Some African diamonds shone with a brilliant blue light, and a large greenish one produced such an intense radiance that it almost looked like a lighted candle. In fact the light was quite sufficient to read by, and the history of that famous stone in the Temple of Hieropolis seemed really probable. A collection of small diamonds from various countries, placed in any receptacle that is air-tight, will produce parti-colored fiery lights, blue, pink, red, orange, yellow, green and pale green, all mingling together.

In a third recipient, Crookes placed a quantity of uncut rubies, which, when the electric light fell upon them shone with such a gorgeous red flame that they appeared to be incandescent. Artificial rubies prepared by Feil in Paris gave as brilliant a light as the real ones, and white crystals became rose-colored or deep red. Such wonderful carbuncles would have astonished even the authors of the old legends.

A CURIOUS thing occurred lately in the works of M. Fleury, at Cette (Hérault). The feed-water of the boiler giving much incrustation, M. Fleury was advised to put into the boiler some fragments of zinc as a de-incrustant, and did so. In a few days, spite of oiling, the steam-engine began to work very badly, the piston catching a great deal, and it soon became necessary to stop and make examination. The piston was found to be covered with a thick adherent layer of copper. It was put on the lathe, and at certain ovalised points, the metallic layers were so thick that the tool worked in copper alone. The explanation given by M. Fleury is this: The boiler was connected with the engine by copper pipes. Particles of zinc carried off by the steam would form with the copper numberless small galvanic couples; hence the transport of copper to the piston, which would principally attract them by reason of its motion, and of the heating produced. It is remarked in *Les Mondes*, that the eminently electric properties of expanding steam may have helped in development of the phenomenon.

DRAPER'S SELF-RECORDING, MERCURIAL BAROMETER.



We are indebted to Dr. Daniel Draper for preparing an abstract of his weekly Meteorological report for this journal, the third of which appears this day in another column.

Dr. D. Draper is director of the Meteorological Observatory of the Department of Public Works, Central Park, where all observations are made by self-recording instruments, especially designed and arranged for this purpose.

The great object Dr. Draper had in view when designing these instruments, was to combine simplicity of construction with perfect efficiency. His great success is well known to all familiar with Meteorological Science, and we propose in the course of a few articles to fully describe these instruments, and illustrate the subject with excellent wood cuts.

We commence the series with a description of the apparatus for recording Barometric observations.

"I was led to construct this form of barometer from the fact that with the photographic one it cannot be told what the atmospheric fluctuations are until the next morning, when the photographic plate is developed. Even then, if there has been much variation in temperature, it alters the sensitiveness of the collodion film, so that it is very difficult to read the tracing. The construction of the pencil instrument is as follows:

In the pencil barometer the glass tube is 36 inches in length, the upper portion being of larger diameter than the lower; it is held firmly in a fixed position, and filled in the usual manner with quicksilver; its lower or open end dips into a tube or reservoir containing the same metal. This reservoir is suspended on two spiral steel springs, and has freedom of motion up and down. When the pressure of the atmosphere diminishes, a portion of the mercury flows out of the tube into the reservoir; this becoming heavier, stretches the steel springs, causing the ink pencil fastened to them to mark downwards. If the pressure increases the reverse movement takes place. The ink pencil makes its mark on a ruled paper register,

carried at the rate of half an inch per hour from right to left by a clock.

There is a third steel spring of the same length and strength as those on the reservoir, stretched by a weight to a distance equivalent to 30 inches on the barometer scale. The object of this spring is to give the correction of temperature for those sustaining the reservoir. The register paper should always be set to the same line on which the pencil of this spring marks.

The movements of the mercury on the register can be magnified to any required extent by increasing the length of the spiral springs. In this instrument it is multiplying twice.

DESCRIPTION OF INSTRUMENT.

The tube marked *a b* is of glass; the upper part is of a larger diameter than the stem, *a* being ¾ of an inch internal diameter and 10 inches long, while the stem, *b*, is ⅛ of an inch bore and 26 inches long. The total length of the tube is therefore 36 inches. The reservoir, *c*, is suspended from a brass frame, *d*, fastened to the back of the case. This frame also holds the upper ends of the steel springs, *e*, *e*, *é*. The glass reservoir, *c*, is of the same diameter and length as the upper part of the tube, *a*; on its open end is turned a flange to hold it in a brass frame, *f*, to which are fastened the lower ends of the steel springs, *e e*; it also carries an ink pencil, *g*, that touches the ruled paper on the board *h h*, which is drawn aside by the clock, *i*. The spring, *é*, is for the correction of temperature on the other springs. Heat has a slight effect on them, causing them to lengthen about $\frac{1}{16}$ of an inch from 90 degrees Fahr.; to allow for this, the third spring, *é*, is weighted with a lead weight and pencil, it marks its fluctuations on the upper line of the register sheet. In this manner this instrument gives the correction for temperature (or reduction to 32°) from the fact that it weighs the mercury instead of measuring its length, which is affected by heat.

Ink pencils of the barometer and other instruments are made by drawing narrow glass tubing to a fine point, which lightly touches the paper register, leaving a mark of red ink that has been diluted with about one quarter of its volume of glycerine. The glycerine prevents the ink from drying too rapidly. The advantage of this form of pencil over lead ones is that it requires little or no pressure to produce a mark.

To receive the atmospheric fluctuations a suitable ruled paper is fastened by means of small brass clamps, *k k*, to the board, *h h*, which is hung by rollers to the thick steel rod fastened to the sides of the case, on which the paper is carried from right to left by the clock, *i*, at the rate of ½ an inch per hour, by means of the pulley on the hour arbor of the clock. The wire that connects the register board to the clock is soft steel, number 28 wire gauge; having only one turn round the pulley it readily slips so that the board can be pushed sideways for the adjustment of time, or for the renewal of the sheet of paper."

ON AN OCCURRENCE OF GOLD IN MAINE.*

By M. E. Wadsworth.

The gold under consideration here is found on Seward's Island, a small island in the town of Sullivan, Hancock County. The gold is found in quartz veins cutting an eruptive mass of diabase. This diabase forms a dike of about forty feet in thickness, lying approximately parallel to the bedding of an indurated fine-grained argillaceous mica schist; all dipping nearly S. 30° W., 24° to 42°. The dip averages about 35°, and the strike is far from being uniform. Crossing the diabase at various angles, but generally from north to south, are segregated quartz veins. In some places the rock is a confused reticulated mass of these veins, with patches of diabase lying between them. The veins vary in width from a mere seam to even a foot in breadth. Starting where only one or a few of them are visible, they gradually increase in number, until they become quite numerous, while they will doubtless be found to fade away as they began. The diabase and schists are cut by several dikes of diabase running approximately at right angles to the strike of the schist, or parallel to the veins. The vein stone is quartz, together with some calcite, tremolite and chlorite, and carries tetradymite and gold.

So far as examination has been made, the veins in the diabase carry gold, and the decomposed diabase immediately adjacent to the quartz veins also contains that metal to a greater or less extent. The gold occurs principally in small grains in the vein in conection with the tetradymite, bits of decomposed diabase, and in the cavernous portions, but not in the compact quartz of the vein itself. The tetradymite is in irregular grains and masses, showing a brilliant metallic lustre, and a well-marked basal cleavage. The locality is worked for it gold, and was visited by the writer in December last

Cambridge, Mass.

Science Observer Special Circular No. 16

The following simple electrical experiment is described in *L'Electricien*. A small box of pasteboard is closed with a lid of fine glass, on the upper surface of which collodion is applied several times (but not so much as to render the lid opaque). In the box are placed insect forms, made of sponge or cotton. On rubbing the collodion surface with dry fingers, in dry weather, the insects move about in a curious manner.

PHOTO-MICROGRAPHY.

By Dr. Carl Seiler.

All workers in microscopy, doubtless, appreciate the necessity of correctly recording, not only in writing, but also by means of pictures or drawings, many of the appearances seen in the field of the microscope. We can do this by drawing an outline of the objects observed, by the aid of the *camera lucida;* but not only does this require some practice, but also a considerable amount of time, and even then the resulting picture will not be a correct representation of the field of the microscope, because it will always be tinged more or less by the imagination of the draughtsman, and will be more or less diagramatical in consequence.

With photography, on the other hand, an exact reproduction of the image thrown upon the screen can be obtained, and in much less time than it takes to make even a comparatively simple drawing with the *camera lucida*. It is the object of this chapter to give an idea of the means employed to obtain a photographic picture of a microscopic object—means which are in the hands of every microscopist, and which do not require a great outlay of money.

A room with a southern exposure, which can be darkened; a mirror, movable in all directions, outside of the window; an achromatic combination of lenses of from eight to ten inches focal length; a microscope which can be tilted so as to be horizontal, and a stand to hold the screen and sensitive plate, are all the apparatus absolutely necessary besides the chemicals used in ordinary photography.

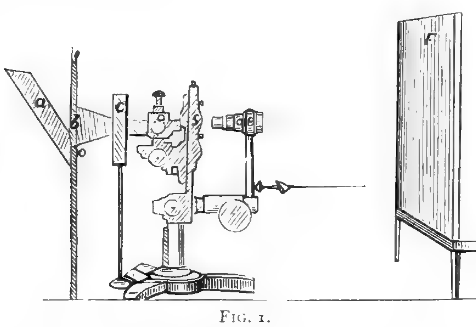

Fig. 1.

These different pieces are disposed of as follows (Fig. 1): The mirror (*a*), which should be eight or ten inches long by about four inches wide, is attached to a board which fist into an opening in the dark shutter of the southern window, and is to be moved by rods from the inside. Instead of this mirror, or in conjunction with it a heliostat is of great advantage to throw the light of the sun constantly in one direction, for, if once adjusted, it need not be disturbed, and thus a great deal of time is saved. Until recently such an instrument was too costly for the use of students, but of late Mr. Kuebel, of Washington, D. C., has put a heliostat in the market which works very satisfactorily and which is sufficiently low in price to be within the reach of many who desire to work in photo-micrography. The board in the shutter has in its centre a circular opening containing an achromatic combination of lenses (*b*), such as the back combination of a one-fourth portrait photographic lens.

The microscope is secured on the window-sill in a horizontal position, so that the axis of the tube is in a line with the axis of the achromatic combination, and at such a distance from it that the burning focus is about half an inch from the back combination of the sub-stage condenser (*d*). The eye piece is then removed from the microscope, and the tube lined with black velvet, to prevent internal reflection, as far as possible, and the whole apparatus is covered with dark cloth, to prevent stray rays of light entering the darkened room. This done, the sun's rays are reflected from the mirror outside the window, through the achromatic combination, which acts as a concentrator and throws a powerful light through the condenser, through the object on the stage (*s*), and thus a brightly illuminated image is formed by the objective (*o*) on the screen, which latter, when the negative is to be taken, is replaced by the sensitive plate.

This image, when thus formed, must be focused with the greatest care and accuracy, in order to obtain a sharp negative; and as the screen must be at some distance from the microscope in order to obtain the necessary magnification of the object, it is necessary to have some contrivance for turning the fine adjustment at a distance. For this purpose it will be found that a small pulley, placed alongside of the microscope, having an endless band running over it and the milled head of the fine adjustment, answers the purpose very well, when the axis of the pulley is connected by means of a universal joint to a fishing-rod, which by its sections can be made longer or shorter, thus bringing its end close to the screen.

The tube of the microscope, even when all internal reflection has been obliterated, still remains a drawback, inasmuch as it reduces the size of the image, or rather the disk of light, the more, the longer it is. There are, however, some stands made in which the tube can be entirely removed, such as the old Ross stand, and they are therefore very desirable for photo-micrographic purposes.

Any good objective of wide angular aperture and good definition can be employed for photography, provided monochromatic light is used in making the negative. When such is the case the visual and chemical foci fall in the same plane and a special correction of the objective for photography becomes unnecessary.

Such a light is obtained by passing the rays of the sun through a cell containing a strong solution of ammonio-sulphate of copper (*c*) before they enter the sub-stage condenser. I have found some difficulty in making the cell containing this solution, as the copper salt will dissolve almost any cement, and if exposed to the action of the air, very rapidly becomes decomposed, and the solution is thereby rendered useless for the purpose. I have used with satisfaction a cell made of a brass ring, lined on its inner side with lead or tin, having a thread cut on its outside, to which flanged rings are secured. Upon the edges of the inner ring a ring of rubber packing is applied, and upon it a disk of plate glass is laid, which is tightly pressed upon the rubber by the flanged ring. Thus a cell is obtained very similar to the round, flat spirit levels, and which will hold the ammonia sulphate of copper solution for months without change. In filling the cell care should be taken to leave room for a small air bubble, for if the cell is completely filled the heat of the sun's rays will expand the solution sufficiently to cause leakage.

This solution, besides giving monochromatic light, at the same time filters out almost all the heat rays from the light, so much so that an immersion lens may be used for any length of time without the drop of water evaporating.

At the present time, when dry plate photography has been developed to such an extent that it has superseded, in a great measure, the wet process, it has been thought that it would be the most simple, economical and satisfactory for photo-micrography; but after repeated trials by myself, as well as many others working in the same direction, it has been found that it is not only more expensive, but also takes more time, in the long run. The reason of this is that it is impossible to judge, with any degree of certainty, as to the actinic power of the light forming the image on the screen by merely looking at it, and that a trial plate only will give an idea of the length of exposure necessary for a given day, time of day

objective, and subject, to be photographed. It is true we can expose a dry plate for trial, but then we must develop it immediately, and the time of developing a dry plate is about three times that of developing a wet one, and a dry plate is also about three times as costly as a wet one. Therefore the old wet collodion process is the best.

The collodion to be used should be an old one, and contain some free iodine. I have found that a mixture of "Anthony's red labeled" and "McCollin's delicate half-tone" collodions—both commercial articles—some five or six months old, gives very satisfactory results. The nitrate bath should contain forty grains of nitrate of silver to the ounce of water, and should be slightly acidulated with nitric acid. The developer should be a weak one: twelve to fifteen grains of the double salt ammonio-sulphate of iron to the ounce of water, containing a few drops of a solution of gelatin and acetic acid as a restrainer.

After the negative has been fixed in the usual way, with hyposulphite of soda or cyanide of potassium, it is almost always necessary to intensify it, which is easily done by flowing the plate while wet with a watery solution of iodine until the film becomes white; then it is to be washed under the tap and flowed with a solution of sulphide of ammonium, which imparts to the negative a dark brown color, and thus strengthens its printing quality.

The object to be photographed should be as thin as possible, because the lens will depict only one plane of it, and it should present as much contrast and differentiation of its elements as possible; this is especially the case in animal tissues, and when high powers are used, the focus should be taken with the greatest care *for one particular point to be brought out;* a general focus not particularly sharp in any one point, will not give a satisfactory negative.

The screen upon which the image is focused should be of plate glass, having an extremely fine ground surface on one side—the side next to the object. Such a surface can easily be prepared by flowing the glass plate with a good negative varnish, and when this is set but not yet dry, lightly breathing on it, when an extremely fine and even frosting of the surface will show itself, sufficient to arrest and reflect the rays of light forming the image.

In photo-micrography, as well as in ordinary microscopy, proper illumination of the object is of the greatest importance, and frequently a poor objective will show a better definition in the hands of a skilled manipulator than the best objective can when the light is not properly managed. In this one point lies the difficulty of photo-micrography, and it is the stumbling block over which so many fall who undertake to photograph microscopic objects.

As a general rule the best light is obtained when the back lens of the sub-stage condenser is about half an inch beyond the burning focus of the larger condenser in the shutter, that is about eight and a half inches from this condenser, and when the light is *absolutely central.* But this distance cannot be strictly adhered to, inasmuch as different objectives require different illumination. In practice, I find that in order to obtain the proper distance of the condenser for a particular objective, it is best to put a blood-slide, upon which the corpuscles are in one layer only, on the stage, and project the image on the screen, moving the condenser backward and forward until, when sharply focused, no concentric rings are seen in the disks. The object to be photographed can then be substituted for the blood-slide, and the light will be found to be all that is desired. (*Compendium of Microscopical Technology.*)

PROFESSOR HELMHOLTZ will issue a collection of his scattered scientific memoirs in the autumn.

PLANTÉ AND FAURE BATTERIES.

The annexed illustrations of the secondary batteries, which are exciting so much interest at the present time will, with the accompanying description, enable the reader to understand their construction. At the recent soirée given by the Council and academical staff of King's College, several forms of electric-lighting apparatus were used; but that which attracted most attention was a battery of forty-four accumulators of Faure's design, working twenty of Swan's lamps. The cells were charged in Paris by a Gramme machine, and were arranged in groups of four in cubical boxes, the whole being coupled up in series. The current supplied by this arrangement, shown by a galvanometer in the circuit while the lamps were alight, was about twenty-three webers, and was perfectly steady—the Faure battery yielding an almost equal current during the whole time, until the charge becomes exhausted, when it breaks down suddenly, without any noticeable warning. Mr. Spottiswoode also uses the Faure battery to work Swan

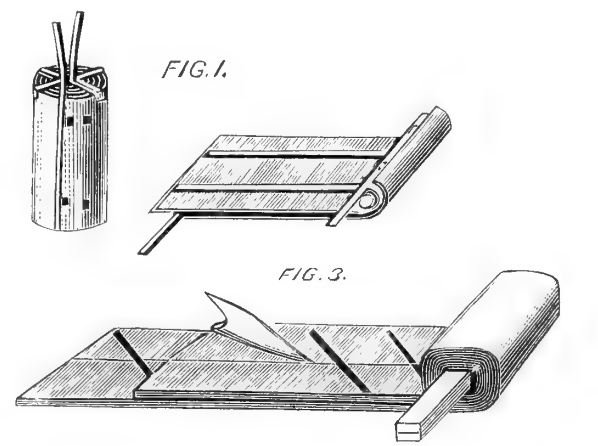

FIG. 1.

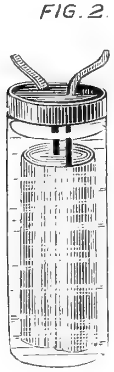
and Maxim lamps in his private house. Figs. 1 and 2 represent the Planté cell. The preparation is as follows: Two sheets of lead (it may be as thin as stout lead-foil) are laid the one on the other, separated by two strips of india-rubber, the whole being rolled up as shown in Fig. 1. The roll having been completed, the cylinder used in its formation is withdrawn, and it is consolidated by a wrapper of gutta-percha, and inserted in a glass jar filled with water and 1-10th part acid. An electric current is then made to pass through the cell; oxygen is given off, and produces a thick cushion of peroxide of lead on one sheet; hydrogen is given off at the other sheet. If the current with which the cell has been charged be cut off, and the two sheets are connected, a current will be produced, owing to the presence of the oxygen, which leaves the sheet where it has accumulated and attacks and oxidises the other sheet. This secondary current, which is very small at first, gains strength each time the operation is repeated; in course of time the surfaces of the sheets are changed, the one being covered with a cushion of peroxide of lead, the other with lead reduced to a spongy mass. The cell is then complete, and in a state of electrical accumulation. That was Planté's first successful battery. Subsequently he tried the plan of separating the two sheets of lead by canvas, the cell taking the form of Fig. 2. He then found that it was necessary to leave a small space between the sheets to provide for the escape of the gases which were produced at the end of the charge; subsequently india-rubber bands were employed in preference to canvas. M. Planté also tried carbonate of lead, minium, &c., but without improving upon the results already obtained. The



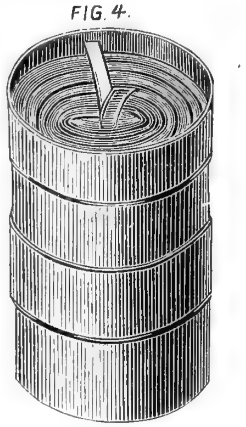


Fig. 2.

Faure battery is similar to the above:—Two sheets of lead are taken, about 7½in. wide; one about 23in. long and about 1-25th of an inch thick, the other 15in. long and 1-48 in. thick. Each of these is furnished with a strong strip of lead at one of its ends. Each sheet has a layer of red lead spread on its surface, the lead being made into a paste with water, the larger sheet having about 800 grammes on its surface, and the smaller 700 grammes. On each surface a sheet of parchment is laid, and the whole is introduced into a sheathing of thick felt. The sheets are laid one above the other; at the same time several bands of india-rubber are placed in an oblique fashion, as shown in Fig. 3. The roll is placed in a leaden jar strengthened by copper bands, and covered in the interior with red lead and felt. The cell then presents the appearance shown in Fig. 4. One of the pieces of lead which jut out is curved and soldered to the outer jar, acidulated water is put in, and the battery is ready for work.

We give the above figures as a guide, but there is no special reason for adhering to them, and it may be doubted whether either the parchment or felt is an absolute necessity; for good batteries have been constructed by painting stout lead-foil with red lead made into paste with water slightly acidified with oil of vitriol, and wrapping the plates in flannel or canvas which has been previously coated with the red lead paint. The painted surfaces are of course put together. Thin lead is used to keep the weight down as much as possible and to reduce the cost.

THE LESSON OF THE COMET; DOES IT SHOW A NEW FORCE?

By Samuel J. Wallace, Washington. D. C.

There is one important consideration in relation to a comet and its tail which does not seem to have been properly noticed. A comet is generally supposed to be a mass, cloud or assembly of masses, particles and possibly gases, which travel together through the heavens, but do not actually form a single cohering body.

Now the remarkable point is this. When this assembly of matter of various sizes and conditions approaches the sun at a great velocity it seems to be acted upon by two forces in opposite directions at the same time, the one driving it forward toward the sun and the other driving it out away from the sun, and apart laterally.

And these two forces seem to act at different rates on different parts of the matter, so as to drive some parts forward, forming the head of the comet; to drive other parts forward with a less force, and spread them apart, forming the brighter part of the tail; while they act to actually drive other parts away into space, as the brush of the tail.

This is an action like that familiar to us in concentrating ores and in separating grain from the chaff. When ores are powdered fine and sifted down a shaft, up which a strong current of air is blown, the heaviest and richest particles fall through the opposing current to the bottom while the lighter and worthless particles are blown up and away. In this manner the rich ore is separated from the poor, and in a like way grain is separated from the chaff. This occurs because there are two forces acting against each other—the wind and gravitation—which act at different rates on the different particles and separate them.

The comet looks as if it was undergoing this very operation of concentration, or separation of the heavy parts from the light parts, under the action of gravity driving inward to the sun or some other opposing force driving outward and apart.

What makes this so remarkable is that the substance of the planets seems to have been separated in this very same manner. If we take the recognized specific gravities of the several planets and set them down in the order of their occurrence from Neptune, the furthest, inward to Mercury, the nearest the sun, beginning with one as the unit, we will find a gradual increase in weight per cubic foot from one for Neptune up to about nine for Mercury. If we set down the velocity of the planets in the same manner we will find the singular fact of an increase in the same way, from one for Neptune to about nine for Mercury. So that the velocity and the weight per foot increase together in a way that looks very suspicious of some connection between them.

What makes it look so singular is that the distance from the sun decreases almost in the very ratio of these two proportions multiplied into each other; or in the very way which it would do if the planets were formed of matter which had been concentrated by the heavy parts being driven toward the sun by gravity and the lighter parts being driven away by some other force—such as that which seems to be driving off the tail of the comet—so that each planet was formed of matter separated by its specific gravity in a general way, according to its distance from the sun and its velocity. Another thing which confirms this singularity is that the average weight of the meteoric masses which fall on to the earth, made up mostly of iron and some lighter rock, is very nearly that of the earth itself, taken as a whole, or about five and a half on the same scale, due to its position and velocity.

All this leads us to suppose that there is a force driving outward from the sun, as gravity drives toward it, but acting in proportion to the size of particles as gravity acts in proportion to their weight, which separates matter so that its average distance from the sun and its velocity shall conform to its average weight.

If this is true, as it seems, it throws light upon an obscure point, which may be considered as one of the most sublime within the reach of science; the nature of that wonderful mystery of gravitation itself, which holds and moves all the innumerable hosts of heaven in their everlasting circuits.

The course of modern thought is to render inconceivable the action of gravity as of an immaterial agent.

The theory of Lesage that it is the result of converging corpuscles of wave beats from all sides tending to drive bodies together is both sublime and in accordance with the habits of modern thought. But it utterly fails in one half of the problem. It does not explain what becomes of the dynamic energy of this force after it strikes a mass of matter, by which disappearance it is supposed to produce a shadow outward on all sides, to which the result of gravitation of masses to each other is attributed.

But if it should appear that there is a force thus going outward from the sun and other matter, as comets and planets in this way seem to indicate, then we are compelled to account for it also, which is the very force that Lesage's theory failed to show, and which his force requires for its complement.

This would require only to suppose the form of the force changed, in quantity proportionate to the quantity of matter, by passing through it, so as to act against particles in proportion to size, and to some other features, of which velocity and kind are elements, instead of in proportion to weight only, as before.

We cannot blame Lesage for overlooking the inconsistency of the utter disappearance of so much dynamic energy as his theory requires, because in his day the idea of the conservation of energy had not grown up; and it was a great, a sublime, grasp of thought, to conceive of a relation of mechanical action which was parallel in its nature to that utter, that bewildering, mystery of gravitation, which seemed as if it could only be due to the fiat or action of Creative Energy itself, acting forever and everywhere *de novo;* yet, at the same time, always with an absolutely steady and measured force and relation to quantity of matter, to distance in space, and to length of time, which indicated kinship in character to the other proximate and not ultimate forces of nature.*

But we cannot so easily overlook the failure of those who have later considered this theory to notice this great dynamic hiatus, and to follow it up to some conclusion.

These facts, stated, of the comets, of the planets, and of meteorites, indicate very clearly that there is a peculiar propulsive force acting outward from the sun.

And this force is of the general nature required to fill this hiatus.

Can we further determine anything of its nature?

We have already seen that it seems to act upon some kinds of matter in preference to other kinds; and that there seems to be different varieties of this selective difference caused by and in some proportion to velocity.

This last is a curious feature. How can velocity act to increase the action of a force on one kind of matter more than on another? Can any of the facts of ordinary knowledge give us any indications?

If we subject different substances to dry friction, electro-static disturbance is produced; the different kinds of substance will be acted upon differently, and perhaps the difference may be increased by the increase of the friction.

Now the condition shown in the comet is very much like that of an electrified body. But we must not jump to conclusions without examining the attendant conditions which would govern the facts.

We can suppose that the velocity of a body or assemblage of bodies through the ether, required to transmit light, or through a space containing other stray particles of matter, might produce a friction that would set up in it an electrified state; and which would be increased by increase of the velocity.

We can suppose that the light and electrical bodies, and the heavy metals would be electrified to different degrees; or at least that there would be different electric states produced,

And we can suppose that THE FORCES ACTING OUTWARD FROM THE SUN ACT ON PARTICLES IN SOME PROPORTION TO THEIR ELECTRIFIED STATES; and that on striking an assembly of particles it is reflected from their members, something like light is, in a great number of directions, which tends to drive them outward, and, in a less degree, to disperse them apart, as shown by the tail of the comet.

These suppositions show that the requirements which observation seems to call for have parallellisms within our knowledge, and indicate the course of new enquiries.

As a result of these and other considerations we may be led to infer that the growth of the solar system has been affected by such causes. That the heavy metals have, in coming into it, taken positions at last, very much dependant upon their weight and kind, in which respect the Earth, Venus and Mars, in their great interior masses, may represent the region of iron, while Mercury may represent the region of still heavier metals, and the outer planets the great mass of lighter substances; the average or mean distance of a body from the sun being governed inversely as the square of its mean velocity.

Thus a comet and its tail may become the missing link in astronomy and in science.

* We may believe that under the whole face and system of Nature there is an ultimate creative force which acts immediately each instant, to keep alive, to measure, and to guide, all of the actions and reactions taking place; but that is a conclusion and not a "knowledge." If it is true, yet it chances that the character of the action is such that we recognize all actions and reactions as taking place in chains having equality of links and certain peculiarities we call laws; which constitute proximate causes.

CORRESPONDENCE.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. No notice is taken of anonymous communications.*]

To the Editor of "SCIENCE":—

I have been interested in reading Mr. Rock's account of his observation of the great Comet on the 6th of July. On that evening the comet was hidden at this Observatory by clouds until about ten o'clock, local time, when Mr. Wilson went into the dome to observe its position with the eleven-inch refractor. He soon returned, however, and called my attention to the remarkable appearance of the nucleus. I went to the dome and from that time until three o'clock we alternately examined the Comet, making sketches and measures. The fan had its usual appearance, but when first observed a bright red jet projected from the nucleus into the dark region on the side of the nucleus opposite the fan. This jet was totally different in appearance from those usually seen. It was at first straight and in brightness rivalled the nucleus itself; in fact at the first glance it seemed to form one with the nucleus. On a closer inspection, however, I saw that it had a transparent appearance but still intensely bright and red. The next glance showed that there was a dark line separating it from the nucleus. Mr. Wilson had already called my attention to this dark line before I went to the dome. During the first few minutes a decided change took place. The jet seemed to separate and form a nucleus of its own, so that for a time the comet appeared double; gradually, however, the detached portion grew fainter, until when last seen, at about three in the morning, although plainly visible, it was no brighter than the fan-shaped appendage on the opposite side of the nucleus. I noticed the band of light which Mr. Rock speaks of as connecting the "node" with the nucleus, and mentioned it to Mr. Wilson at the time, but this afterwards disappeared, leaving a separate mass floating like a cloud in the dark region opposite the fan.

There can be no question that a great outburst took place in the comet on that evening, nor that a portion of the nucleus became detached. The phenomenon was watched very carefully for five hours and I think I could hardly be mistaken in what I saw. ORMOND STONE.

CINCINNATI OBSERVATORY, *July* 19, 1881.

To the Editor of "SCIENCE."

In Mr. Rachel's reply, in No. 52, to my letter in No. 47 of "SCIENCE," he appears to entertain a different conception of the law of gravitation from that which I supposed to be usually entertained by astronomers. As there may be many others who share his view, it seems advisable to give a more detailed exposition of what I think was Sir Isaac Newton's own conception, and is that of many more recent astronomers.

Newton's law of gravitation is that "every particle of matter in the universe attracts every other particle with

a force that is directly proportioned to the mass of the attracting particle and inversely to the square of the distance between them." The first question arising is, what are we to understand by "particle" in this theory? Certainly not a mass of utterly indefinite size. Undoubtedly Sir Isaac meant a mass of unit size, since the very terms of the proposition require this. For if every particle attracts every other particle with a certain vigor, then it must necessarily attract two particles with twice the vigor with which it attracts one. Or if a particle of unit mass attracts another with unit vigor, then it must attract two others, or one other whose mass is double the unit vigor. And as each of these two others attracts it with the unit vigor, then their sum, or their double mass, must attract it with double the unit vigor. It is simply the principle, still older than Newton in its expression, that "action and reaction are always equal and opposite."

But if it be granted that such will be the reaction between a unit and a double unit mass, the whole question is settled. For if the second mass may be doubled it may be quadrupled, or may be increased a million fold, without any difference in the principle. And likewise the first mass may be increased without affecting the principle. A mass of one unit attracts a mass of ten units with an energy equal to ten units, since it attracts each of the ten with unit energy. And each unit of the ten reacts on the one with unit energy, so that their combined attraction equals ten units. Again, if the first mass contain two units, each of these separately acts upon each of the ten with unit energy. Thus as each unit of the two exerts ten units of energy, the two together exert twenty units. In other words, the energy which the first mass exerts upon the second is proportioned to the product of the number of mass units in the first into the number of mass units in the second; and the action of the second upon the first also is in proportion to the product of their units.

This is the true principle of the attraction of gravitation. We may take the unit mass of any size we wish. In the action between the earth and the moon, for instance, we may take the mass of the moon as the unit, that of the earth being about 75 units. The moon will attract each unit of the earth with unit energy, and the whole earth with an energy of 75 force units. But each unit of the earth will react upon the moon with unit energy, and the whole earth will exert on the moon an energy of 75 force units. Thus the moon attracts the earth with precisely the same vigor as the earth attracts the moon. Of course the resulting motions are not the same, but the resulting momentums are precisely equal. As the earth is 75 times the weight of the moon a motion of one foot per second in the earth would give it a momentum equal to that given the moon by a motion of 75 feet per second. It is well known that the moon does not revolve around the centre of gravity of the earth, but that these two bodies revolve around their common centre of gravity. But this common centre is within the mass of the earth, and may be found by dividing the distance between the centres of the earth and moon by the ratio of their weights. If we take this distance as 240,000 miles, and divide by 75—the weight of the earth as compared with the moon—the common centre of gravity will appear to be 3200 miles from the earth's centre.

Or we might consider this case from the principle of inertia. The earth having 75 times the mass of the moon has 75 times the inertia, or resistance to exterior forces. Thus its movement in response to lunar attraction is only 1-75th that of the moon in response to terrestrial attraction. But its weight being 75 times greater, its momentum in response to lunar attraction must be precisely equal to the moon's momentum in response to the earth's attraction; or, in other words, their vigor of action upon each other must be precisely equal. This movement of the earth under the action of the moon does not affect the line of its orbital movement, since it is less than the length of the earth's radius. Its movement is like that of a bead with a large aperture, which advances along a string moving from side to side, but not leaving the string. But as the earth moves about 46 millions of miles in its orbit while completing one of these gyrations, the effect is excessively minute. That of the moon, in fact, which swings 240,000 miles to each side of the orbit each fortnight, is very slight when compared with the length of the orbit.

But if, the earth being 75 times the mass of the moon, it also attracted the moon 75 times more vigorously than the moon attracts the earth, this common centre of gravity would be found by dividing 240,000 by 75^2 and would be but 36 miles from the earth's centre. As to which of these results is the more correct the books will show.

I am, therefore, obliged to repeat the idea advanced in my former article. An atom falling towards the earth attracts it with as much energy as the earth attracts the atom, and they move toward each other with equal momentums. But the great weight of the earth reduces its rate of motion towards the atom to a speed inconceivably small, while the small weight of the atom gives it an excessively rapid speed towards the earth. It would be strange if, at this late date in the history of the theory of gravitation, I had been the first to advance this idea as Mr. Rachel seems to suppose. Perhaps my mode of presenting it may be original, but I can readily quote other expressions of the same idea. Thus Dr. Ball, Royal Astronomer of Ireland, speaks as follows, in his article on Gravitation in the new edition of the Encyclopedia Britannica: "It has been found that the intensity of the attraction of gravitation between two masses is directly proportional to the product of those masses." This is precisely the result I have reached in the above argument. Again he says: "Let m, and m' be the masses of two bodies, and let r be their distance. The force with which m attracts m' is equal in magnitude though opposite in direction to the force with which m' attracts m. The reader may perhaps feel some difficulty at first in admitting the truth of this statement. We speak so often of the effects which the attraction of the sun produces on the planets that it may seem strange to hear that each planet reacts upon the sun with a force precisely equal and opposite to the force with which the sun acts upon the planets." He illustrates as follows: "Suppose the earth and the sun to be at rest in space, and prevented from approaching each other under the influence of gravity by a rigid rod extending from one to the other. If now the sun pressed toward the earth more vigorously than the earth toward the sun the greater pressure of the sun must overcome the lesser pressure of the earth, and the whole arrangement would be driven through space in the direction in which the rod points outward from the sun. For there would be a motion producing vigor in the sun unopposed by a sufficient resistance in the earth. And yet, in the event of such a movement, we would have the kinetic energy of their motion created out of nothing, which is now well known to be impossible." Such is Dr. Ball's argument briefly stated. It leads to the same result as mine, and I therefore claim to be in full accord with the Newtonian law of gravitation.

In regard to the other points of Mr. Rachel's letter there is nothing on which I desire to dwell. As to the use of the phrase "Latent Heat," the scientific world will be very ready to give it up if a term can be suggested more significant of the character of the energy indicated. But there would be nothing gained by simply substituting one unmeaning name for another. Mr. Rachel himself uses the phrase "Radiant Heat," yet he must be aware that the mode of motion so called is very different from ordinary Heat Motion. Radiant Heat is readily convertible into Static Heat; but so is

Electricity; and we have the same warrant to consider Electricity as some modification of Heat. In fact the term "Radiance" would be a more distinctive appellation than "Radiant Heat."

As to trust in authorities, of course we must trust in them as long as their explanations seem most in accordance with facts, but no longer. Well-established facts are the only trustworthy data of Science. No theory can be sustained against the pressure of unconformable facts. In short, every theory is in danger while a single fact remains unexplained. For the facts of nature are so closely linked that each in some way bears upon all, and all upon each. And yet it is by no means advisable to stop theorizing, for correct theories are themselves facts of science—facts concerning forces and relations as deduced from facts concerning things. And every partially correct theory is a footstool through which higher levels of conception may be reached; while every theory proved incorrect is a warning board, advising all future scientists not to waste time in following a path that leads nowhere.

CHARLES MORRIS.

TEXT-BOOK OF EXPERIMENTAL ORGANIC CHEMISTRY for Students, by H. CHAPMAN JONES. D. Van Nostrand. New York, 1881.

Although termed a text-book, the author admits that this little volume will be found of greater use as a companion for the student in the laboratory, who wishes to study organic chemistry both practically and theoretically.

We recommend this volume to those who have a limited time at their command for study, and are not overburdened with cash, the author having wisely restricted the number of experiments, and suggested only such as are available in a laboratory of the humblest pretensions, and the use of expensive chemicals is altogether avoided. The author has shown considerable judgment in arranging this work, the plan of which is excellent, because while the subject has been reduced to its simplest form, the instructor will find all that is necessary for teaching the elementary stages of practical organic chemistry, and it will serve as a reliable guide to the average student who relies on his own resources for instruction.

CONTRIBUTIONS TO METEOROLOGY: being results derived from an Examination of the Observations of the United States Signal Service, and from other sources. By ELIAS LOOMIS, Professor of Natural Philosophy in Yale College.

A pamphlet reprinted from the *American Journal of Science*, being the subject matter of a paper read before the National Academy of Sciences. Washington, April 19, 1881.

ON THE GROUP "*b*" ON THE SOLAR SPECTRUM. By WILLIAM C. WINLOCK. From the proceedings of the American Academy of Arts and Sciences. Presented by Professor Wolcott Gibbs. June 9, 1880.

The most complete charts of the solar spectrum now available are Kirchhoff's, which were published in 1861, and Angström's, published in 1869. Kirchhoff employed a battery of four flint-glass prisms, with a collimator and observing telescope each of about 4 centim. aperture and 49. centim focal length; while Angström used telescopes of about 4.6 centim. aperture, and 36.3 centim. focal length, and a diffraction grating made by Nobert, containing about 133 lines to the millimetre.

Such great advances have been made very recently in the construction of optical instruments, and more especially in the ruling of diffraction gratings, that it would now be possible to enlarge Angström's great chart almost as much as he improved upon Fraunhofer's first maps. But it would be an almost endless undertaking for a single observer to attempt a map of the whole spectrum, from the ultra-violet to the invisible red, brought to light by our most powerful instruments, and accordingly most physicists who have paid especial attention to solar spectroscopy have devoted themselves to a careful study of detached portions which appear of unusual interest. As a contribution to this work, the following observations upon the group of dark lines "*b*," of the solar spectrum, were undertaken by Mr. Winlock, at the suggestion of Dr. Gibbs, and carried on under his immediate supervision.

A PRACTICAL TREATISE ON THE MANUFACTURE OF STARCH, STARCH-SUGAR AND DEXTRINE, based on the German of Ladislaus Von Wagner and other authorities, by JULIUS FRANKEL. Edited by Robert Hutter. Illustrated by 58 engravings, covering every branch of the subject. Henry Carey Baird & Co., 810 Walnut street, Philadelphia, 1881. Price, $3.50.

The increased manufacture of Glucose and the prospect of this substance becoming a staple article of produce in the United States, makes this volume a welcome addition to the excellent series of technical works published by this house.

Those about to engage in the manufacture of Glucose will find this treatise an indispensable guide, and, as we understand, it is the only work in the English language describing in detail the processes and machinery made use of in this important class of industry.

It is stated in the preface that this subject has been heretofore surrounded by more or less mystery than any other manufacture of recent years, and that access to factories has been barred to all but workmen, and that inventors and manufacturers of the necessary machinery have refused to furnish drawings of the machines. It is therefore evident that the present work, which has been prepared with care, intelligence and zeal by one who is a master of the subject, must be a valuable acquisition to those interested in this industry.

Mr. Frankel introduces the subject by describing the Chemistry of Starch, its technology and methods of manufacture. The Chemistry of Starch-sugar is then taken up and its manufacture in all its branches explained in detail. The author concludes with an exhaustive description of Dextrine and its manufacture.

It was Professor Kirchhoff, of St. Petersburg, Russia, who made the important discovery in 1811, that starch boiled in diluted sulphuric acid is transformed into sugar, but the origin of glucose manufacture dates from the time of Napoleon I., when the Engl sh were blockading the Continent. At the time it caused a great and general sensation, as it was then thought that grape sugar was identical with cane sugar, and hence could in every respect be substituted for that product. This new branch of industry was, therefore, pursued with energy, and immense quantities of starch-sugar were manufactured, but subsequently, when it was proved that this material was by no means identical with cane sugar, being less soluble, of less sweetness, and not at all suitable to serve as a substitute for the former, then for a number of years the demand ceased. Of late years a revival has taken place in this industry, and in 1876 Germany alone produced in her 47 glucose, starch-sugar and syrup factories 100 million pounds, and as we stated in a recent article 500 tons a day of glucose are now produced in the United States.

It is singular to observe that such substances as Starch, Grape-sugar and Cane-sugar, which have such opposite properties in some respects, are almost chemically alike. If starch absorbs two molecules of water, it becomes transformed into glucose (grape or starch sugar), while cane sugar contains one molecule more than starch and one molecule less than the starch sugar. The chemical

composition of these substances may be compared by arranging their formulæ in the following manner:

$$C_{12}\ H_{20}\ O_{10},\ \text{or}\ C_{12}\ H_{10}\ O_{10} = \text{Starch.}$$
$$C_{12}\ H_{22}\ O_{11},\ \text{or}\ C_{12}\ H_{11}\ O_{11} = \text{Cane Sugar.}$$
$$C_{12}\ H_{24}\ O_{12},\ \text{or}\ C_{12}\ H_{12}\ O_{12} = \text{Grape Sugar.}$$

Grape-sugar is largely diffused throughout the animal kingdom, and is found in most of the sweet tasting fruits. It is contained in the honey of the bee, and is separated in large quantities in the urine of those unfortunates who suffer from that disease of the kidneys called *diabetes mellitus*. Grape-sugar is not only found in nature but can be produced chemically. Thus it is formed as a result of the action of diluted acids, diastaste, gluten, saliva, etc. on starch, and for this reason starch is used for its production on a large scale.

The fullest directions are given in this work for the manufacture of glucose from starch, and we congratulate the publishers on producing a book at a moment so *apropos*, and we regret we cannot devote more space to the subject; we advise, however, all interested in this new and rising industry to obtain a copy of the work, for it apparently presents all the facts bearing on the manufacture of glucose, in a very convenient form.

REPRODUCING DRAWINGS, DESIGNS, &c.

The following method of reproducing drawings, &c., in any desired color, has been patented by M. M. Tilhet, of 18 Rue de la Paix, Paris. The paper upon which the design is to be reproduced in order to prepare a negative copy is first passed through a bath composed of the following materials in about the proportions given: White soap, 30 parts by weight; alum, 30 parts; Flanders glue, 40 parts; the white of eggs or albumen beaten up, 10 parts; glacial acetic acid, 2 parts; alcohol at 60 degrees, 10 parts; water, 500 parts. The paper, after having been removed from this bath, is passed through a second bath composed as follows: Burnt umber, ground in alcohol, 50 parts by weight; black pigment, 20 parts; Flanders glue, 10 parts; water, 500 parts; bichromate of potash, 10 parts. The paper having been thus treated must be kept when dry in a dark place. In order to prepare positive paper for the prints, a bath is used similar to the last, but without the umber, for which black pigment is substituted. Or, if it is desired to obtain colored proofs instead of black ones, the black pigment is replaced by a pigment of red, blue, or any other desired color. To prepare the copies, the design or drawing is placed in an ordinary photographic printing frame, the back of the design being next to the glass, and a sheet of negative paper prepared in the way first described is placed in contact with it. The frame is then exposed to light, two minutes exposure being sufficient in good weather. The sensitive paper is then removed from the frame in a dark place and is placed in water, when the design becomes visible in white, and the paper is then allowed to dry. In order to obtain positive pictures from the negative thus prepared, the latter is placed in the printing-frame with a sheet of the positive paper prepared in the manner above described in contact with it, and after exposure to light for a sufficient time, that is to say, about two minutes, the positive paper is removed in a dark place, and is plunged into water, which removes the part of the pigment which has not been affected by the light, without its being necessary to touch it. Any number of copies of the design or drawing may be produced by the novel method described upon any kind of paper, and in any color or colors. The proportions of the different materials used to prepare the baths as above described may be varied to suit varying circumstances, such as the weather and the character of the design or of the paper.

METEOROLOGICAL REPORT FOR NEW YORK CITY FOR THE WEEK ENDING JULY 23, 1881.

SATURDAY, AUGUST 6, 1881.

The crime of Guiteau has directed public attention to the subject of mental diseases; we will therefore endeavor to explain the teachings of some of the most prominent of modern alienists who have recorded the results of their investigations, and classified the various phases of this, the greatest curse of humanity.

The first point of interest to be discovered is, can any line be drawn between partial and absolute insanity; if one faculty of the mind is affected do all succumb?

On this point, as on most others bearing on this subject, there is much difference of opinion; but the most advanced alienists appear to be now satisfied that a partial form of insanity exists, which is termed monomania. The German and French alienists have long since recognized this distinction and invented terms to express it, but it appears to be due to Dr. Edward C. Spitzka to have introduced this term with its proper modifications into English psychological literature.

The delusions of the monomaniac are what would be day-dreams in other people, "but which have become fixed realities for the former, owing, it is said, to a faulty cerebral association system, which permits collateral circumstances to act as supports for the patient's erroneous conception."

The general intellectual status of monomaniacs, though rarely of a very high order, is moderately fair, and generally the mental powers are sufficient to keep the delusion under check for the practical purposes of life, and although many are what is termed crotchety, irritable and depressed, yet the sole mental symptoms of the typical cases of this disease consists of the fixed delusions.

Without describing in detail the various features of monomania, let us take an imaginary case of this character, and sketch its leading characteristics. To protect us from any reproach of exaggeration or of drawing a fictitious image, we will take an extract from a paper by Dr. Edward C. Spitzka read before the New York Neurological Society, as far back as November 1880.

The monomaniac after experiences incidental to the early stages of the disease at length concludes that he is a person of some importance.

"*Some great political movement now takes place, he throws himself into it either in a fixed character that he has already constructed for himself, or with the vague idea that he is an influential personage. He seeks interviews, holds actual conversations with the big men of the day, accepts the common courtesy shown him by those in office as a tribute to his value, is rejected, however, and then judges himself to be the victim of jealousy or of rival cabals, makes intemperate and querulent complaints to higher officials, perhaps makes violent attacks upon them, and finally is incarcerated in a jail.*"

The writer of this paper had no intention of being prophetic in his utterances, but our readers cannot fail to observe the very close relation the above picture bears to any mental portrait which might be drawn of the assassin Guiteau.

It is curious that all through this train of ideas to which the monomaniac abandons himself there is seen a chain of logic and inferences; there is no gap anywhere. If the inferences of the patient were based upon correctly observed facts and associated with a proper correlation with his actual surroundings, his conclusions would be perfectly correct.

We have therefore in the monomaniac an individual with full reasoning powers, and intellectually the equal of most men. In what respect does his status differ from the sane man? The answer is, that he is possessed *with a fixed delusion* or insane project.

To follow the subject intelligently, let us now enquire what an alienist terms a delusion, and analyze its nature. This can be done profitably, for we are told that such a preliminary investigation is the most direct step for those who would be initiated into the mysteries of the insane mind.

Genuine delusions are divided into two fundamental classes; the first styled SYSTEMATIZED DELUSIONS as contrasted with the second class of UNSYSTEMATIZED DELUSIONS.

It may be here stated, that assuming Guiteau to be a monomaniac, his delusions would be of the first class.

The highest general mental development among constitutional lunatics is found among those who cherish

systematized delusions of social ambition; the delusion being often the outgrowth from a dream, or from an actual hallucination. These men usually imagine themselves the worst enemies of mankind, or are social reformers, inventors, poets, &c.; but as Spitzka remarks, it is often noticed, especially with patients of high culture, that the delusions are not so monstrous as to lead to an error in the patient's sense of identity, but limited to his self-esteem in the abstract.

Systematized delusions may also be of an expansive errotic character, when the patient constructs an ideal of the other sex, and may on some occasion discover the incorporation of his ideal, in an actual personage, usually in a more exalted position than his own. Systematized delusion may also be of an expansive religious nature, or lastly of a DEPRESSIVE CHARACTER.

We would like to give our readers a formula by which they might detect a *systematized delusion*, but although alienists are specific in their language and ample in their detail, brevity is not attempted, as perhaps not possible in treating so complicated a subject.

When, however, we see an individual without any manifest disturbance of his emotional and effective states, in full possession of the memories accumulated in the receptive sphere, and able to carry out most or all of the duties incident to his social position, yet firmly believing in the reality of that which from his education and surroundings, we should expect him to recognize as absurd, or radically wrong, the probability is that the phenomenon is due to a *systematic delusion.*

The one fundamental character which distinguishes the delusions of systematic delusional lunatics, is the correlation with their surroundings, or of their unelevative physical status. However falsely the patient's sensations and external circumstances may be interpreted, yet, after all, there is a *pseudo* logical chain running from them to the delusion which they keep to create and to sustain. This is absent in the case of patients exhibiting unsystematized delusions. Again, up to a certain stage, the *systematized delusion* is analogous to a healthy conception, this is never the case in an *unsystematized* delusion.

The factors engaged in producing the systematized delusion are two-fold. One, the predisposition we have recognized as presumably based upon anomalous condition of the brain, and the other some exciting cause which must be studied.

For instance; the general mental tone of the patient. If he be of sanguine disposition, the delusion is often the outgrowth of a day-dream, on the plan of the saying that the wish is father to the thought. If he be of a suspicious turn, delusions of persecutions are apt to arise.

Again, the physical state may influence the patient. If this be fair, delusions are apt to be expansive, and to involve social and sexual matters.

And lastly, the circumstances of the patient, as the age in which he lives, the education he receives, his social condition. All these modify the character of the delusions of this class of the insane. It is admitted that while all these factors are of the highest importance, they will never create a *systematic* delusion, unless the cerebral predisposition exists.

Of the *unsystematic delusions* we shall be brief, as they are characteristic of the acuter insanities, and are, therefore, more easily recognized. The patient exhibiting them never acts in strict accordance with his assumed character, and there is no consistency in his behavior. The unsystematized delusional lunatic will tell you that he is possessed of a million dollars, but he cannot account for his being richer today than he was yesterday.

It is pointed out that the great line of demarcation between the two classes of delusions lies in the fact, that, in the systematized delusion all the powers of logic and mental qualities that the man ever had are utilized by him in the construction and defense of his delusion, and as Spitzka points out is of great medico-legal importance, are also utilized in the carrying out of his schemes of defense or *revenge.* On the other hand, the unsystematized delusionist is deprived of his logical power, and apart from his hallucinations is unable to specify any support for his morbid ideas, and his actions betray that same lack of system which his delusions do.

We are indebted to two papers* by Dr. Edward C. Spitzka in presenting this classification of delusions of Monomaniacs, and we are somewhat surprised to find that he appears to ascribe all these classes of delusions to direct cerebral troubles, in fact he ridicules their being attributed to functional complications and diseases of other organs of the body.

The expert alienist can no doubt draw the distinction, and decide correctly on the true source of the mental disturbance, but it cannot be doubted that much error in this respect is exhibited by the inexperienced, for delusions of every kind are manifested at least temporally in many forms of disease, which in some cases may be so persistent as to appear chronic. As Dr. Spitzka himself frequently protests in his papers on the indiscrimate power which courts and physicians possess, who often consign "useful members of society to the living tomb of an asylum, and to the tender mercies of an ex-horse car conductor, or ex-night watchman or other politician," he will excuse the exception we take to the too ready desire of many persons to place in the category of "maniacs," men who are merely hypochrondriacal or depressed and vicious in disposition.

We have indicated the form of insanity, which may be ascribed to the case of Guiteau, but we have no desire to prejudge the case. The crime was barely committed before Cabinet Ministers, Physicians, Editors, and a large portion of the public, immediately jumped to the conclusion that the assassin was mad; that such a verdict was hastily given all must now admit. Whether the evidence, which will undoubtedly be produced at the trial, will justify the first impression, and release the prisoner from the responsibility of this crime, will be a matter to be watched with considerable interest.

*Insane delusions, their mechanics and their dragnostic bearing. The Journal of Nervous and Mental Disease, January, 1881. Monomaniac or "Primære Verruecktheit." Read before the Neurological Society, Nov. 5, 1880. Reported in St. Louis Clinical Record.

WE recently called attention to a report made by Professor Leeds to the Chemical Society, of New York on the adulterations of certain articles of food. The tenor of the report was to show that food products in general were unadulterated and pure, and to cast ridicule on those who asserted to the contrary. Among other specific statements Prof. Leeds stated that he had made a special examination of sugar syrups, and asserted that the result of his investigations showed, that they were free from any admixture of glucose.

Side by side with Prof. Leeds' report we gave the statement of Prof. Wiley that 500 tons of glucose was made daily in the United States, the bulk of which was used for adulterating cane sugars, and that the glucose of commerce as sold in the Western States was largely composed of syrup made from starch.

We publish in this issue a letter from Prof. Wiley in confirmation of his report, stating that the manufacture of a sugar, which is a mixture of glucose and cane sugar, is carried on in New York city or its vicinity.

AMYLOSE.

As a thousand tons of sugar made from starch will within a few months be placed on the market daily, half that amount being already the consumption of that article of commerce, it appears desirable to make use of some name by which this substance may be known and at the suggestion of Prof. Wiley, we propose "AMYLOSE" as an appropriate term.

AMYLOSE will include all varieties of syrups and sugars manufactured from starch. (Lat. *Amylum*, *Starch*).

NOTE ON PHOTOGRAPHS OF THE SPECTRUM OF THE COMET OF JUNE, 1881.

BY PROFESSOR HENRY DRAPER, M. D.

The appearance of a large comet has afforded an opportunity of adding to our knowledge of these bodies by applying to it a new means of research. Owing to the recent progress in photography, it was to be hoped that photographs of the comet and even of its spectrum might be obtained and peculiarities invisible to the eye detected. For such experiments my observatory was prepared, because for many years its resources had been directed to the more delicate branches of celestial photography and spectroscopy, such as photography of stellar spectra and of the nebulæ. More than a hundred photographs of spectra of stars have been taken, and in the nebula of Orion details equal in faintness to stars of the 14.7 magnitude have been photographed.

It was obvious that if the comet could be photographed by less than an hour's exposure, there would be a chance of obtaining a photograph of the spectrum of the coma, especially as it was probable that its ultra-violet region consisted of but few lines. In examining my photographs of the spectrum of the voltaic arc, a strong band or group of lines was found above H, and on the hypothesis that the incandescent vapor of a carbon compound exists in comets this band might be photographed in their spectrum.

Accordingly, at the first attempt, a photograph of the nucleus and part of the envelopes was obtained in seventeen minutes on the night of June 24th, through breaks in the clouds. On succeeding occasions, when an exposure of 162 minutes was given, the tail impressed itself to an extent of nearly ten degrees in length.

I next tried by interposing a direct vision prism between the sensitive plate and object glass to secure a photograph which would show the continuous spectrum of the nucleus and the banded spectrum of the coma. After an exposure of eighty-three minutes, a strong picture of the spectrum of the nucleus, coma and part of the tail was obtained, but the banded spectrum was overpowered by the continuous spectrum.

I then applied the two-prism spectroscope used for stellar spectrum photography, anticipating that although the diminution of light would be serious after passing through the slit, two prisms and two object glasses, yet the advantage of being able to have a juxtaposed comparison spectrum would make the attempt desirable, and moreover, the continuous spectrum being more weakened than the banded by the increased dispersion the latter would become more distinct.

Three photographs of the comet's spectrum have been taken with this arrangement with exposures of 180 minutes, 196 minutes and 228 minutes, and with a comparison spectrum on each. The continuous spectrum of the nucleus was plainly seen while the photography was in progress. It will take some time to reduce and discuss these photographs and prepare the auxiliary photographs which will be necessary for their interpretation. For the present it will suffice to say that the most striking feature is a heavy hand above H which is divisible into lines and in addition two faint bands, one between G and *h* and another between *h* and H. I was very careful to stop these exposures before dawn, fearing that the spectrum of daylight might become superposed on the cometary spectrum.

It would seem that these photographs strengthen the hypothesis of the presence of carbon in comets, but a series of comparisons will be necessary, and it is not improbable that a part of the spectrum may be due to other elements.

271 MADISON AVENUE, NEW YORK.

OBSERVATIONS ON SIREDON LICHENOIDES.*

BY WM. E. CARLIN.

Como Lake is a body of water about two miles and a half in circumference. It has no known outlet, but is fed by a stream of pure spring water about two feet wide and a foot deep, which, continually running, prevents the lake's absorption by evaporation. The lake is quite shallow and can be easily waded at almost any part, being not more than 10 feet deep in the deepest place that I have been able to find. The bottom of the lake is soft and is covered in most places with grass and weeds. The water is strongly impregnated with alkali, and a large number of cattle are said to have died a number of years ago from drinking it. It is very disagreeable to the taste. The amount of water varies about 14 inches during the year, being highest in the spring from the melting snows, and lowest in the autumn. This is the home of the *Siredon lichenoides* (Baird). They never enter the stream of fresh water, preferring the alkali water of the lake. They seem to suffer no inconvenience, however, if placed in fresh water. I have caught as many as a hundred and fifty and

*From the Proceedings of United States National Museum.

placed them in a cauf, and have never had one die from the change. The change to fresh water undoubtedly hastens the metamorphosis into the *Amblystoma* form, as I have noticed quite a change in the course of twenty-four hours in individuals placed in the cauf, while an equal number kept in the alkali water in the boat have shown no change in any of them in several days. I have kept six at different times in jars of fresh water until they have completed their metamorphosis. I made no systematic note of appearance from day to day, but my observation was careful and regular. In two cases the change in external appearance was so abrupt that I would have been almost certain that another salamander had been substituted for the one in the jar had I not had him so completely under observation that it was impossible. The gills had assumed a stubby form about half the length that they were the night before, and the gill on the back on the back of the body was nearly half gone; it took air quite often, and I removed it from the jar and placed it in a box with some lake grass around it to keep it moist. It completed the metatmorphosis in a few days. I did not feed it any during this time. While it was in the jar it was well fed with flies. The jar was placed upon a table in the telegraph office. The flies at first had to be pushed in front of it with a pencil. It finally got to know that tapping the jar with a pencil meant a fly, and would rise to the surface immediately and snap at whichever it saw first, pencil or fly. It furnished train-men continual amusement while here, and they kept it constantly gorged. Those that I kept well fed in jars and seldom changed the water, say once in three days, usually began to show a slight change in from two to three weeks, and all of them completed the change into the *Amblystoma* inside of six weeks, while I have had but three changes of those kept in the cauf (sixty of them) in three months. During that time they have not been fed at all. The *Siredon mexicanus* is said to never undergo the transformation in its home, and Professor Marsh doubts that it ever makes it here. This doubt I can put at rest. They do make the change here, and in large numbers. During the latter part of the month of July and the entire month of August, if the day is rainy or misty, they come from the lake to the shore in large numbers, and secrete themselves under some piece of wood or rock where they can keep moist. Sometimes they venture out in a shower, and the sun catches them before they can obtain shelter either in the lake or under cover, and in a few minutes kills them. They can be found dried hard anywhere about the lake, on the shore or in the grass. While catching *Siredon* I have seen and caught a number of *Amblystoma* in the lake, with the metamorphosis, as far as I could see, as complete as those we find half a mile from the lake. They cover the ground by thousands during a warm summer rain, coming from every conceivable place where they could have found shelter, from under rocks, boards, old ties, and out of gopher holes. I have a cat that eats them greedily. She has fished several out of jars on the table and devoured them during the night when there was no one to watch her; and I am told by a resident that the numerous skunks that live around the lake live principally on them. They are of two colors, a blackish green and a yellowish green color. I have had two of the blackish green complete the change in sequence, while one of the yellowish green was completing it under the same circumstances of change of water and food. I think this will be found to be the result in all similar cases. I have caught them in all stages of growth and in all stages of their changes into the *Amblystoma* state. During the months of July and August they lie close to the shore of the lake, where it is shallow; but after the first frost they disappear completely, or at least I have never been able to find them. I think they must bury themselves in the mud at the bottom of the lake, as I have stirred up the grass often and have not seen them issue from it.

AN ANALYSIS OF WATER DESTRUCTIVE TO FISH IN THE GULF OF MEXICO.*

BY F. M. ENDLICH.

Having completed the examination of sea-waters from the Gulf of Mexico, so far as the scant supply would permit, I have the honor to offer the following report thereupon, the water in which the fish die being designated as A, the good water as B:

	A.	B.
Specific gravity....................	1.024	1.022
Solid constituents (total), per cent...	4.0780	4.1095
Ferric compounds, per cent.........	0.1106	0.0724
Injurious organic matter...........	ratio=3	ratio=2

I find that the water A contains a large quantity of *Algæ* and *infusoria*. It is eminently probable that the former may have had an injurious effect upon the fish. Specimens of the algæ have been submitted to Professor Goode, who will send them to some expert, in order that their specific gravity may be determined.

The "dead fish" in possession of the United States National Museum are such that any examination of the organs of respiration will be of no avail.

I cannot find, even by spectroscopic analysis, any mineral constituents in the water A which could noxiously affect the fish.

In my estimation the death of fish was caused by the more or less parasitic algæ, which are found in large quantities in water A, but do not occur at all in water B.

In case the same phenomenon should recur, the presence of an expert in the questions involved, more particularly chemistry and botany, would most likely lead to definite results,

Prof. S. F. BAIRD,
Secretary the Smithsonian Institute,
WASHINGTON, D. C.

A MICROSCOPICAL STUDY OF THE IRON ORE, OR PERIDOTITE OF IRON MINE HILL, CUMBERLAND, RHODE ISLAND.†

BY M. E. WADSWORTH.

The attention of the writer was first particularly called to this formation by some specimens presented to him by Mr. H. B. Metcalf in the Spring of 1880. These did not appear to the writer to be any common ore of iron, but rather fragments of a basic eruptive rock containing much iron. Sections were accordingly made which revealed its true character.

The formation was described by Dr. Charles T. Jackson in his report on the Geological Survey of Rhode Island in 1840. He states that Iron Mine Hill "is a mountain mass of porphyritic magnetic iron ore, 462 feet in length, 132 feet in width, and 104 feet in height above the adjoining meadow. From these measurements, which were made over only the visible portion of this enormous mass of iron ore, it will appear that there are 6,342,336 cubic feet of the ore above natural drainage. ...Its specific gravity is from 3.82 to 3.88....This ore is remarkable both on account of its geological situation and its mineralogical and chemical composition. It appears to have been protruded through the granite and gneiss at the same epoch with the elevation of numerous serpentine veins which occur in this vicinity. This will appear the more probable origin of this mass, when we consider its chemical composition in comparison with that of the iron ore, which we know to have been thrown up with the serpentine, occurring on the estate of Mr. Whipple, and the fact that the ore at Iron Mine Hill is accompanied by serpentine mixed with its mass in every

* From the Proceedings of United States National Museum.

† From the *Bulletin of The Museum Comparative of Zoology.*—Harvard College.

part, gives still greater reason for this belief." (*l. c.*, pp. 52, 53.)

He gives as the result of his chemical analysis of the "Porphyritic Iron Ore from Iron Mine Hill, Cumberland," the following (*l. c.*, p. 53):—

SiO_2	23.00
Al_2O_3	13.10
Fe_2O_3	27.60
FeO	12.40
MnO	2.00
MgO	4.00
TiO_2	15.30
H_2O and loss	2.60
Total	100.00

In 1869 the Rhode Island Society for the Encouragement of Domestic Industry published a report relating to the coal and iron in Rhode Island, from which we glean the following. The iron ore is regarded as practically inexhaustible, the mass at Iron Mine Hill visible above drainage being estimated at two millions of tons.

"It is also conceded, as regards quality, that the Cumberland ore is free from sulphur and phosphorus, the most common and worst impurities, and that it contains manganese, the most prized of all the elements found in connection with iron. For these reasons the Cumberland ore is sought by manufacturers at a distance, to mix with softer ores and improve their quality, and is now exported from this State for that purpose."

It seems that this Iron Mine Hill ore was employed in 1703, mixed with the hemitite of Cranston, R. I., for the casting of cannon. The work was done at Cumberland, and, in part at least, "the cannon used in the celebrated Louisburg expedition, in 1745," were cast from these ores. The manufacture was abandoned in 1763, owing to an explosion of the furnace, by which the proprietor was killed.

During the administration of John Adams the same ores were also used for the manufacture of cannon. It seems that the Cumberland (Iron Mine Hill) ore was employed in the manufacture of charcoal iron at Easton, Chelmsford, and Walpole, Mass., as late as 1834. "The Cumberland ore, mixed with equal quantities of Cranston hematite or bog ore, produced, for a long period, a charcoal iron unsurpassed in this country. . . . The Cumberland ore contains an uncertain percentage of titanium, which, while it improves its quality, helps make it refractory. The ore is porphyritic, the magnetic oxide being associated with earthy minerals, principally feldspar and serpentine." It would seem that in 1869, and before, the ore was largely shipped to Pennsylvania to mix with other ores.

A letter of Professor R. H. Thurston, published in this report, states: "The Cumberland iron ore is of the kind known to mineralogists as 'ilmenite;' among mettalurgists as 'titaniferous magnetic ore,' and iron manufacturers, on account of its peculiar value for producing steel, would term it a 'steel ore.' . . . The Cumberland ore is conveniently located and of inexhaustible extent; it is perfectly free from noxious elements, though somewhat refractory; it will furnish a very strong iron or a most excellent steel; it can be smelted within the State at a profit; it can be made directly into steel at a much greater profit; steel made from it will bring the highest prices in the market."

Professor Thurston states that the mean of various analyses made of this ore is about as follows:

SiO_2	22.87
Al_2O_3	10.64
Fe^2O^3 / FeO	44.88
MnO	2.05
CaO	0.65
MgO	5.67
TiO	9.99
Zn	0.20
H_2O and loss	3.05
Total	100.00

The ore on one side of the hill, where it has been most extensively quarried, shows a dark, somewhat resinous groundmass, holding large striated crystals of feldspar. The resinous lustre and greenish-yellow color, as observed under the lens, are caused by the presence of olivine. The olivine becomes more strongly marked on the slightly weathered surfaces seen on the faces of the quarry. Under a lens of high power, the olivine shows clearly on the fresh fractures. The olivine in weathering decomposes to a yellowish and reddish-brown ferruginous powder, leaving the other constituent of the rock, the magnetite, well marked. The magnetite decomposes more slowly, and forms an incoherent mass after the decay of the olivine. The rock gelatinizes with hydrochloric acid, and yields a titanium reaction. A fragment allowed to stand a day or two in weak hydrochloric acid yielded gelatinous silica copiously.

A section made with special reference to the feldspar crystals shows large porphyritic crystals of the latter enclosed in a mass of magnetite and olivine.

The magnetite forms irregular, more or less connected masses, making a sort of sponge-like structure. Its rounded and irregular cavities are filled with olivine, which also occupies the interspaces between the magnetite masses. The olivine is in rounded forms, which sometimes show one or more crystal planes. It is cut through by numerous fissures, that usually show a ferruginous staining along their sides. The olivine also holds grains of the magnetite. Except the fissuring and ferruginous staining, the olivine is comparatively clear, and shows little signs of alteration.

The plagioclase feldspar shows well-marked lines of cleavage and fracture, and is somewhat kaolinized along these lines. It contains a few irregular flakes of biotite together with grains of olivine and magnetite.

The order of crystallization appears to have been, first the magnetite, then the olivine, and lastly the feldspar.

This rock is similar to the celebrated iron ore of Taberg, Sweden, as described by A. Sjören in the Geologiska Föreningens Forhandlingar (1876, III. 42-62; see also Neues Jahrbuch für Mineralogie, 1876, 434, 435.) The Taberg rock has been worked as an iron ore for over three hundred years. This Swedish ore is called by Sjören "magnetite-olivinite."

The feldspar is confined to the peridotite found on one side of the hill, where the peridotite passes into a compact greenish-black rock, showing patches of serpentine and grains of magnetite. From this fact it seems necessary to regard the feldspar as abnormal and local in the rock, which in general is composed of olivine and magnetite or their alterative products.

The structure remains about the same in the non-feldspathic portions as it is in those before mentioned as holding feldspar. But the olivine is entirely changed to a greenish serpentine which shows beautiful fibrous polarization. The serpentine retains the form of the olivine grains, their inclusions, and the network of fissures before mentioned. In some of the sections considerable carbonate was seen, presumably dolomite. In one section part of the olivine grains, especially towards their interior, remained unchanged, but on their edges they were altered to serpentine. Another change was observed here: the formation of secondary crystals of irregular outline that belong probably to actinolite. Some are elongated and narrow; other are short and broad, traversed, by cleavage planes. They evidently belong to the monoclinic system.

The origin of this rock could not be told from its field relations, as its contact with any other rock could

not be found. Since the only method in which its origin can be absolutely shown cannot be used without expensive excavation, it only remains to give the probabilities so far as ascertainable from the mass itself. Such microscopic characters and mineral association have been, so far as we know, only found in eruptive rocks when the origin of such rocks has been studied with sufficient care to determine it. Hence we must conclude it is most probable that this mass is eruptive also, until found to be otherwise.

It closely resembles in structure and composition some of the meteorites, except that its iron is oxidized and not in a native state—a resemblance which for others of the peridotites has long been pointed out. It is rocks of this character, as has been suggested by others, that give us the most probable clew to the interior composition and structure of the earth.

The rock in the field shows, to our mind, no signs of structural planes that should be referred to sedimentation. On one side the rock is massive and jointed, and on the other it is jointed in fine parallel planes. This portion of the rock is more highly metamorphosed than the other, and, as is usual in highly altered eruptive rocks, joints parallel to certain lines of pressure occur. The writer has seen this structure in many rocks that were indisputably eruptive, forming well marked dikes in other rocks.

A rod away from the main mass of the iron ore, near one end, some serpentine appears that cannot be directly connected with the other peridotite. Microscopically its characters and structure are the same as the main rock, and there is no reason to regard it as distinct. The rock nearest to the peridotite is a mica schist some hundred feet away. It shows no characters that would indicate the transition of the ore into it.

The locality was visited by the writer in October last, in company with Professor A. S. Packard, Jr., of Brown University, and Mr. T. S. Battey, of the Friends' School, Providence, R. I. To the latter gentleman I am especially indebted for a copy of the paper of the Rhode Island Society before mentioned, and for other favors.

This examination may serve as an illustration of the aid that microscopical lithology may be to the practical side of life, since now, for the first time since this rock has been worked, can the ironmaster who wishes to use it approach understandingly the metallurgical problems it presents; whether he desires to employ the rock as a whole, or to concentrate the magnetite first.

In direct-vision spectroscopes the number of prisms involves a considerable loss of light. M. Zenger now uses a liquid prism of ordinary form, having attached on its anterior plane a quartz prism of the same refringent angle, but arranged in opposite direction. The posterior face of the liquid prism carries a plane parallel plate. The rays fall normally on the quartz. The loss of light is by this arrangement reduced to a minimum. The spectra obtained are very intense, and the lines are well defined. A single parallelepiped of the kind decomposes the D line to the naked eye, and with a small Galilean telescope, magnifying five times, one can distinguish the difference of breadth of the two lines, and easily see the extreme red and ultra-violet rays, though there are only two prisms of 60 degrees.

M. Poliakoff, the distinguished Russian naturalist, has examined a horse presented by Colonel Prejvalsky to the St. Petersburg Academy, and decides it to be a new species, which he has named *Equus Przewalskii*. A translation of his memoir appears in the "Annals of Natural History," and from this it appears that the new representative of the family of undivided-hoofed mammals is in some respects intermediate between our domestic horse and the wild ass, but it differs from the asinine genus in having four callosities, one on each leg. In the form of skull, absence of dorsal stripe, and other particulars it resembles the domestic horse. This newly-recorded animal is indigenous to the plains and deserts of Central Asia, and has not hitherto fallen under the dominion of man.

COMET (*b*), 1881.

DO WE SEE NON-LUMINOUS BODIES BY REFLECTED LIGHT?

By A. G. Gaines, Pres. St. Lawrence University, Canton, N. Y.

All who have treated this subject have answered the above question with an unequivocal *yes*.

It may appear presumptuous to call the answer in question. Nevertheless, while reflecting recently on some of the peculiar facts of light and vision the thought came to me to doubt this universally accepted proposition; and now I wish to express my more confirmed doubts, and give some reasons for thinking we must revise our views on this point to some extent.

What I now hold is that neither ***transmitted*** nor ***reflected*** light reveal to us in vision either the body transmitting or the body reflecting, but that ***radiant*** light does reveal in vision the radiant body, and that the light by which any non-luminous body is visible is essentially of the nature of radiant light, and is properly to be so called. Paradoxical as these views may seem on bare statement, I think that a little consideration of the facts involved will soon convince us that they must be accepted as true, and show us that the present paradox is due to the illusions of an erroneous point of view.

It is a known and universally accepted truth that ***transmitted*** light does not reveal the transmitting medium. It may be refracted, little or much, but when it reaches the eye it reveals, not the refracting medium, but the body from which it was emitted. The refracting or transmitting body may be ***visible***, but is not visible by transmitted light. Were it perfectly transparent, that is, were it to transmit ***all*** the light coming to it, it would be invisible. This is no new truth, but one universally held and taught; and thus far we are all agreed.

Now let us attend to *reflected* light. As we attend to it we shall learn that reflected light does not reveal the reflector but the body emitting it. If bodies are seen by reflected light, they should be more clearly seen in proportion as they reflect more perfectly the light falling on them. The facts are exactly contradictory to this. In proportion as any given surface is a good reflector it is to that degree invisible, and when a surface becomes a perfect reflector it becomes invisible. Can it then be true that bodies are seen by *reflected* light when it is palpably true that the better they reflect light the less visible they are? The reflected light makes visible the body emitting it, not the reflecting body, and it results that, in studying the stars, the astronomer uses nearly indifferently a reflecting or a refracting telescope. Plainly then, we would say, it is not by reflected light that bodies are visible. This conclusion cannot be escaped by any conjectures as to the extent and form of the reflecting surface. The minutest surface reflecting the sunlight gives a brilliant, dazzling star, not a revelation of itself. Curved, convex or concave, or variously warped surfaces give only images variously enlarged or diminished, or variously distorted, of the body emitting the light, and not at all of the surfaces reflecting it. If the microscope be applied to the surface, the facts are still found to be as above stated. No theory of minute reflecting surfaces changes any of these facts, unless it were imagined that a surface might be so small as to *decompose* the light falling on it, but this result would be destructive of the theory now objected against. Thus it appears from all the facts stated and referred to that the proof is conclusive that, in no case is a body seen as such by the light it *reflects*.

If, now, we go on to inquire as to the light by which bodies are seen, we may find some good reasons for believing it to be essentially *radiant light*, even when proceeding from non-luminous bodies. Note, then, that it is the peculiarity of radiant light that it is emitted in straight lines in every possible direction from every luminous point. The light, hence, by which such a point or body is seen is *divergent* light, and the office of the optical apparatus is to bring it to a focus on the retina. It is not possible for a single point (the minimum of visible surface,) in any reflecting surface to reflect light in every direction; and for light thus to proceed in every direction from a luminous point is the distinguishing characteristic of radiant light. What thus characterizes the light of what are called luminous bodies will be found to characterize the light by which all non-luminous bodies are visible. From every point of any such visible body the light proceeds in every possible direction; whence we note that every such point is a point of dispersion or radiation, and not a point of reflection. Here, as we learned in the case of luminous bodies, the light by which any ordinary non-luminous body (so-called) is seen is *divergent*, and the office of the optical apparatus is to bring it to a focus on the retina. This brings before us the perfect similarity of the conditions under which luminous and non-luminous bodies are seen; and which seem to compel us, hence, to regard the light by which non-luminous bodies are seen as having essentially the same qualities and relations as radiant light.

If, now, we seek to know how this can be explained, seeing that non-luminous bodies are not original sources of light, I think we may find a nearly perfect analogy in the facts of heat that may afford us much help. We are tolerably familiar with radiant and reflected heat. The heat which a body reflects follows all the laws of reflected light, and has this peculiarity, that it does not change the temperature of the reflecting surface. For the rest, the heat which falls on a body, and, as it is said, is *absorbed* by it, raises the temperature of the absorbing body, and immediately said body begins to *radiate* heat, and the heat thus radiated shows all the essential characteristics of radiant heat. What we wish to have particularly noted here is, that this *heat* has been all along said to be *radiated, not reflected*. By the principle of the correlation of forces the heat which is said to be absorbed is transformed first into increased molecular activity in the absorbing body, and then again transformed into what is emitted as radiant heat; and this emission is in straight lines in every direction from every point in the surface of the body radiating. All this is plain, and in perfect agreement with the accepted theory of heat. We have now only to apply these facts and principles, by analogy, to light, and we may obtain an equally plain and consistent theory of light as to visible bodies.

We have already called attention to the fact that the light which a surface *reflects* does not reveal that surface. The light by which any non-luminous body is seen is emitted, let us say, *radiated*, from every point of its surface. This may now be explained by supposing the light (luminous energy) received by such a body as in some degree or manner absorbed by the superficial particles of the body, and then radiated from every such particle as a centre, analogous to what we believe of heat. The light thus taken in appears to be always *decomposed*, with numberless variations of results; so that the light emitted or radiated is always of a different *color* from that received. This difference of color affords us another contrast between the light by which bodies are seen and reflected light; this last being always of the same color as the incident light. In making this statement we have in mind the fact that the same surface may both reflect and radiate light; and that, hence, in each case we must take care not to confound the one with the other in making our observations. When this caution is observed, the statement above concerning the color of reflected light will not, we think, be called in question.

The explanation, then, that I would offer is, that the light which falls on non-luminous bodies (so far as it is not reflected) is somehow absorbed by them, decomposed, and then radiated, at least in part, that the body is visible by this *radiated* light, and not at all by that light which it reflects. In these actions and reactions between the luminous energy falling on a non-luminous body and the body itself, we think it not improbable that there are some correlations of force; and that these may be essential parts of the change that enables the light radiated to make visible the non-luminous body.

If the views presented in this paper be allowed, they enable us to place the facts of phosphorescence, and may be of fluorescence, in harmony with the action on light of ordinary non-luminous bodies; and differing from these chiefly, if not wholly, in *degree* only. And is it not true that this so-called phosphorescence is possessed in some degree by every visible body? We do not now speak of cases of slow combustion, like exposed phosphorus, but those continuing to emit light for a time after being cut off from extraneous light, like snow and the diamond. We would look for the explanation of these greater degrees in phosphorescence in the power of the bodies exhibiting it to absorb and decompose light more deeply, and then more tardily radiate the luminous energy, than is true of non-luminous bodies generally.

It may be proper here to notice the facts of *iridescence*, with which our theme may have some interesting connections. Inasmuch as the facts of iridescence are explained by the interference of the luminous waves, caused by the reflection of light from very thin laminæ, it might be thought the same explanation would apply to *decomposition* of light by ordinary non-luminous bodies. We think the facts in the two cases so different that the same explanation is not applicable to both. In the first place, the facts of iridescence agree with the usual characteristics of *reflected* light; while, on the contrary, we have noted in this paper that the facts in the case of ordinary visible bodies do not so agree. And, in the second place, the results of the decomposition of light in iridescence

agree with the results obtained by prismatic decomposition; while the results in the other case do not. We think it would be correct to say that iridescence does not reveal non-luminous bodies in the same way, nor with the same certitude, as that light reveals them by which they are ordinarily visible. In making this last statement we have in mind the fact that the iridescent surface, in addition to its iridescence, also emits or radiates light in the same manner as ordinary visible bodies; and that these two facts are not to be confounded in our observations and reasonings. Without pursuing the subject further into details, these are some of the reasons why we think the facts of iridescence are not inconsistent with the main doctrine of this paper.

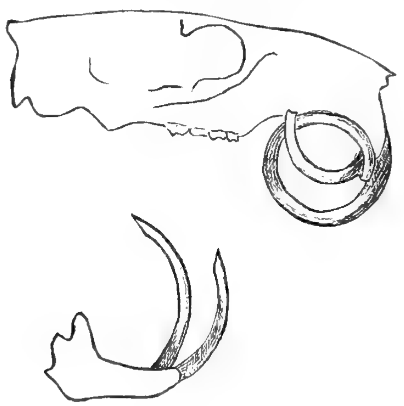
We conclude then, by reason of the facts and relations to which we have now called attention, we cannot believe that it is correct to say that non-luminous bodies are seen by *reflected light*; and we offer the suggestion that the light by which such bodies are seen should fairly and properly be called *radiant light*, as manifesting all the essential qualities of such light.

CORRESPONDENCE.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. No notice is taken of anonymous communications.*]

To the Editor of "SCIENCE."

In an article on overgrown teeth of Fiber Zibethicus (which by a singular typographical error is printed Fiber Wibethicus) in "SCIENCE" for July 16th, the writer describes a not very uncommon phenomenon among rodents to which I can add an interesting example.



The inclosed drawing represents a similar case, being a woodchuck (Arctomys monax); it will be noticed that one of the upper teeth has grown far enough to form a semicircle while the other upper incisor has described a somewhat larger curve and finally thrust itself through the first and then continued to form a *complete circle*, as will be evident from the figure. This specimen was mounted here (with one other similar but not so extreme a case) and is now in the Museum of Comparative Zoology at Cambridge.

F. W. STAEBNER.

July 20, 1881.

WARD'S NATURAL SCIENCE ESTABLISHMENT, Rochester, N. Y.

COMET (c) 1881.

To the Editor of "SCIENCE."

The comet discovered by Mr. Schaeberle at Ann Arbor, July 13, promises to become a very interesting object, not only because it will soon be visible to the naked eye, but also because its orbit shows great similarity to the great comet of 1337, as may be seen by the following comparison:

	1881 (Stone)	1337 (Hind)	1337 (Lanzier)
Distance of perihelion from node	122° 30′	108° 44′	90° 41′
Longitude of node	98 43	99 6	93 1
Inclination	141 35	137 6	139 32
Logarithm perihelion distance	9.7959	9.97	9.92

The difference between the orbits of the two comets is perhaps not greater than the uncertainty of that of 1337. The latter was first seen in China on the 26th of June, and afterwards in Europe on the 24th of October.

Schaeberle's comet has been observed here on a number of mornings, and its increase in brightness has been quite perceptible. This morning the tail was very apparent, the sky was very cloudy, or I presume it would have been visible to the naked eye. It ought to be quite plainly visible at any rate before the end of this week. It will be at perihelion and nearest the earth about the 20th of August, and will remain at approximately the same distance from us for a week or more. A few days before that time its right ascension will have become equal to the sun, so that when at its greatest brilliancy it will be visible in the evening. While it will undoubtedly become a magnificent object, it will not probably equal the great comet now receding from us.

EDWARD S. HOLDEN.

ADULTERATION OF SUGAR.

To the Editor of "SCIENCE."

DEAR SIR—In the leading editorial of "SCIENCE" of June 18, you speak of the different results obtained by Prof. Leeds and myself of examination of commercial sugars and syrups for glucose and grape sugar. I can only take exception to one statement contained therein, *i. e.*, the one which intimates that these different results form the theme of a scientific controversy. Since the reception of your letter I have renewed my inquiries for statistics, and can now say that I do not believe my estimates of the quantities made in the United States are very wide of the truth. Dealers and manufacturers are extremely reticent on the whole subject, and it is only by hard work and often indirection, that one can get at the truth. In your own city, New York, there is a large establishment for making "New Process Sugar," the Manhattan Refining Company, unless it has lately changed its name. Yet a prominent New York chemist stated publicly, and published over his own signature, that he had made diligent search for this establishment, and it could not be found. At the same time, to my personal knowledge, a western firm had just received a large consignment of "New Process Sugar" from this firm.

At the Boston meeting of the A. A. A. S., I stated on the strength of this personal knowledge that I believed the Manhattan Company was no myth. This statement was published in the Boston and New York papers, and was seen by the proprietors of the Manhattan Company. They wrote to assure me that I was right in my statement, sending me at the same time samples of their different sugar for analysis.

Within the past year the mixing of sugars has largely increased, and is now carried on in New York, in Buffalo, in Chicago, and at other points. A prominent

sugar dealer has just told me "some of these establishments turn out five hundred barrels daily."

From the best information I can get, I would place the daily yield of mixed sugars at 1500 to 2000 barrels. This, remember, is only a careful estimate from all the data I can get. The process is increasing just as fast as *dry white* grape sugar can be made.

With regard to table syrup, I can only reiterate my former statements. In response to a recent inquiry a prominent dealer has just written me as follows:

"My observation leads me to believe that fully four-fifths of all the syrup sold throughout the western and northwestern States and Territories are composed of glucose, with enough cane syrup or molasses added to give it the color most desirable to the buyer or consumer."

I have no accurate information respecting the eastern trade. I am not without a suspicion, however, from the appearance of some syrups which I have lately seen on Boston tables, that the beautiful syrup made from the corn of our western prairies, has invaded the very stronghold of the dirty refuse syrups of the sugar refineries.

Respectfully,

H. W. WILEY.

BOSTON, *July* 27, 1881.

WATER AS FUEL.

To the Editor of "SCIENCE":

I am interested in the paper of Dr. Rachel, in "SCIENCE," July 9, on the use of water in combustion.

The subject is a most important one; and I regret a mistake which a reader might fall into from an inadvertency, I suppose, in not more clearly distinguishing between the degrees of temperature at which the transfer of oxygen takes place from the hydrogen of the water to the carbon set free by the dissociation of the naphtha, and the number of heat units set free or absorbed by such transfer, which is a very different thing.

It is not a case of the dissociation of water, but of the dissociation of naphtha, and the *transfer* of oxygen from the hydrogen to the carbon so set free; a carbon which was very loosely held by the hydrogen in naphtha.

It is only a trade of so much carbon for so much hydrogen; the absolute heat of which, according to authorities, are almost exactly equal in complete burning.

But while the trade is thus equal in absolute heat, there is practically an enormous gain; and it is very important to see just what it is.

We get our heat all in hydrogen instead of in carbon, and so avoid the enormous practical losses which attend the usual mode of burning carbon.

We get our heat in hydrogen, which is the easiest of all things to get all of it out by burning, instead of in carbon which is one of the hardest of all things to get it all out of, the difference being much like that between the ease of getting our money out of a bank or out of a lot of debts where from half to three-fourths or nine-tenths is almost always finally lost.

The practical man does not understand very well what it means when he is told that the use of coal under boilers only produces five per cent of its energy in work. It means this: that a series of enormous losses is made in trying to get the heat out of the carbon in burning. An enormous quantity goes off as black smoke and soot, not burned. An enormous quantity goes off as carbonic oxide, giving up only a third of its heat, instead of giving it all up by burning to carbonic acid. An enormous quantity of heat is lost in heating up the great quantity of gases and air, that pass off without being fully burned, which prevents a high temperature. An enormous quantity of heat is carried up the chimney, because a little coat of soot and ashes on the boiler does not allow it to go into the boiler fast enough while passing so rapidly to the chimney. Is it any wonder that an enormous revolution is to be made by a mode of burning where water is used not for any energy to be got out of it, but by which the heat is taken from carbon, and put into hydrogen, where it all flashes into usable form the instant the air can reach it? Where the whole heat is liberated at one point where it is wanted, instead of in a long, imperfect flame? Where there is not a particle of soot or dust to tarnish the boiler and prevent the heat from passing into it wherever it strikes? And where the heat is nearly all in that low form of invisible radiance which is best suited to radiate on to, and be absorbed by, the boiler without waiting for the heated gases to actually strike it to give up their heat by slow convection?

It is a fact well known in the use of the alcohol and gas flames, that if you want them for heating alone you want the non-luminous flame only; because with a luminous flame a large part of the heat is in the form of light, which is not so readily absorbed by substances as heat, as it is with the non-luminous flame; and another large part is held by the gases as convective heat, and cannot so freely pass into substances by radiation, as in the radiation from the non-luminous flame.

Thus the revolution in combustion by the use of water consists in transferring the heat from carbon to hydrogen, by which all the great losses of burning are avoided, and the entire heat is obtained clean, without smoke, at the exact point desired, and in the form which takes right hold of the work without loss of time or energy.

These things are of an incalculable value; very much better than any mysterious supposed increase of heat from the water itself.

Though it is important to form a non-luminous gas by means of water to utilize the carbon, yet the water so added takes up a share of the heat to raise its temperature along with the other gases, and so reduces the temperature in proportion to its quantity.

So, if we need high heats we must use the least quantity of water, which will turn all the carbon into a suitable gas.

If we add water enough to make the carbon of 100 pounds of naphtha into carbonic acid, it will take 250 pounds of water, if we assume that the naphtha averages a composition of $C_6 H_{14}$, containing 84 pounds of carbon and 16 pounds of hydrogen; and the result would be 30 pounds of hydrogen and 310 pounds of carbonic acid. This would require 1530 pounds of air to burn it, and produce 1880 pounds of gas, of which over one-seventh would be due to the water, and the temperature would be less than $\frac{5}{7}$ of what it would have been without, if an equally perfect burning could have been secured without; because the water, as steam, has about twice the capacity for heat, as the other gases.

If we only add enough water to make all the carbon into carbonic oxide, it will take only half as much water; 125 pounds to 100 pounds of naphtha making about one-thirteenth of the gas after burning; and reducing the temperature only one-seventh.

But if we use only 36 pounds of water to 100 pounds of naphtha, one gallon of water to four gallons of naphtha, the gases may be something like this:

Marsh gas, CH_4, 80 pounds.
Carbonic oxide, CO, 56 pounds.

which with 1530 pounds of air (20,000 cubic feet) to burn it, will make 1666 pounds of gas; and the water added will only reduce the temperature one-twenty-fifth part, instead of so much as before.

In each case the air to burn it, and the units of heat produced, will be the same; but the temperature will vary with the proportion of water added, and, also, with the quantity of unburned air passing through.

One of the great advantages of the water process is the condition of blast with which the fuel unites with the air, by which the thorough mixture and burning is secured. And it is very important that the quantity of air going into the furnace be regulated so as to furnish only about

the right amount. All that is more or less than the exact amount required, reduces the temperature so much.

In ordinary furnaces, it has been estimated that much more than half the heat is lost by this one item alone. If the air passes freely in above the coal, twice as much goes in as is burned; if it all passes in under the grate, then only one-third the heat is given off, as only carbonic oxide escapes.

Probably the advantages with crude petroleum or with coal, of the water process, would be of still greater value.*

SAMUEL J. WALLACE.

WASHINGTON, D. C.

BOOKS RECEIVED.

OBSERVATIONS OF DOUBLE STARS made at the United States Naval Observatory by ASAPH HALL, Professor of Mathematics, U. S. N. Rear Admiral Rogers, U. S. N., Superintendent, Washington, 1881.

In introducing this work Professor Hall gives some very interesting details respecting the methods used in making observations at the Naval Observatory and the condition of the instruments.

He also presents his reasons for undertaking these observations and indicates the scope of the present work.

He states that his regular observations with the 26-inch refractor of the Naval Observatory were begun in the spring of 1875, the instrument at that time being in charge of Professor Simon Newcomb. "Professor Newcomb gradually withdrew from observing with this instrument, which came under my direction sometime in July of the same year. The micrometrical measurements which had been made by Professors Newcomb and Holden were chiefly of the satellites of Uranus and Neptune, and the discussion of these measurements of the two outer satellites of Uranus brought out very clearly what had been indicated before by Von Asten; viz, the existence of a large constant difference in the angles of position measured by Mr. Otto Struve, director of the Imperial Observatory at Pulkowa. As it is our intention to repeat the measurements of the satellites of Uranus and Neptune after a few years, and as it seemed probable that similar differences might exist in the observations of double stars, it occurred to me that the best way of comparing and uniting the observations of different astronomers would be for each one to observe the same double stars at nearly the same time. I wrote to Struve proposing that this should be done, and that he should select the list of stars. In reply he informed me that such a series of observations was already in progress between himself and Baron Dembowski, and after adding to the list of stars a few of greater distances, this list and an account of the proposed work were published by Struve in the "Vierteljahrsschrift der Astronomischen Gesellschaft." Band xi, p. 227.†

It was understood that each observer should avoid all knowledge of the observations of other astronomers, in order that his work might be done independently, and in my own case this rule has been carefully adhered to. But now nearly four years have elapsed since Struve's publication, and it is probable that all the astronomers engaged in this work have collected such a number of observations that the publication of my own results will not influence the independence of theirs. Moreover, the end of the year 1879 seems to be a favorable epoch for publishing my observations of double stars made before 1880, since I hope to make some changes which in the future will enable me to observe under conditions more favorable to accuracy.

I have therefore collected and revised all my observations of double stars, and the results are given in the following pages. In order to make this collection complete I have concluded the few observations made in the year 1863 with the equatorial of 9.6 inches aperture. The whole number of observations is 1614.

It will not be necessary to give any general description of the 26-inch refractor made by Alvan Clark and Sons for the Naval Observatory, since such descriptions can be found in the annual volumes of the Observatory for 1873 and 1874. It will be sufficient to say that the form of the mounting adopted by the makers for this Equatorial is such that the instrument, notwithstanding its great size, is handled with ease; and the harp-shaped piece that supports the polar axis is very convenient when observing near the zenith. Generally the instrument is pointed on a star by means of what are called the "rough circles." These circles are the edges of the hour and declination circles, which were painted white, and then divided by lines of black paint, the hour circle into spaces of ten minutes of time and the declination circle into degrees. This method of pointing is usually accurate enough to find the object, but as the painting was not well done errors as great as 15′ to 20′ could be made in some parts of the rough declination circle. An accurate reading for the position could be made by means of the finely divided circles, but this involves considerable time and trouble. On account of the delay in the observations which would be caused in making the change, and of the natural inertia in getting rid of a poor thing to which one has become accustomed, this defective circle for the declination was used until June, 1879, when the circle was painted white and divided again under the care of Mr. Gardner, the instrument maker of the Observatory. The settings are now much more accurate and give but little trouble, and the saving of time is very great. It is possible that a few cases may be found where, on account of an erroneous setting in declination, I have observed a different object from the one supposed.

The ease and rapidity with which observations can be made with a filar micrometer depend largely on the performance of the driving-clock. The accuracy of the observations also is in a measure dependent on this performance, but patience and skill on the part of the observer will in a good degree make up for a poor performance of the clock. The motive power of our driving-clock comes from a small water-wheel which is driven by water drawn from the Potomac water pipes. At first the water was applied directly to the conical pendulum, but the pressure of the water was so variable that weights attached to an endless cord (Huygen's loop), were placed between the water-wheel and the pendulum by Professor Newcomb. When this had been done the performance of the clock is said to have been tolerable; but in the autumn of 1875 it became very troublesome, and the observer was frequently annoyed by the stopping of the clock. This trouble continued and became worse until July, 1876, when the clock was dismounted by Mr. Gardner and myself. The lower end of the shaft of the conical pendulum had been given a conical shape, and had rested in a conical cup. The friction and heat had been so great that the lower end of this shaft had become very rough and twisted to a gimlet shape, thus stopping the clock. The bearing of the shaft was changed and made of a plane agate surface, the lower end of the shaft being rounded to a slightly curved surface. The friction of the upright shaft of the water-wheel was also diminished by clamping a set of friction wheels to this shaft and letting them play on a horizontal iron surface. The weights on the Huygen's loop were changed for cups carrying shot. With an average pressure of the water, and the machinery well oiled, these

* This superiority of the non-luminous combustion for heating was discovered by Professor Henry. He says: "With this arrangement the light of the flame was increased, while the time of bringing the water to the boiling point was also commensurably increased, thus conclusively showing that the increase of light was at the expense of the diminution of the temperature."

† Mittheilung über unternommene Beobachtungsreihen zur Vergleichung von Mikrometer messungen. 1876, Anfang Juni. OTTO STRUVE.

weights are 7½ and 3½ pounds, but the weights can be varied to suit the resistance and the pressure by changing the shot. Since these changes the performance of the clock has been tolerably good. Still this clock needs much care, and being dependent on an unsteady pressure of water a delay in the observations sometimes occurs. The great length of the telescope, which exposes it to the action of the wind, is also a hindrance to the steady driving of the clock.

The difficulty in turning the dome, of about 42 feet diameter, has increased. This difficulty is caused probably by the uneven settling of the supporting walls, and the bulging of the dome in the direction of the slit. The labor of turning the dome through a revolution is so great that lists of north and south objects are prepared beforehand by the observer in order to avoid as much as possible the turning of the dome.

After some practice, and on becoming familiar with the instrument and micrometer, my manner of observing a double star has been as follows: In order to measure the angle of position the two wires are separated a convenient distance and the stars are placed between them. The position-circle is turned by the hand until both stars appear midway between the wires, and then the circle is read. The light having been taken out of the micrometer, the wires are turned thirty or forty degrees forward and backward several times before the light is thrown on the wires again for the purpose of making the settings of the circle as independent as possible, and another reading is made. Generally four readings of the position-circle are taken. Then this circle is turned 90° from the mean of the readings and the double distance is measured. First the stars are bisected by the wires and the micrometer is read; then the wires are reversed and the stars are bisected again. The wires are then restored to their original position and another double distance is measured. Two such distances are generally observed. An estimated value of the angle of position is always recorded, as well as the sidereal time of the observation, and also an estimate of the weight of the observation. This weight depends simply on the condition of the images of the stars, and the numbers **1** to **5** are used for expressing the weights; **1** denoting a very poor condition of the images, **3** an average condition, and **5** a perfect condition. I have very rarely observed double stars when the images were so poor as to be given the weight **1.** As far as possible I have avoided all knowledge of the angles and distances observed by other astronomers. In my observing-list these quantities are omitted, and no comparison with other observations is made until my own observations of a star are completed. It is possible, therefore, that in some cases my angles may differ by a multiple of a quadrant from those observed elsewhere.

I have omitted observations of color and of magnitude. These observations have now become a specialty, and such observations as I could make would not do much more perhaps than tend to introduce confusion. In the case of stars observed by the Struves, to which most of my observations belong, I have adopted their magnitudes. In most cases these magnitudes are brighter than those of the scale to which I have been accustomed; thus what the Struves would call a 7th or 8th magnitude I would call an 8th or a 9th.

Very few of the observations have been made in the twilight, which offers the best conditions for observing double stars, since, the observer residing at a distance from the observatory, it has not been convenient to do this.

With such a large objective great changes occur in the appearance of the stars during a single night. Generally so long as rapid changes of temperature are going on the performance of the object-glass is not good. But on a few nights of the year, when all the atmospheric conditions are favorable, the performance of the glass is excellent, and its separating power is all that could be desired. Usually ruddy and reddish stars are the most difficult to observe, a result which may be caused by the figure of the objective. After having been in use two years the form of the lenses seemed to have undergone a slight change, and in the beginning of May, 1876, the surfaces of the flint lens were refigured by Mr. Alvan Clark and his son, Mr. Alvan G. Clark. This is the only change that has been made in the objective. On a single occasion water collected between the lenses, and they were taken out, cleaned by Mr. Gardner, and returned to their cell with very little trouble.

Until March, 1878, all the observations were made with my left eye; but having used my eyes very much during the preceding year, and having done a good deal of computing by gaslight, my eyes became weakened. In March, 1878, while observing the stars in the Trapezium of Orion with a field illumination which was very unsteady, my left eye suddenly became bloodshot. After a rest of a week the eye resumed its natural appearance, but on observing again the blood reappeared in the eye. I then began to use my right eye, and have used it since in most of the observations. From a number of trials I think that this change of eyes has produced only a small change in my habit of observing an angle of position. Still it is possible that some systematic difference in the angles may exist on account of this change, as there was at first some awkwardness in observing with my right eye. In all my observations the head of the observer was kept in an upright or natural position."

The elaborate introduction of Professor Hall leaves us little scope for further explanation. We may state, however, that the tables in which these observations are condensed cover nearly 150 folio pages, and will be accepted as a valuable addition to the literature of this subject, which has been much developed of late by the researches of Mr. Burnham and others.

A PARASITE IN ÆGERIA SYRINGÆ. HARR.

By G. H. French, Carbondale, Ill.

When examining the stems of some lilac bushes in my yard, I found a place in the bark of one where it seemed that an Ægerian pupa might soon protrude for the purpose of liberating the moth. Upon cutting away the thin film of bark, I found the end of a chrysalis visible. I carefully cut away the wood, took this out and put it in a jelly dish surrounded with lilac leaves to prevent its drying up, and waited for the imago to come forth. June 5th, a week after the chrysalis had been put into the jelly dish, I saw something among the leaves which I supposed was the expected moth, but which proved to be a hymenopter. I did not know but the insect might be one of the boring bees that often resort to the holes left by Ægerians in which to rear their young, but an examination of both the insect and the empty pupa case assured me that I had a parasite. The chrysalis was certainly that of an Ægerian, having all the characteristic marks of the pupæ of that family; and the insect in emerging from it had gnawed a hole near the end on the left side instead of the usual method of emergence of insects from their own pupa cases. More than this, the specimen was a true Ichneumonide and not a Crabronide as I at first thought it might be. This is the first time I have known of any parasite working in the Ægerians.

I make the parasite to be *Phæogenes Ater*, Cres. It is shining jet black, 40 of an inch long, the antennæ 25 jointed, the first 8 black, the next 4 white and the rest dark brown. The joints of the legs are a little pale.

It is impossible for me to say when the parasite was introduced into its host; but it must have been before it pupated, because the chrysalis when taken from the bush was entire, showing no broken place. That the Ægerian was *Æ. Syringæ*, I have no doubt, I do not know of any other boring in the lilac.—*Papilio.*

TABLES FOR QUALITATIVE CHEMICAL ANALYSIS, with an Introductory Chapter on the Course of Analysis, by Professor HEINRICH WILL of Giessen, Germany. Third American, from the eleventh German, edition. Edited by CHARLES F. HIMES, Ph. D. Henry Carey Baird & Co., Philadelphia, 1881. Price, $1.50.

In this work a series of fourteen tables are presented which will be found of the highest value to the chemical student, and will be the means of saving a large amount of time if used by those engaged in chemical analysis. These tables are compact, but sufficiently explicit, and the summary view of the general course of qualitative analysis, and of the classification of compounds, according to the properties relied upon for their detection, afford a thread, as it were, around which chemical facts may crystalize as they accumulate. These tables appear well adapted for a course of college studies, and their popularity and scientific character is indicated by their general adoption in the German Universities. With such an endorsement, we anticipate a large sale for this book among American students of Chemistry.

TRICHINÆ IN RATS.

In regard to Dr. GLAZIER's belief that rats are not the "headquarters" of trichinæ elaborate, expressed in his official report on trichinæ and trichinosis, the following, taken from the *Geitschrift für unkros Kopische Fleischschan*, is of interest:

Dr. MERKEL, County Physician at *Nuremberg*, *Bavaria*, had asked the Microscopical Society at that city to examine as many rats for trichinæ as they could collect for the purpose. He distributed blanks among the members, which he requested to be filled. Within six months 111 of these troublesome animals had been so examined, with the following result:

Of 40 rats caught at or near abattoirs, 8 (20%) showed trichinæ, while 71, caught on private property, showed 8 (11.27%); total, 111 rats, showed 16 (14.4%).

This would certainly confirm the idea that the neighborhood of those places where swine will devour anything that offers—which they would presumptively do otherwise only after having been fed—rats are more dangerously infected than where the porcine tribe is more regularly cared for.

SOME NEW FACTS ABOUT RABIES.—It is known that M. Pasteur is directing his attention to the subject of rabies. The virus of that disorder of course exists in the saliva, but M. Pasteur has now proved that it does not exist there only. The brain substance also contains it, and, used to inoculate healthy animals, will reproduce the disease as effectively as the saliva. Matter from the medulla oblongata and the frontal portion of one of the brain hemispheres and the liquid of the brain have been thus employed with success. Again, one of the great difficulties in research on rabies arises from the uncertainty of development of the evil after inoculation or a bite, and the long time of incubation. M. Pasteur is now able to communicate the disease surely, and to shorten considerably the time of incubation. His method is to inoculate directly the surface of the brain, having recourse to trepanation, and using as inoculating matter the cerebral substance of a mad dog as pure as possible. In that case the first symptoms of rabies appear infallibly in a week or two, and death ensues in less than three weeks. In these researches, of which we may expect to hear more shortly, M. Pasteur has the co-operation of MM. Chamberlain, Roux and Thuilier.

SATURDAY, AUGUST 13, 1881.

The Proceedings for the past year of the American Association for the Advancement of Science have been distributed to the members; they do honor to the Society by whom they are issued, and hold forth the brightest hopes for its future.

The friends of the Association will learn with satisfaction that the number of members steadily increase, and that the roll of honor now comprises one thousand five hundred and fifty-five names, a glance at the list showing that it represents the intelligence of the United States.

The very laudable objects of the Association are the advancement of Science, which it endeavors to carry into effect by arranging annual meetings of its members, "to promote intercourse between those who are cultivating Science in different parts of America, its Constitution expressing the desire to give a stronger and more general impulse and more systematic direction to scientific research, and to procure for the labors of scientific men increased facilities and a wider usefulness."

It will thus be seen that the leading feature of the Association is *co-operation*, the secret of all success and the keystone of human progress. Perhaps in no country in the world does this necessity for co-operation exist to a greater degree than in the United States, with its vast amount of territory and great area.

Men of education, with minds specially adapted for the highest scientific work, are often isolated from their fellow workers, and thousands who are "cultivating" Science are spread over the States and Territories, silently plodding over problems of vital interest or investigating the great scheme of Creation. Surely an Association which is a bond of union between such a widely dispersed class should be recognized on its merits by those for whose benefit it is established, and we may add, that the only practical sign of appreciation of the advantages offered, is active membership.

The Association at present numbers fifteen hundred members, and has an income of less than six thousand dollars, a sum which is well husbanded and turned to the best advantage by the executive officers of the Association, who are enabled this year to present two handsome volumes to each member, which are alone equivalent in value to the subscription paid.

We desire, however, to see the list of members largely increased, and considering the Association has existed over thirty years, the number should not be less than five thousand, an income would then be at the disposal of the Executive Committee which would enable it to encourage scientific research in a manner worthy of the Association and the cause of human progress which it represents.

We desire also to see the permanent fund of the Association placed on a more substantial footing, and supported by those who can strengthen it from their superabundant wealth, without a financial effort on their part.

We speak within bounds when we assert, that it is a standing scandal and reproach on the *men* of intelligence of the United States, to find that the *single patron* of the "American Association for the Advancement of Science" is a *woman*. Is there no American gentlemen with sufficient chivalry to follow so bright an example? We trust that the meeting of the Association, which will open next week, will not close without at least one response, to the challenge we now make.

ASTRONOMICAL OBSERVATORIES.

By Simon Newcomb.

Among the contributions of public and private munificence to the advance of knowledge, none are more worthy of praise than those which have been devoted to astronomy. Among all the sciences, this is the one which is most completely dependent upon such contributions, because it has the least immediate application to the welfare of the individual. Happily, it is also the science of which the results are best adapted to strike the mind, and it has thus kept a position in public estimation which it could hardly have gained if it had depended for success solely upon its application to the practical problems of life. That the means which have been devoted to its prosecution have not always been expended in a manner which we now see would have been the best, is to be expected from the very nature of the case. Indeed, a large portion of the labor spent in any kind of scientific research is, in a certain sense, wasted, because the very knowledge which shows us how we might have done better has been gained through a long series of fruitless trials. But it is due both to ourselves and the patrons of astronomy that as soon as any knowledge bearing upon the question of

the past application of money to the advance of science is obtained, use should be made of it to point out the mistakes of the past and the lessons for the future. It is now patent to all who have made a wide study of the subject that large amounts have been either wasted or applied in ways not the most effective in the erection and outfit of astronomical observatories. Since Tycho Brahe built his great establishment at Uraniburg, astronomical research has been associated in the public mind with lofty observatories and great telescopes. Whenever a monarch has desired to associate his name with science, he has designed an observatory proportional to the magnitude of his ambition, fitted it out with instruments on a corresponding scale, and then rested in serene satisfaction. If we measure greatness by cubic yards, then Peter the Great and "Le Grand Monarque" were the founders of two of the greatest observatories ever built. That of St. Petersburg was completed in 1725, the year of Peter's death, and was an edifice of two hundred and twenty-five feet front, with central towers one hundred and forty feet high. It had three tiers of galleries on the outside for observation, and was supplied with nearly every instrument known to the astronomers of the time, without reference to the practicability of finding observers to use them. It was nearly destroyed by fire in 1747, but was partially rebuilt, and now forms part of the building occupied by the Imperial Academy of Sciences. The Paris Observatory, built half a century earlier, still stands, its massive walls and arched ceilings reminding one rather of a fortress than of an astronomical institution.

Notwithstanding the magnificence of these structures, they have had little essential connection with the progress of astronomy. It is true that the work done at both establishments takes a prominent place in the history of science, but most of it could have been done equally well under wooden sheds erected for the protection of the instruments from the weather. In recent times, the St. Petersburg Observatory has been found so unsuitable for its purpose that no observation of real value can be made, and its existence has been nearly forgotten. The great building at Paris, though associated with a series of astronomical researches second to none in the world, has really served scarcely any other purpose than those of a physical laboratory, store-house and offices. The more important observations have always been made in the surrounding garden, or in inexpensive wings or other structures erected for the purpose.

With these establishments it will be instructive to compare the Greenwich Observatory. The latter has never won the title of great. It was originally established on the most modest scale, for the special purpose of making such observations as would conduce to the determination of the longitude at sea. Although it has now entered upon its third century, no attempt has ever been made to reconstruct it on a grand scale. Whenever any part of it was found insufficient for its purpose, new rooms were built for the special object in view, and thus it has been growing from the beginning by a process as natural and simple as that of the growth of a tree. Even now, the money value of its structure is less than that of several other public observatories, although it eclipses them all in the results of its work. Haeckel lays it down as a general law of research that the amount of original investigation actually prosecuted by a scientific institution is inversely proportional to its magnitude. Although this may be regarded as a humorous exaggeration, it teaches what the history of science shows to be a valuable lesson.

A glance at the number and work of the astronomical observatories of the present time will show how great a waste of means has been suffered in their erection and management. The last volume of the "American Ephemeris" contains a list of nearly 150 observatories, supposed to be, or to have recently been, in a state of "astronomical activity." The number omitted because they have lain inactive it is impossible to estimate; but it is not unlikely that, in this country at least, they are as numerous as those retained. It is safe to say that nearly everything of considerable value which has been done by all these establishments could have been better done by two or three well-organized observatories in each of the principal civilized countries. Indeed, if we leave out of account local benefits, such as the distribution of time, the instruction of students, and the entertainment of the public, it will be found that nearly all the astronomical researches of really permanent value have been made at a very small number of these institutions. The most useful branch of astronomy has hitherto been that which, treating of the positions and motions of the heavenly bodies, is practically applied to the determination of geographical positions on land and at sea. The Greenwich Observatory has, during the past century, been so far the largest contributor in this direction as to give rise to the remark that, if this branch of astronomy were entirely lost, it could be reconstructed from the Greenwich observations alone. During the past twenty years, the four observatories at Greenwich, Pulkowa, Paris and Washington have been so far the largest contributors to what we may call geometrical astronomy that, in this particular direction, the work of the hundred others, in the northern hemisphere at least, can be regarded only as subsidiary.

This remark, it will be understood, applies only to that special branch of astronomy which treats of the positions and motions of the heavenly bodies. The other great branch of the science treats of the aspect and physical constitution of these bodies. It dates from the invention of the telescope, because, without this instrument and its accessories, no detailed study of the heavenly bodies is possible. The field open to the telescope has, during the last twenty years, been immensely widened by the introduction of the spectroscope, the ultimate results of which it is scarcely possible to appreciate. Photography has recently been introduced as an accessory to both instruments; but this is not so much an independent instrument of research as a means of recording the results of the spectroscope and telescope. To this branch of the science a great number of observatories, public and private, have duly contributed, but, as we shall presently see, the ratio of results to means is far less than it would have been had their work all been done on a well-organized system.

Nearly all great public observatories have hitherto been constructed for the purpose of pursuing the first branch of the science,—that which concerns itself, so to speak, with the geometry of the heavens. This was naturally the practice before the spectroscope opened up so new and rich a field. Even now, there is one sound reason for adhering to this practice—namely, that physical investigations, however made, must be the work of individuals, rather than of establishments. There is no need of a great and expensive institution for the prosecution of spectroscopic observations. The man of genius with imperfect instruments will outdo the man of routine in the greatest building, with the most perfect appliances that wealth can supply. The combination of qualities which insures success in such endeavors is so rare that it is never safe to count upon securing it. Hence, even now, a great observatory for the prosecution of physical research would be a somewhat hazardous experiment, unless the work it was to do were well mapped out beforehand.

Considering the great mass of observatories devoted to geometrical astronomy, the first thing to strike the professional student of their work is their want of means for a really useful and long-continued activity; and this notwithstanding that their instrumental equipment may be all that could be required. The reason is that their founders have not sufficiently taken into account the fact that the support of astronomers and the publication of observations is necessary to the usefulness of such an

establishment, and requires a much larger endowment than the mere outfit of the building. Let us take, for instance, that omnipresent and most useful instrument, the meridian circle. Four or five of these instruments, of moderate size, located in good climates, properly manned, under skillful superintendence, working in co-operation with each other, would do everything necessary for the department of research to which they are applicable, and a great deal more than is to be expected from all the meridian circles of the world, under the conditions in which they are actually placed. They could, within the first five years, make several independent determinations of the fundamental data of astronomy, including the positions and motions of several hundred of the brighter fixed stars. In five years more, they could extend their activity so as to fix the position of every star in the heavens visible to the naked eye; and, during the ten years following, could prepare such a catalogue of telescopic stars as there is no prospect of our seeing during the next half-century.

There are probably not less than twenty meridian circles in this country alone, most of them antiquated, it is true, yet, so far as average size and cost are concerned, amply sufficient for the work in question. How many there may be in other countries it is impossible to estimate, but probably fifty or upward, and the number is everywhere constantly increasing. Should we seek out what they are doing, we should probably find half of them rusting in idleness upon their pivots. With others, some industrious professor or student would be found making, unaided, a series of observations to be left among the records of the establishment, or immured in the pages of the "Astronomische Nachrichten," with small chance in either case of ever being used. We may be sure that the solitary observer will soon find something else to do, and leave the instrument once more in idleness. Others we should find employed in the occasional instruction of students, a costly instrument being used where a rough and cheap one, which the student could take to pieces and investigate at pleasure, would answer a far better purpose. Yet others we should find used in distributing time to the neighboring cities or states, or regulating chronometers for the shipping of a port. I dare not guess how many we should find engaged in work really requiring an instrument of the finest class, and gaining results which are to contribute to the astronomy of the future, but in our own country there would hardly be more than three.

The general cause of this state of things lies upon the surface. It is as true in astronomy as in any other department of human affairs that the best results can be attained only by a careful adaptation of means to ends. Failures have arisen, not from the intervention of any active opposing agency, but because observatories have been founded without a clear conception of the object to be attained, and therefore without the best adaptation of means to ends. To build an observatory before knowing what it is going to do is much like designing a machine shop and putting in a large collection of improved tools and machinery before concluding what the shop is to make, and what are the conditions of the market open to its products. Some hints on the considerations which should come into play in the erection of any new observatory may not be out of place, as pointing out the remedy for the evils we have described.

Heretofore, the practice has usually been first to decide upon the observatory, and to plan the building; next, to provide instruments; and lastly to select an astronomer, and, with his advice, to decide what direction the activities of the establishment should take. This order of proceeding should be reversed. The first thing to be done is to decide what the observatory shall be built to do. The future astronomer would, of course, have a controlling voice in this decision, and should, therefore, be selected in advance. One thing which it is especially important to decide is to which of the two great divisions of astronomical research attention shall principally be directed. If the prosecution of geometrical astronomy is kept in view, the conditions of advance in that department of the science must be kept in mind. The public is too apt to associate astronomy with looking through a telescope. That some of the greatest astronomers of modern times, such as Kepler, Newton, Hansen, Laplace and Leverrier, scarcely ever looked through a telescope as astronomers, is not generally understood. For two thousand years, astronomy has furnished the great geometers of the world with many of their profoundest problems, and thus has advanced hand in hand with mathematics. It borrows its fundamental data from observation, but the elaboration and development of its results taxes the powers of the mathematical investigator. The work of making the necessary observations is so much easier than that of developing the mathematical theories to which they give rise, that the latter is comparatively neglected alongside the former. It is lamentable to see what a collection of unused observations are found in the pages of scientific periodicals, to say nothing of those which have remained unpublished in the records of observatories. Under these circumstances, it is not worth while to found any more observatories for the prosecution of geometrical astronomy, except under special conditions. Among these conditions we may enumerate the following:

First. The institution should have such an endowment as to secure the continuous services of two or three observers, and to publish at least the results of their observations in a condensed form.

Second. The instrument should be of the finest class, but not necessarily of large size. This is not a difficult condition to fulfill, since such instruments are not very costly. One reason for observing it is that it is only within the last few years that the highest perfection has been attained in the construction of instruments of measurement.

If these two conditions can be really fulfilled, it is very desirable to add a few more to the great number of meridian circles now in existence, for the simple reason that it is easy to exceed them in perfection. It is, however, to be remarked that a good climate is a scientific prerequisite for the success of an observatory of any kind. The value of observations is decidedly lessened by the breaks in their continuity due to the intervention of clouds. It is therefore extremely desirable that, so far as possible, new observatories should hereafter be erected under sunny skies.

If an observatory is to be devoted to physical research, a more modest outfit, both in the way of endowment and of instrumental means, may be sufficient to serve an excellent purpose. Instead of being a great co-operative work, requiring the continuous labor of several persons, physical research may be divided up into sections almost as small as we please, each of which may be worked by an individual astronomer with any instrument suited to the purpose in view. To the success of such an observatory, a clear sky is even more necessary than to one engaged in measurement. Whether a great telescope will be necessary, will depend principally upon what is to be done. The consideration which is really of the first importance is the astronomer. The man who is really wanted will do more with the most inexpensive instruments than another one with the most costly ones. As already remarked, physical research is mainly the work of the individual, and what we want is to secure the services of the ablest man and then supply him with such means of research as are necessary to the problems he has in view. New questions are arising so frequently, and the field of physical research is now so wide, that it is impossible to lay down any general rules for a physical observatory, except that means should be furnished for supplying the investigator with any instrument he may want.

A third class of observatories are those intended for instruction in astronomy. The requirements, in this direction are so different from those necessary to research that it is impossible to combine the highest efficiency in both directions with the use of the same instruments. The number of observatories especially designed for pure instruction are very few in number. The instruments necessary for the purpose are of the simplest kind; indeed, so far as mere training is concerned, the engineer's level, transit, and theodolite can be made to serve most of the purposes of the astronomical student. What the latter really wants is that training of the eye and the mind which will enable him to understand the theories of instruments, the methods of eliminating the errors to which they are subject, and the mathematical principles involved in their application. In this, as in nearly every department of professional education, we may lay it down as a rule that the wants of a liberal and of a professional education are, so far as the foundation is concerned, identical. We are too prone to lead the student into the minute details of a subject without that previous training in first broad principles which, though it may not immediately tell on his progress as a student, will be felt throughout his life to whatever field of work he may devote himself. Such a transit instrument as Hipparchus might have made,—a wooden level mounted on an axis and supplied with slits to serve the purpose of sights,—properly mounted in the meridian, could well be made to take the place of the transit instrument for purposes of instruction. Scarcely any higher skill than that of a cabinet-maker would be required in its construction. The object at which the student should then aim would be, with the aid of this instrument, to determine the error of his clock or watch within a few seconds. If he is really acquainted with the principles of the subject, and has his eyes properly trained, he will have no difficulty in soon learning to do this.—(*North American Review*).

MICHIGAN FLORA.

By Charles F. Wheeler and Erwin F. Smith, Hubbardston, Michigan.

The following interesting sketch forms the preface to a catalogue of the Phænogamous and vascular Cryptogamous Plants of Michigan, Indigenous, Naturalized and Adventive, which can be obtained of W. S. George & Co., of Lansing, Michigan:

The climate of the Upper Peninsula of Michigan is colder than that of the Lower Peninsula, the surface is considerably broken, especially in the western part, and the flora is in many respects decidedly northern, resembling in part that of British America, and in other respects like that of N. New England and Canada. Pines, firs, cedar, larch, junipers, elms, poplars, black ash, basswood, maples, and birches, are the principal trees. *Pinus strobus*, the prevailing species southward, is here largely supplanted by its more northern and less valuable congener, *P. resinosa*, whose tall, slim trunks are, however, in good demand for driving piles. Under-shrubs, like *Rubus Nutkanus* and *Taxus baccata*, var. *Canadensis*, are common, and indicate a tendency toward northern types that we find more strongly developed in the herbaceous plants. Among the latter we note as found rarely, or not at all, in the Lower Peninsula, but frequently northward, and often having a high northern range, such plants as *Anemone parviflora*, *Viola Selkirkii*, *Potentilla frigida*, *Stellaria borealis*, *Saxifraga Aizoon*, *S. tricuspidata*, *Pinguicula vulgaris*, *Castillea pallida*, *Halenia deflexa*, *Physalis grandiflora*, *Tofieldia*, *palustris*, *Salix adenophylla*, *Eriophorum alpinum*, *Aspidium fragrans*, etc., etc.

The influence of climate on vegetation may be summed up in a few words. The climate of the Lower Peninsula is not as severe of as that of the Upper, nor so even, but is subject to frequent, sudden, and extreme changes of temperature—as great a variation during the winter season as 53° Fahr. in less than 24 hours having been recorded. Such rapid changes more or less affect vegetation, especially the tender branches of cultivated trees, which are sometimes seriously injured. In one or two instances a like effect on our forest trees has been noticed. The annual range of temperature is about 116°, and the annual mean 46°. Of rain-fall, including what falls in form of snow, we have, yearly, about thirty inches. Our snow-fall is much less, for the same latitude, than that of New York and New England. In the center of the peninsula, we seldom have more than a few inches at a time.

The proximity of the Great Lakes exerts a marked influence in equalizing the temperature and the effects are marked upon our flora.

Trees like *Liriodendron Tulipifera*, *Asimina triloba*, *Cercis Canadensis*, *Gleditschia triacanthos*, *Cornus florida*, *Nyssa multiflora* and *Morus rubra*, which belong to Ohio and Central Illinois, have crept northward, favored by the mild influence of the lake winds, through the central and western part of the Lower Peninsula, often beyond the middle, and the same is true of smaller and less noticeable plants.

As might be expected from the uniform surface of the peninsula, the flora is much alike throughout. Probably three-fourths of our species are common to all sections, though by no means equally distributed; some being very abundant in one district and rare in another at no great distance. In most cases such change is due to soil rather than to difference in elevation, temperature, or atmospheric moisture.

The Lower Peninsula is covered with a deep drift of alternating sands, clays and gravels, and the flora of any section depends chiefly on which of these happens to lie uppermost. With reference to its flora, the Peninsula may be roughly divided into two great divisions—the hard-wood and the soft-wood lands; one representing the Appalachian flora, and the other, the Canadian.

The hardwood country lies south of latitude 43°, and consists of very fertile sand, clay, or loam, mostly cleared of the original forest, and largely cultivated.

The sandy or stony drift of many river valleys in this section supports a heavy growth of oak, frequently interspersed with walnut and hickory, while the margins of the streams, and the neighboring swamps, abound in soft maples, swamp and chestnut oak, white and black ash, elm, hackberry, sycamore, butternut and similar trees. Willows, dogwoods, viburnums, and buttonbush, are common shrubs in the swamps; and hazel, hawthorn, wild cherry and plum, June berry, witch-hazel, etc., are abundant on the dryer ground.

On the uplands, and away from streams, clay, loam, and a peculiar blackmuck soil, supersede the sands and gravels of the valley. The prevailing timber here is beech and maple and oak forest in about equal proportions. Beech and maple (*Acer saccharinum* and var. *nigrum*) generally grow together, forming magnificent forests of great extent. The best wheat farms are usually found on uplands near streams, where the oak timber gradually shades into beech and maple. Plains of fertile sand covered with a low, or scattering growth of oak (oak openings) are frequent, and always very desirable for farming purposes. Four species of oak are usually found on such plains—*Q. alba*, *macrocarpa*, *coccinea* and *tinctoria*.

Marshes densely covered with tamarack are common in this part of the State, and nourish in their thick shade such plants as *Drosera rotundifolia*, *Sarracenia purpurea*, *Rhus venenata*, *Ribes rubrum*, *Chiogenes hispidula*, *Salix candida*, *Smilacina trifolia*, *Pogonia ophioglossoides* and *Calopogon pulchellum*. Arborvitæ, red cedar and black spruce are comparatively rare.

A similar tract of soil and timber occurs in the upper end of the Peninsula, north of a line drawn from Thunder Bay west to the head of Grand Traverse Bay. This is commonly known as the "Traverse Region," and has a flora much like that we have just described, with the exception that some of the southern species disappear, and northern ones begin to take their place, or if found growing further south, here first become frequent.

The littoral flora of Little Traverse Bay is rich in interesting species, among which may be mentioned a small form of *Cakile Americana, Lathyrus maritimus, Potentilla Anserina, Tanacetum Huronense, Artemisia Canadensis, Cnicus Pitcheri, Juncus Balticus, Triticum violaceum, T. dasycarpum*, a peculiar form of *Bromus ciliatus, Calamagrostis longifolia, C. arenaria, and Equisetum variegatum.* The flora of the low dunes at the head of the Bay comprises, among others, the following species: *Juniperus Sabina*, var. *procumbens, Prunus pumila* and *Cornus stolonifera*, half buried in the drifting sand, *Hypericum Kalmianum, Salix glaucophylla*, and varieties, *Lilium Philadelphicum*, etc. In a moist depression were found *Arabis lyrata, Coreopsis lanceolata, Arctostaphylos Uva-ursi, Primula farinosa, Lithospermum hirtum, Triglochin maritimum*, var. *eltaum, Carex aurea, C. Œderi*, etc., etc. In thickets near the shore were found *Abies balsamea, Picea alba, Sheperdia Canadensis, and Rubus Nutkanus.* Deep forests of hemlock and yellow birch (*B. lutea*) mixed with a fine, tall growth of striped maple (*A. Pennsylvanicum*) are frequent, having underneath a tangled growth of *Taxus baccata*, var. *Canadensis*, and under all a carpet of *Lycopodium annotinum.* Alternating with these are sandy plains covered with a dense growth of *Vacciniums*, yielding a great abundance of fruit. Sugar maples and basswood are also abundant in this region, and reach an immense size. In fact, finer groves of maple it would be difficult to find in any part of the State.

The pine country proper lies between the two tracts we have thus described, and embraces about 15,000 square miles. It is composed largely of sand hills and plains, either scantily furnished with vegetation, or densely covered with pine forest. Argillaceous tracts wooded with beech and maple also occur, like oases in a desert; and swamps abound, with the usual lowland timber. Forests of hemlock spruce are frequent, and there are occasional ridges of oak. Birch (*B. lutea*) also begins to be a common forest tree, and attains a large size. The usual timber of the barrens is Jack Pine (*P. Banksiana*). Climatic and other influences have combined to produce groves composed entirely of this species of large size and of great beauty, for, instead of being "a straggling shrub, or low tree" (Gray), it rises, often 50–60 feet, straight and symmetrical. All through this region *Pinus strobus* is the prevailing species and furnishes most of the lumber, but *P. resinosa* is frequent as far south as Clare county, and occurs sparingly in the northern part of Isabella county, which appears to be its southern limit.

Such is the general character of the sylva down to about latitude 43°, but in the western part of the State, owing perhaps to moister climate, or to favorable soil, hemlock spruce is more abundant, and reaches much farther south, nearly or quite to the Indiana line, and the same is true of white pine.

Portions of the counties of Clare, Missaukee and Roscommon represent an undulating plateau, which is 700–800 feet above the level of the great lakes, and has an interesting flora, as yet little studied. This region was examined in June, 1876, and revealed a number of northern plants. In the southern part of Clare county were found *Ledum latifolium, Kalmia glauca, Physalis grandiflora* (not before found south of the Upper Peninsula), *Corydalis glauca*, and *Geranium Carolinianum*—the two latter species growing luxuriantly in the deep woods, after fires. In the shade of the Jack Pines grew *Prunus pumila, Potentilla tridentata* (not before observed in Lower Peninsula), *Krigia Virginica, Arctostaphylos Uva-ursi, Linaria Canadensis, Kœleria cristata, Carex Houghtonii*, etc., etc. Near Houghton Lake were found *Adlumia cirrhosa, Ribes lacustre, Dracocephalum parviflorum, Streptopus roseus*, and *S. amplexifolius*; and in Muskegon river, near its source, *Potamogeton lucens. Pinus resinosa* was noticed frequently, growing with common pine, and near the center of Clare county it became more abundant, forming groups. Single individuals stretch upwards 150–160 feet, their clean, copper-colored boles often rising 100 feet to the first limbs.

The flora of the deep pine woods is interesting, though rather monotonous. Very little undergrowth is found, and their gloomy recesses nourish only such plants as love thick shade. Here the club-mosses (*Lycopodiums*) find a congenial home, and flourish luxuriantly, while *Clintonia borealis* covers the ground. The great round-leaved orchid (*Habenaria orbiculata*), with its tall, greenish spike and twin leaves close to the earth, is also frequent and striking. We shall also meet *Mitchella repens, Smilacina bifolia, Trillium grandiflorum*, perhaps, and a few ferns, particularly *Asplenium Filix-fœmina*, and *Phegopteris Dryopteris.* Other species occur, of course, but not so abundantly. In more open places, and on ridges, we meet *Rhus aromatica* and *Comptonia* along with wintergreen (*Gaultheria*) and trailing arbutus (*Epigea*), and are often fortunate enough to find the wax-white, fragrant flower of *Moneses uniflora* or *Polygala paucifolia*, hiding its shining leaves under a wealth of showy pink blossoms.

The floral treasures of the pine region lie, however, in its swamps and lake borders rather than in the deep woods. Therein grows *Linnea borealis* in all its delicate beauty, carpeting the ground, and close at hand, the odd, brown-purple flower of *Cypripedium acaule* and the small yellow blossom of its water-loving relative *C. parviflorum.* In such swamps, or within a stone's throw of them, may be found many other plants of equal interest, such as *Medeola Virginica, Ledum latifolium, Andromeda polifolia, Kalmia glauca, Lonicera oblongifolia, Cardamine pratensis, Gerardia aspera, Mitella nuda, Eriophorum vaginatum*, etc. On lake margins we shall find *Lysimachia* and the blue *Pontederia* and more rarely, *Nesæa* and *Eleocharis quadrangulata.* The lake itself, most likely, will be full of *Nymphæa, Nuphar, Utricularius*, and a world of *Potamagetons* and similar water weeds. Shrubby *Vacciniums* line the bluffs, and here and there gleam the white trunks of paper birches against the dark background of pines.

In the thick-pine country, where the lumberman's axe has let in the sunlight, new plants spring up freely. Here, *Prunus Pennsylvanica* and poplars are frequent, and the blackberry is omnipresent. *Aralia hispida* and *Physalis pubescens* are also peculiar to such land, and in August *Gnaphalium decurrens* may be seen whitening thousand of acres.

One seldom beholds a drearier sight than a dead and deserted lumber region. The valuable trees were all felled years ago, and the lumberman moved on to fresh spoils, leaving behind an inextricably confused mass of tree tops, broken logs, and uprooted trunks. Blackberry canes spring up everywhere, forming a tangled thicket, and a few scattering poplars, birches, and cherries serve for arboreal life, above which tower the dead pines, bleached in the weather and blackened by fire, destitute of limbs, and looking at a distance not unlike the masts of some great harbor. Thousands of such acres, repellant alike to botanist and settler, can be seen in any of our northern counties.

In certain districts considerable beech is found associated with the pine. The soil of such tracts is usually of better quality, and can be rendered productive without much labor. It may be noticed that in such cases the pine also grows thriftier and makes better lumber.

Sections of this and the Traverse region of Michigan are still sparsely settled, or not at all, and have been visited rarely by botanists. Consequently, we may expect many editions to our flora, as well as corrections, when this region is as thoroughly known as the south half of the State now is; our ignorance, rather than nature's parsimony, explaining why we have so few species credited to us. The most promising field for the botanist evidently lies in the Houghton Lake region and northward, and in the upper Peninsula, many parts of the interior of which are botanically unknown.

Our flora, as here presented, contains in all 113 families (orders), and 1,634 species. The composites claim the largest number of species, 182—about one-ninth of all. Sedges follow with 176 species; grasses, 139; rosaceæ, 61; ferns, 56; leguminosæ, 55; figworts, 46; mints, 40; mustard and crowfoot, 39 each; heath family, 35; and umbelliferæ, 27. We have 165 trees and shrubs, about 20 of which are valuable timber trees. At least 40 of our trees and shrubs are worthy of cultivation for ornament. Sugar maples and elms are commonly planted, while the tulip tree, basswood, Kentucky coffee tree, black walnut, and butternut, among deciduous trees, and hemlock, white pine, black spruce, arbor vitæ, and red cedar, among evergreens, deserve more attention. About 20 species of woody and herbaceous native climbers are frequent, and some are worthy of cultivation, (see State Pomological Report of '79 for a list.) Ninety medicinal plants are admitted into the U. S. Pharmacopœia, 45 belonging to the primary list, and an equal number to the secondary, while a number of others deserve attention at the hands of Pharmacists.

It may be stated in conclusion that, in the preparation of this catalogue, we have spared no pains to make it thoroughly reliable, a majority of the species enumerated having passed through our hands, and the remainder being admitted only on good authority. We have preferred to make a *useful* rather than a a *large* catalogue, and, on this ground, we have rejected a number of species, some of which may yet make good their claim to be considered as part of our flora. We cannot hope to have escaped all errors, and crave charitable judgment for any such the kind reader may discover, trusting that they may be found errors of omission rather than of commission.

In our arrangement of orders, we have preferred, as more convenient, to follow the 5th edition of Gray's Manual rather than later works. The vexatious subject of synonomy has received considerable attention, and will, we believe, be found brought down nearly to date. Further observations will be published from time to time in the form of addenda, towards increase of which we solicit correspondence and contributions from all parts of the State.

IONIA, MICH., January 20, 1881.

DISRUPTION OF PLANETARY MASSES FROM THE PRIMEVAL NEBULA.

V.

By EDGAR L. LARKIN.

It has been shown in this series that the gaseous sphere could not have parted with any form of ring known to geometers. All varieties of segmental rings were examined, and their displacement found impossible by known laws of mechanics. The nebula subsided from space to the dimensions of the orbit of Neptune, else its assumed rotation could not have been equal to the orbital velocity of that planet.

Indeed, it must have revolved faster, for matter along the line of the centre of gravity of the ring moved with the rate that Neptune now has. Then the outside of the ring moved faster and the inside slower than the Neptunian velocity. But the inside was required to move with greater rapidity than any other point to exceed attraction and disrupt the mass. From this consideration alone the doctrine of ring detachment is subverted.

We are now to demonstrate that no particle whatever can be detached from a revolving sphere whether gaseous, fluid or solid, by any force known to man. Tangental force in no case overcomes radial, being unable from known physical laws, which teach that not an atom ever left a rotating cosmical mass. We have made calculation of the maximum effect of tangental force on matter on the equator of the sphere when coincident with the orbit of Neptune, radius being 2,780,000,000 miles. And if the solar parallax is modified, bringing Neptune somewhat nearer, the figures will not be in material error. It is a law of mechanics that if matter is thrown off the periphery of a revolving sphere by force evolved by rotation, the detached portion always, when maximum power is exerted, traverses a line tangent to the curvature at the point of departure. If a revolving globe should burst, the pieces would be projected along tangental lines and never rise higher. But what is a tangent to the Neptunian orbit, and what is its departure from the curvature of that mighty sphere whence Neptune's mass is said to have been detached? It is apostulate of the Hypothesis that the nebula was a sphere, else it could not have parted with matter in the form of a ring. We adopt the idea that it was round, and for the purposes of trigonometry imagine the surface to have been as level as still water. We are in search of the departure of the tangent from the curve at different distances along the equator, to learn how far tangental force was able to project matter above the periphery.

The length of 1″ of arc on the equator of the nebula was 13,478 miles, and we made selection of 8″ of arc or 107,824 miles to find the amount of its deflection from the tangent. The curvature cannot be detected by tables of logarithmic functions carried to the sixth decimal place—thus:

$$\begin{array}{lr} \log.\ \sin.\ 1' = & 6.463726 \\ \log.\quad 60 = & 1.778151 \\ \hline \log.\ \sin.\ 1'' = & 4.685575 \\ \log.\quad 8 = & .903090 \\ \hline \log.\ \sin.\ 8'' = & 5.588665 \\ \text{and} & \\ \log.\ \tan.\ 1'' = & 4.685575 \\ \log.\quad 8 = & .903090 \\ \hline \log.\ \tan.\ 8'' = & 5.588665 \end{array}$$

That is, the logarithmic sine and tangent of 8″ are the same; hence the arc cannot be told from a straight line by ordinary tables. This being the case, radii drawn to the centre from each extremity would be equal in length, and it follows that any particle of matter on the equator of the primeval sphere, after having traversed more than a hundred thousand miles under the influence of tangental force, was no further from the centre than when it started, making the formation of a ring, or detachment of an atom, alike impossible.

Not deeming it true that an arc of such length had no curvature, and not having logarithmic tables for exact computation of functions near their limits, we were obliged to use the cumbersome method of natural sines, cosines and tangents, carrying the calculation to the twentieth decimal place to secure accuracy.

To find the cosines of such minute arcs use was made of the formula—$\text{Cos.} = 1 - \frac{1}{2}\ \text{sin.}^2$, and for secants—$\text{Sec. } A = \frac{1}{\text{cos.}} A.$

Applying these formulæ to the arc of 8″ it was found that the secant was only 1.94 miles longer than the radius. That is, the curvature of the sphere at any point distant 107,824 miles from another, made a point of tangency, is less than two miles! Let us watch the career of an atom destined to be cast off the equator to

become a part of the Neptunian ring. Conceive the sphere at rest; let some unknown law cause it to rotate, with constantly accelerating velocity, until finally equatorial atoms are moving so fast that tangental force just counteracts gravity. The particles will be balanced and without weight. Increase rotation, and the atoms will move on a tangent instead of the surface of the sphere.

But they had to move 50,000 miles before it could be determined whether they were traversing the periphery or tangent, and over 50,000 more miles in order to attain an elevation of two miles! To do this the maximum force was required, as it alone was able to project matter to the tangent.

Nothing in nature can exceed the feebleness of this maximum tangental force. An atom on the equator required 8h. 54m. to traverse 107,000 miles, and then it was not quite two miles further from the centre. Yet this gentle force cast off a ring whose mass was 102 sextillion tons, if the Hypothesis is true.

No theory ever advocated concerning the development of the planets has so little in its favor as that of ring detachment. Below is a table showing the increase of distance of equatorial atoms from the centre of the sphere after having traversed different arcs from the point where they became balanced between the opposing forces, centripetal and tangental.

The first column gives the arcs, the second their length in miles, and the third shows the gain in distance from the centre of the nebula, after reaching the extremity of arcs, providing the matter touched the tangents.

Arcs.	Length in Miles.	Altitudes of Matter in Miles.
8″	107,824	1.94
10″	134,780	2.78
15″	202,170	7.
25″	336,950	20.
1′	808,671	117.
10′	8,086,710	11,759.
1°	48,520,266	417,061

But no atom could rise above the periphery, for the entire periphery itself would rise. Thus, let a particle become subject to tangental force and fly along a tangent. Let the force be enormous, sufficient to hurl equatorial matter along a tangent of 1° or 48,520,666 miles, and it will then be 417.061 miles more distant from the centre. The next atom behind would follow and all others on the same line around the sphere. The next inner particle would become elevated, and the next until the space 417,061 miles filled with gas, the result of the process being that the equatorial diameter of the nebula increased 834.122 miles. But this diminished rotation allowed gravity to regain dominion and bring down the protuberance to a level as before. This mutation must obtain in all rotating masses so long as they remain gas or liquid, the areolar velocity being a constant. During the ascent and fall of the equatorial matter it is seen that no particle wandered away, but every one returned at the command of gravity. When a mass solidifies its rotary velocity cannot accelerate, and since matter is unable to part from a fluid sphere it cannot possibly leave a solid. Hence no cosmical mass, whatever its size, density or rate of revolution, ever detached an atom by force generated by rotary motion. Suppose the nebula received an impulse that imparted inconceivable velocity of revolution, causing peripheral matter to rush on a tangent of 20°, flattening the mass into the shape of a bi-convex lens, then rotation must have almost ceased, when gravity reasserted mastery. Let one imagine himself to have been placed on the equator of the nebula, assuming the gas visible, which was not the case. An ordinary tree could then be seen with a telescope at a distance of 50.000 miles! The top of a common terrestrial mountain would have been in sight at a distance of more than 100,000 miles! The observer would have found himself in the midst of a mighty plain, and would have been able to see mountains a hundred thousand miles in every direction, so slight was the curvature. At a distance of 1° or 48,000,000 miles the depression below a tangent was only 417,000 miles. The diameter of the sun is 852,000 miles; therefore, if it were placed on the circumference of the primeval sphere, its semi-diameter could be seen at that enormous distance. Reverse nature's laws, making it possible that tangental force can disrupt a revolving mass, then with the sphere's known rotation of 3.36 miles per second (admitting the Hypothesis true) could a ring have been abandoned? Could the rotary motion even cause currents to flow from the latitudes to the equator, or even produce an equatorial elevation in so vast a level capable of detection by some distant micrometer? We answer no, because Neptune, with the same velocity, keeps on its orbit. We fail to see why the theory of ring displacement was ever entertained, since no analogy in nature suggests it.

NEW WINDSOR OBS., *Aug.* 8, 1881.

MICROSCOPICAL TECHNOLOGY.

DR. CARL SEILER'S METHODS.

MOUNTING.

For mounting, both resinous and aqueous solutions may be used, which each possess advantages over the other, and for this reason a controversy has been going on for some time, between eminent microscopists, in regard to the advantages of glycerine, on the one hand, representing the aqueous mounting media and balsam, on the other, representing the resinous class. The truth is, that both should be used, as occasion requires. Glycerine, or its equivalents, should be used when it is desired to bring out delicate striæ, lines, hair-like projections, such as cilia on the epithelium of the respiratory tract, processes of the ganglionic nerve cells, and so forth, and for delicate vegetable preparations. Balsam should be used when clearness and transparency of the object, and brilliancy as well as durability of the staining is desired.

In order to clearly understand this the student will do well to mount two preparations of the same tissue, the one in balsam, or other resinous medium, and the other in glycerine or its equivalent, and then compare the results. He will find that the one medium is better suited for a particular preparation than the other.

Balsam. Among all resinous substances Canada balsam is the best for mounting purposes, provided it has been properly prepared. To do this, take a clear sample of balsam and evaporate it in a water bath, to dryness, that is, until, when hot, all odor of turpentine has disappeared, and, when cold, it is hard and brittle, like resin. This will take several days; and great care should be exercised in keeping the water bath full of water, for as soon as the temperature in the balsam is raised above 212° F. it turns brown, and is then unfit for use.

When thus evaporated the balsam is again heated in the water bath and enough of Squibb's absolute alcohol is added to dissolve it and make the solution of the consistency of thin syrup. It is now allowed to cool and poured into a spirit lamp, the wick having been removed, in which it is kept for use, the glass cap of the lamp protecting it from dust and preventing the evaporation of the alcohol. If, after using for some time, the solution becomes too thick, it should be warmed by placing the spirit lamp in warm water and adding to it some warm absolute alcohol. If the alcohol used in dissolving the balsam or in diluting the solution is not strong enough, a white precipitate will form, which may be redissolved by the application of heat, but will reappear when exposed to the air, in a thin layer on the

slide, and the solution thus becomes useless for mounting.

Having cleaned his slides and covers, and having his balsam solution prepared, the student may now proceed to mount the objects in the following way: Place one of the stained sections which have been kept in alcohol in a small shallow dish containing some absolute alcohol, and allow it to remain there for some minutes, so as to remove all traces of water which may remain in it from the staining fluid and which have not been removed by the washing in the weaker alcohols. Then float it on the surface of some oil of cloves, also contained in a shallow glass or porcelain dish, until it has become transparent, when it should be removed from the oil, spread out on a glass slide and covered with a thin cover glass which has been taken from the bottle filled with alcohol and wiped dry with a soft rag. The specimen is now ready to be examined under the microscope, in order to see whether it will pay to permanently mount it in balsam. If found good the cover glass is carefully removed and all superfluous oil remaining on the section and on the slide is taken up with the edge of a piece of blotting paper, the object covered with a drop of the balsam solution, a fresh, dry cover is placed upon it, taking care to exclude any air bubbles, and pressure is made upon the cover to press out all superfluous balsam. In order to prevent the formation of air bubbles in the specimen the cover should be held by the forceps, near the edge, the opposite edge should be carefully placed into the balsam and the cover gradually lowered over the section until it lies flat upon it. If, after pressing the cover down, it is found that the balsam does not extend to the edge of the cover all round, a small drop of balsam should be placed near the edge, at the point where the balsam under the cover joins the empty space, when it will run in by capillary attraction. The slide is then laid aside to allow the balsam to dry spontaneously, which will take place in from four to six weeks, or it may be placed in a drying oven, the temperature of which is not raised above 130° F., when it will be ready for finishing in a much shorter time. An excellent apparatus of this kind is sold by dealers in microscopical appliances. It consists of a box of copper containing movable trays, surrounded by another larger box, also of copper, so that a space remains between the two boxes, which, when the oven is used, is filled with water through an opening at the top. A thermometer is inserted through this opening, and a lamp is placed under the outer box, which raises the temperature of the water up to any desired degree, and thereby warms the air in the inner box. A current of air is established through the inner box by ventilators, both at the top and bottom. Specimens which have been double stained with indigo should not be exposed to either heat or sunlight, as they will fade under these circumstances.

The fact that the oil of cloves or other volatile oils which may be used in its stead shrink many of the more delicate tissues, and the difficulty attending the removal of large thin sections from one solution to the other, as well as the danger of tearing while they are spread upon the slide, has led the author to discard the oil of cloves as a clearing agent, and to adopt a plan of mounting in balsam, which avoids all these dangers and which has the advantage that the slides may be finished immediately.

MOUNTING IN BALSAM.

After one of a number of sections which have been stained together has been examined in oil of cloves, and has been found to be good, the others may be inferred to be also good and worth mounting. One of them is placed in absolute alcohol, and after it has remained therein for some time, is floated upon a cover glass, which need not be wiped dry after taking it from the bottle of alcohol in which the covers are kept, held in a pair of forceps whose ends have been bent so as to stand at right angles to the shafts, and to close on top of each other. The cover with the section on it is then lifted out of the alcohol, when the specimen will be found to be evenly spread out, needing but little unfolding at the edges, which sometimes fold over; the lower surface is to be wiped dry and a drop of the alcoholic solution of balsam is placed on the section, which, on the cover, is set aside in a place free from dust, to clear up and allow the balsam to get dry. After fifteen or twenty minutes another drop of balsam should be placed upon it, in order to prevent the drying of the tissue. After twelve hours the balsam has dried sufficiently on the cover so that the specimen can be mounted, in the following manner: Take the cover up with a pair of forceps and place a drop of crude benzole* on the balsam and quickly place the cover, with the balsam down, on a clean slide, as near the centre as possible, and taking care to avoid air bubbles. Then warm the slide over a spirit lamp, place on a turn-table and quickly centre the cover so that its edge does not seem to shake when the slide is rapidly revolved. Next run a ring of cement around the edge, as will be described presently, and then press gently upon the cover, to cause the section to lie flat, and to press out the surplus of balsam, which, with a little management of the pressure, will run into the ring of cement. Another ring of cement may then be applied, when the slide is ready to be labeled and put away.

The cement for balsam mounting which is most satisfactory was devised by Mr. T. W. Starr, of Philadelphia, and is prepared as follows:

Clear Canada balsam,	370 grains.
Deodorized benzine,	140 grains.
Spirits turpentine,	120 grains.
Gum dammar,	185 grains.

Mix the balsam and benzine well together in a bottle, then add the turpentine and shake until mixed; finally, add the gum dammar, in selected pieces, and shake frequently till dissolved. If necessary, the solution should be filtered through absorbent cotton, previously moistened with turpentine. A portion of this is to be placed in a small glass-capped vial, to the cap of which is attached a small *sable* brush, which will come to a point, the ordinary camel's hair brush not being suitable for ringing, as it spreads too much. If the solution is too thick to flow readily it should be diluted with spirits of turpentine until the proper consistency is obtained. This fluid is also an excellent mounting medium when the object has previously been cleared in oil of cloves or turpentine. For ringing, this cement may be colored by adding to it a few drops of alcoholic solution of aniline of any shade desired, or it may be mixed with white zinc, when the resulting ring will appear as if made of porcelain.

The specimen to be ringed is placed upon the turn-table, and if any balsam has soiled the slide or the cover it must be removed by scraping with a sharp knife and afterward wiping with a soft linen rag wet with benzole. As a matter of course, the balsam should be hard, so that the cover will not be displaced by the scraping and wiping. If the cover should not be in the centre, and a self-centering turn-table is used, the slide is to be warmed until the balsam becomes soft, when the cover may be centered on the turn-table. Having thus prepared the slide, the brush in the cement bottle is removed and the surplus scraped off, so that it is almost dry; with the left hand the turn-table is spun round rapidly and the point of the brush applied to the edge of the cover for a moment only, holding the brush slanting in

*The refined benzole or benzine, which is frequently sold for benzole, is to volatile for our purposes.

the right hand, and that hand resting upon the stand of the table. The brush is then moistened a little more with the cement and again applied to the edge of the cover, without, however, allowing the hair of the brush to touch the glass; the small drop at the point of the brush only should be in contact with the glass and be carried around by the rapid spinning of the turn-table. The slide is then set aside so as to allow the ring to become thick by evaporation of the benzine and turpentine, when the applications of cement may be repeated until the desired thickness is obtained.

If colored or white zinc cement is to be used it should not be applied until after the first rings of clear cement have become hard, as otherwise the colored cement will run in under the cover and be disseminated among the mounting medium. If white zinc cement has been used, it may be still further improved by running one or two fine lines of asphaltum varnish around it, but not before the cement has thoroughly hardened.

The making of a neat ring around the edge of the cover is an art which can only be acquired by practice and experience, and therefore a few hints in regard to the causes of failure will greatly help the beginner.

If the ring, when finished, shows irregularties both at its inner and outer edge, the cement used is too thick and should be diluted with turpentine. If the ring is too broad—wider than about one-thirty-second of an inch, unless intentionally widened—the brush has been pressed down too hard upon the glass, which causes it to spread, or too much of the cement has been applied at once. This is especially the cause when irregularities or bulging in the edges of the ring are noticed.

If the ring is filled with minute air bubbles, the brush has been kept too long in contact with the glass in making the first ring, or its point has been brought in contact with the first ring in making the second application, when only the minute drop should have touched the glass; or, finally, the solution may be too thick.

MOUNTING IN GLYCERINE.

When a preparation is to be mounted in glycerine, it should, after having been stained, be placed in dilute glycerine for twenty-four hours, and then for the same length of time in strong glycerine (Bower's), in order to make it transparent. The section is then carefully spread upon the slide; a clean cover, which has been wiped dry, is placed upon it and pressed down, to remove the excess of glycerine from under the cover, and a small spring-clip is applied, so as to hold the cover in position during the subsequent manipulation of washing. The excess of glycerine must now be removed as carefully as possible by washing it off with a stream of water, either from a syringe or from a tap, taking care not to displace the cover in doing so. The slide is then stood on edge to dry, the spring-clip still holding the cover, and when all the water has evaporated it is ready for ringing. In order to do this the spring-clip must be removed, the slide placed upon the turn-table, the cover centered and a ring of some water-proof cement applied, in the manner described above.

The best cements for this purpose are, first, the so-called Bell's cement, which may be obtained from any dealer in microscopical supplies, and the composition of which is a secret with the makers; and second, the author's gelatine cement, which is prepared as follows:

Take of—

Coxe's gelatine,	2 drachms.
Gum ammoniac,	10 grains,
Acetic acid, No. 8,	1 ounce.

Dissolve the gum ammoniac in the acetic acid and filter through absorbent cotton; then warm the acid and gum solution by placing the vessel containing it in a water bath and add the gelatine, stirring until it is dissolved, when the resulting solution should be filtered or strained through muslin. After a ring of this cement has been made around the edge of the cover, and has become set, it should be painted over with a solution of bichromate of potash in water (ten grains to the ounce) and exposed to either sunlight or ordinary daylight. The action of the light is to make the chromate of gelatine which has been formed insoluble and thus perfectly waterproof. After this gelatine cement ring has become hard, it should be covered with a ring of white zinc cement, when it will be found that none of the glycerine will leak out, even after the specimen has been kept for years.

If thicker pieces than thin sections, such as pieces of the mucous membrane of the intestine or bladder of animals, are to be mounted in glycerine or other watery medium, a cell must be employed. This consists of a ring made of either glass, rubber, metal or cement, and which is high enough to prevent the cover-glass from pressing upon the specimen when mounted. In order to do so, the ring, if it be of glass, rubber or metal, is first cemented upon the slide with marine glue or the gelatine cement, and is accurately centered with the turn-table. If the cell is to be made of cement a ring of the required diameter (which must be a little smaller than the diameter of the cover-glass) is spun upon a slide in the same manner as was described for applying the ring to the edge of the cover in finishing slides, and is built up to the required height by repeated applications of the brush. It should then be set aside to dry and harden. Any of the cements may be used for this purpose, provided they will stick well to the glass.

Just before mounting the top of the ring forming the cell must be moistened with gelatine cement; the specimen, which has been made transparent by soaking in glycerine, is then placed in the centre of the ring, enough glycerine is added to fill the cell and the cover is applied. If an air bubble is left under the cover the latter must be lifted up and more glycerine must be added; if, on the other hand, too much liquid has been used, the surplus must be washed off, as described above. A ring of gelatine or Bell's cement is next spun around the edge of the cover, in order to seal up the cell, and it is then finished with white zinc cement.

An excellent substitute for glycerine is Farrant's solution, which combines all the advantages of glycerine and some of those of balsam, inasmuch as it has nearly the same index of refraction as glycerine, and becomes hard like balsam, doing away with the necessity of a waterproof cement. The formula generally given in the text-books for this solution is not correct, and the author has found that the following formula is more satisfactory:—

Picked gum arabic,	4 drachms.
Camphor water,	4 fl drachms.
Glycerine,	2 fl drachms.

Dissolve and strain through muslin.

Specimens to be mounted in this medium must first be made transparent by soaking in strong glycerine, and may then be mounted as though the solution were a resinous mounting medium. Great care should be taken to exclude air bubbles, as they cannot afterward be gotten rid of. This medium is especially adapted for delicate animal membranes and soft vegetable tissues.

Some specimens, especially vegetables, such as seeds, pollen grains, sections of wood, etc., may often with advantage, be mounted dry, *i. e.*, without much previous preparation, and without any mounting medium, but they must then be examined as opaque objects, and must be viewed by reflected light.

If an object is to be thus mounted, a disk is painted with asphaltum varnish in the centre of the slide, which is spun around upon the turn-table while applying the brush with varnish. A disk of dead black paper may

be pasted upon the slide, instead of the disk of varnish, to serve as a dark background. A cell ring is then applied around the edge of the disk, and the object is fastened in the centre of the cell by means of mucilage or glue. This done, the cover is placed upon the ring and cemented down as described above.—(*Compendium of Microscopical Technology.*)

THE DEARBORN OBSERVATORY.

The annual report of the Board of Directors of the Chicago Astronomical Society, together with the report of the Director of the Dearborn Observatory, dated May, 1881, is now published.

The first report is brief, and states that the Society has entered into a contract with the city of Chicago for furnishing standard time to the City Hall. In order that this contract may be more satisfactorily fulfilled, the Directors of the Society have ordered from Messrs. Howard & Co., of Boston, two new clocks, which will cost about $1000. The cost of running wires and other equipments has been $574.

The friends of the Society have contributed the funds required to meet the immediate wants of the Observatory, but the Society reiterate the often-repeated call for a permanent endowment, which will not only enable it to continue its present course of action, but to enlarge its sphere of astronomical work and take an honorable place among the prominent astronomical Observatories of Europe and America. The Directors express a hope that the time has arrived when the public-spirited citizens of Chicago will contribute the amount to accomplish this object, and we heartily trust that the confidence expressed in this respect may receive a prompt confirmation. The Dearborn Observatory is built and equipped with one of the finest equatorials in the United States; the question of endowment is therefore one which calls for immediate action.

In the second report Professsr G. H. Hough states the nature and amount of the astronomical work carried on at the Dearborn Observatory during the past year by himself and Messrs. Elias Colbert and S. W. Burnham.

The planet Jupiter has received the attention of a large number of astronomers during the past two years, especially of amateurs, and much writing of a miscellaneous character has appeared on the subject. As the proper study of markings and spots on celestial objects require the use of a telescope of great optical power, combined with good definition, the following report of observations on the planet Jupiter, made with the Dearborn equatorial, which possesses these conditions, will be read with interest, especially as they do not confirm many observations made under less favorable circumstances.

The planet Jupiter was made a special study during the past year. The first observation was secured on May 6, 1880, and the last on January 30, 1881. During this period the various spots and markings on his disc were subjected to micrometer measurements whenever practicable. It is readily apparent to any one who has examined contemporaneous drawings or sketches made by different observers and telescopes, that they are generally unreliable, unless based on micrometer measurement, and frequently give rise to erroneous deductions with regard to the phenomena in question. We believe the time has passed when mere estimations or sketches are of value in any department of practical Astronomy. Jupiter presents such a variety of phenomena on his disc, at different times, that it has been accepted as an established fact that his surface is subject to sudden and rapid changes, which may be accomplished in a few days or even a few hours.

The observations made at the Dearborn Observatory during the past two years does not confirm this statement. On the contrary, all minor changes in the markings or spots have been slow and gradual, such as might be produced by the operation of measurable mechanical forces. In fact, the principal features have been permanent, no material change being detected by micrometer measurement.

The following is a summary of the observations on Jupiter:

GREAT RED SPOT.

Longitude,	37 nights	560 measures.
Latitude,	12 "	34 "
Length,	20 "	67 "
Breadth,	10 "	32 "
Position of maj. axis,	5 "	16 "
Total		709 "

EQUATORIAL BELT.

Observed on 26 nights—	
Position of the North Edge	87 measures.
Latitude " "	34 "
Width of the Belt	53 "
Total	174 "

EQUATORIAL WHITE SPOTS.

Observed on 18 nights—	
Longitude	240 measures.
Latitude	15 "
Total	255 "

POLAR SPOTS.

Observed on 22 nights—	
Longitude	144 measures.
Latitude	40 "
Total	184 "

Being a total of 1,379 micrometer measurements.

From the micrometer measurements for longitude of spots, the equatorial diameter of the planet is deduced on 50 different nights, and from the latitude measures, the polar diameter on 13 nights.

The following deductions have been drawn from these observations.

ROTATION OF JUPITER.

The period of the planet's rotation, as obtained by different observers, has varied between $9^h\ 49^m$ and $9^h\ 56^m$. The observations made on the great red spot during the opposition of 1879, gave for the rotation period about $9^h\ 55^m\ 34^s$; being 8 seconds greater than the previously accepted value.

The discussion of our longitude measures on the great red spot, made from September 25, 1879, to January 27, 1881, comprising a period of 490 days, gives for the mean value $9^h\ 55^m\ 35.2^s$,

When the individual observations are compared, however, with this value, there is found to be a well marked maximum displacement of the center of the spot amounting to $1''.4$ of arc, indicating that the center gradually oscillated to this extent in longitude, corresponding to an actual displacement on the surface of Jupiter 3,200 miles.

The observations are all well represented by making the rotation period depend on some function of the time.

The period $9^h\ 55^m\ 33.2^s + 0.18^s \sqrt{t}$ satisfies all the observations with a mean maximum error of $0''.5$ of arc. In which the zero epoch is September 25, 1879, and t is the number of days after that date.

This formula gives for the rotation at the date January 27, 1881, $9^h\ 55^m\ 37.2^s$, agreeing essentially with the value deduced directly from the observations made during the two months previous to that date.

The rotation period derived from the observation of polar spots was as follows;

	Latitude.	Longitude.	Interval Between Extreme Observations.	Rotation.
White Spot	+10″.46	3^h 00^m	2 months.	9^h 55^m 39.3^s
White "	−11″.62	3^h 57^m	2 "	31.0^s
White "	—11″.62	4^h 26^m	2 "	33.6^s
Black "	+10″.40	0^h $0c^m$	2 "	31.0^s
Black "	+ 9″.70	2^h 22^m	1 "	40.5^s
Mean of all	--------	-------	--------	9^h 55^m 35.1^s

The latitude is simply the measured distance north or south of the Jovian equator, reduced to the mean distance of the planet from the earth. The zero of longitude is the center of the great red spot.

The white spots were egg-shaped, about 1″ of arc in length, and were only visible under favorable atmospheric conditions.

The rotation period derived from the small spots indicates an average displacement during two months of 2″ of arc, or 4,600 miles, or an average drift in longitude of nearly 3 miles per hour.

ROTATION FROM EQUATORIAL SPOTS.

From July 8 to October 1, 1880, comprising a period of 85 days, the longitude of a white spot, between the equatorial belts, in latitude 2″.3, was observed on 10 nights. The rotation, as deduced from this spot, was 9^h 50^m 00.56^s, representing all the observations within 0″.3 of arc, showing that the motion, so far as we know, was absolutely uniform. From October 28, 1880, to January 30, 1881, during a period of 94 days, another white spot, in latitude 2″.8, and differing 20 deg. in longitude from the first, was observed on 8 nights.

The rotation was 9^h 50^m $09^s.8$, with uniform motion.

If the great red spot is supposed fixed, then the mean drift of the equatorial spots would be about 270 miles per hour in the direction of the planet's rotation, or the spot made a complete revolution around the planet in about 42 days.

The approximate diameter of the equatorial white spots was 1″.2 of arc, or 2,800 miles.

These observations leave the true period of the rotation of Jupiter in a very unsettled condition. The great red spot was frequently measured to ascertain whether it was subject to any marked change, in position, size or shape.

The following are the mean results for the two oppositions of 1879 and 1880, reduced to the mean distance of the planet from the earth:

	1879.	No. of Obs.	1880.	No. of Obs.
Length	12″.25*	9	11″.55	20
Breadth	3″.46	8	3″.54	10
Latitude	6″.95	8	7″.14	12

* Re-computed with the constants of 188 .

The position of the major axis of the spot was measured as follows, the number indicating the inclination of the axis of Jupiter's equator as compared with Marth's ephemeris.

1880, July 27 + 2°.3
" Aug. 6 + 2°.5
" Sept. 4 + 2°.9
" Dec. 3 + 2°.2
1881, Jan. 17 — 0°.8. Definition poor.

These numbers indicate a remarkable degree of permanency with regard to the size, shape and position of the spot, during the two oppositions. Our observations do not warrant the assumption of any considerable change since September 25, 1879.

The actual size of the object, as seen with our telescope, was as follows:

Length, 29,600 miles.
Breadth, 8,300 "

The smaller telescopes make the approximate length considerably less than the real value.

POLAR BELTS.

During the opposition of 1880 the polar belts were not as sharply defined as during 1879, with the exception of Nos. 2 and 3, the latter of which became very conspicuous. During the month of June, when the planet was at about mean distance, no trace of polar markings could be seen. And it was not until July 4, when the distance was 0.948, that the belts 2 and 3 were barely visible. Markings on the southern hemisphere were first seen on July 24, when the distance of the planet from the earth was 0.888.

The latitude of 2 and 3 was as follows:

	1879.	1880.
No. 2,	+ 9″.78	+ 9″.75
No. 3,	+ 5″.98	+ 5″.89

EQUATORIAL BELT.

The great equatorial belt remained without any material change in size or position, as the following measurements will show:

	1879.	1880.
Latitude N. Edge,	+ 2″.59	+ 2″.35
Width	6″.77	7″.04

During both years the position of the north-edge was parallel to Jupiter's equator, as given in Marth's ephemeris.

PHENOMENA.

When a satellite crosses the disc of the planet it usually disappears in our telescope, when one-fourth to one-third across the disk, and reappears at an equal distance from the preceding limb, proving that the center of the disc is more luminous than the satellite.

In the case of the first satellite, it is sometimes seen to transit as a grayish spot, and remains visible when on the middle of the disc; such a phenomenon was observed on December 10, 1880.

On July 3, 1880, the second satellite during transit passed almost directly over the center of the great red spot, when it appeared sensibly as bright as when off the disc.

On November 1, 1880, I had the good fortuue to witness the transit of the shadow of the second satellite over the center of the red spot, and, at the same time, the transit of the shadow of the first satellite over the disc of the planet.

The shadow of the satellite, when fully projected on the red spot, was distinctly visible, but not quite as black as the shadow on the disc, proving that the red spot, although much less luminous than the disc, was yet much more luminous than the shadow.

THEORY OF JUPITER.

The generally accepted theory is, that the planet Jupiter is surrounded by a dense atmosphere, that the belts are the solid portions of the planet, and that the minor spots are clouds floating in the atmosphere. It is difficult, if not impossible, to reconcile the known phenomena with any theory yet proposed. But whether there are a sufficient number of well determined facts to form a better one, is doubtful.

Accurate observations are needed on the markings seen at different times on his disc; not sketches and general statements, but suitable micrometer measurements, from which may be deduced the motions and changes taking place on the surface. And until this method is pursued there is but little hope of solving the problem of his physical constitution.

It has occurred to me, however, that the known phenomena might be explained in the following hypothesis, viz: the surface of the planet is covered with a liquid

semi-incandescent mass; that the belts, the great red spot and other dark markings, are composed of matter of lower temperature. The egg-shaped, polar white spots are openings in the semi-fluid crust. This hypothesis would account for the slow and gradual changes occurring on the surface, which does not seem reasonable on the simple atmospheric theory.

Over the liquid surface is an atmosphere in which is formed the equatorial white spots which are of the nature of cloud.

In conclusion the director expresses what we can well believe to be his sincere regrets at the loss of the valuable services of Mr. S. W. Burnham, who has accepted a position in the Washburne Observatory, at Madison, Wis. During the past year Mr. Burnham, as heretofore, had the use of the great equatorial for double-star observations, and reported the discovery since May, 1880, of about fifty new double-stars, all of which were measured at least three times. About one-half of the number are close double, not exceeding 1″.5 in distance. Among the more prominent stars are 9 persei, 5 persei, κ pegasi, γ foracis and 60 arietis. He also made about 600 measures on previously-known double-stars.

DR. COPELAND and Mr. Dreyer have been compelled to change the title of *Urania*, as it appears that name was appropriated by some *astrological* serial. In future, then, *Urania*, the astronomical serial, will bear the title *Copernicus*.

IT is rumored that Prof. Huxley will be asked to allow his name to be entered for the Linacre professor of physiology vacant by the death of Prof. Rolleston.

COMET (*b*) 1881.

The following observations of the Great Comet of 1881, made at Australian Observatories, have been kindly furnished for publication by Professor Wm. Harkness, U. S. N., to whom they were communicated by Mr. Todd, Superintendent of the Adelaide Observatory.

SATURDAY, AUGUST 20, 1881.

The International Electrical Exhibition at Paris was opened with much *éclat* on the 10th instant by the President of the French Republic.

The brief telegraphic dispatches describing the event, all state that Edison's exhibit was the chief centre of attraction, and that great interest was shown for the forthcoming exhibition of certain novelties which he had sent. These appeared to prove that the energies of the great electrician were far from exhausted on this subject, and that his fertile brain is as active as ever.

We are promised a very detailed report of this exhibition, so defer particulars until it arrives. England and Germany occupy the largest space of the foreign countries represented, America and Belgium coming next in order. All the departments on the day of opening were incomplete, the Americans complaining much of the dilatory behavior of the French workmen, who seemed to have no idea of the value of time.

We presume that the object of exhibitions of this character is to stimulate those engaged in electrical investigations, and to form landmarks in the history of electrical progress. In that light the Exhibition has many advantages, but Edison appears to have suffered from his generous permission to permit all comers to inspect the progress of his inventions. Many misinterpreted what they saw, and came to false conclusions, while men of no mental endowment who were mere clever mechanics, assiduously appropriated the ideas of the man of brains, and have since produced barefaced copies. These men have so far proceeded unchecked, but the time appears to have arrived when Edison has decided to enforce with vigor all those patent rights which he has secured after so many years of patient study and unremitting toil, involving the outlay of an immense amount of money.

The seizure of the "*Maxim*" electric lamps at the Paris International Exhibition appears to have been directed in consequence of such a decision, and we can assure Mr. Edison that the public will heartily sympathize with him in his attempt to enforce his just rights.

We are informed by cable that Sir George Biddell Airy has retired from the office of Astronomer Royal, and his successor appointed.

Sir George was born on the 27th of July, 1801, and was elected a Fellow of Trinity College in 1824. He commenced his career as a scientific teacher in 1826, when he was elected Lucasian Professor. In 1828 he was elected Plumian Professor, and entrusted with the management of the Observatory at Cambridge which had been just then erected and supplied with one of its instruments. On taking charge of the new Observatory he commenced a series of observations, but his able services there will be best remembered by the admirable methods he introduced in the calculations and observations, by which their utility was greatly increased.

Professor Airy had also the satisfaction of superintending the mounting of the Equatorial, the Mural Circle and the Northumberland Telescope (the last entirely from his own plans), at the Cambridge University.

In the autumn of 1835 the office of Astronomer Royal became vacant by the resignation of Mr. John Pond, and at the request of Lord Auckland, Airy received the appointment for this distinguished office, which he has since filled with so much benefit to science and honor to his country, for a period which has covered nearly half a century.

In 1833 he received the gold medal of the Royal Astronomical Society "for his discovery of the long Inequality of Venus and the Earth;" and again in 1846, for his "Reduction of the Observation of Planets made at the Royal Observatory, Greenwich, from 1750 to 1830."

We have the pleasure of directing the attention of our subscribers to a very interesting work by A. B. Hervey, A. M., on "*Sea Mosses*," being both a collector's guide and an introduction to the Study of Marine Algæ. It is published by S. E. Cassino, of Boston. In another part of this issue will be found an extended extract from this book, giving Mr. Hervey's methods of collecting and preserving specimens, and the article will, doubtless, be read with interest at this season, when so many are at the seashore, with full opportunities for commencing the study of this department of Cryptogamic Botany.

SEA MOSSES—TIME AND PLACE FOR COLLECTING.*

Most collecting on our Atlantic coast will be done during the summer and early autumn months. But I must remind those of you who live by the sea, or have it accessible at all times, that many things of the greatest beauty and interest will be missed if you do not go to the shore early. Our finest *Callithamnion C. Americanus* can be had in its rarest beauty early in March and even in February. The finest varieties of our *Rhodomela subfusca* are only to be found in the early spring months. This is true of many other plants. You will be surprised, also, to see what quantities of things you can find as late as November and December. Indeed, if you are to know these plants thoroughly, you must collect them at all seasons of the year. Then you will know when they come and when they go, and when they are in their greatest perfection. Those living and collecting on the Pacific coast are not fenced away by an icy wall, as we are on our shores during two or three months of our hard, inclement winters; so they can collect the year around. Dr. Anderson assures me that most of them are more beautiful and of more luxuriant growth during the Summer than during the Winter months. In general, there are three principal places for collecting "Sea Mosses" by the shore.

First, from the mass of material which the sea throws up upon the beaches, and leaves behind it when the tide goes out. This will be your main resource for getting the plants that grow in deep water. By many causes they will be loosened from their holdings in the depths, and will then float up to the surface and margin of the sea, and will be cast on shore. By carefully turning over these masses, which will be found along almost every sandy or pebbly beach, you will be able to get plants which could otherwise be found only by dredging in deep water. And, by careful search, too, among this material you will find all the deep water forms.

Second, upon the rocks and in the tide pools when the tide is out.

You can collect living plants in their native homes here only. Of course, no Algæ grow upon the sandy beaches. You must, therefore, seek all such as grow between the tide-marks upon rocky shores. Put on a pair of stout rubber boots, and go two or three hours before low tide, and search in every place, following the tide down to its farthest retreat. Many of the best things are found close down by low water mark, and some a little below that. These latter can be got best by taking advantage of the extreme low run of tide which comes about "new" and "full moon." The advantage of going before low tide and following the retreating water down is that you are not so apt to get a drenching, by the unexpected advance of a great wave, as when the tide is coming in; for, if you are close by the water's edge when the tide is rising, busily intent upon getting your floral treasures, you will very likely find yourself soaked with brine, for

"The breaking waves dash high
On a stern and rock-bound coast."

In hunting through the tidal region for plants, hunt everywhere, and collect everything found growing, and when collected, like Captain Cuttle, "make a note of it." If you cannot remember without, carry a small memorandum book and enter in it the habitat of each particular kind as you collect it. The tide pools, that is, the little basins in the rocks out of which the water is never emptied, are the places where the choicest collecting may be had. And the nearer they are to the low tide limits the more likely they will be to have abundance of vegetable life in them. But do not fail to look, also, under the overhanging curtain of "Rockweed" which shadows the perpendicular sides of the cliffs and great boulders. You will often find some beautiful plants there, as, for instance, the *Ptilota elegans*, the *Cladophora rupestris* and other smaller "mosses."

Third, by standing on some low, projecting reef, by the side of which the tide currents rush in and out, you will see many of the more delicate, deep water forms, all spread out beautifully and displayed in all their native grace, carried past, back and forth, in the water. Many of these, like the *Polysiphoniæ*, are seldom thrown on shore in good condition, or if they are, do not long remain so. This, therefore, is by far the best place to take many of these plants. To do this you must be provided with some simple instrument for reaching down into the water, and seize them as they go floating by. I have found nothing more convenient for this than a wire skimmer, which can be got at any house-furnishing tin shop, tied with a stout string to a light, strong stick, five or six feet long. The water passes through the meshes of this with little resistance, but the Alga, with its delicate branches thrown out widely in every direction, is very readily caught by it. It will also serve to a limited extent as an implement for detaching plants from their holdings which grow in deep tide pools, or in the sea, not too far below low water mark. For the rest of your

COLLECTING APPARATUS

you may have as little or as much as is convenient. A simple basket or box, with a few newspapers in it to wrap up and keep somewhat separate the different sorts of your collectings, will do very well. If it is convenient, have a case made with a half-dozen or less wide-mouthed bottles set in it, each provided with a cork. The case should also have a compartment for storing coarse plants, newspapers, paper bags, or whatever you may use for keeping different species, or the plants from different localities separate. Then, as your plants are collected, they may be roughly sorted and put in different bottles. But two or three bottles should be reserved for the most delicate and fragile forms. And as there are several of them which rapidly perish on being exposed to the air, the bottles should be kept partly filled with sea-water. The more delicate *Polysiphonias*, the *Calithamnions*, *Dasyas*, and some others, will need this protection. I have found a quart fruit-jar very handy. I get the kind that I can fasten a string around the neck, so as to carry it suspended in one hand, which leaves the other always free to gather in the plants with. A jar, whose cover goes on and off with the least possible trouble, is the one to be selected. The only disadvantage in using a receptacle of this sort for your collection is that in climbing over the wet and mossy rocks, your feet may chance to slip, and you get a tumble; then, in your efforts to save yourself, you will forget all about your fragile glass jar, and will smash it into a thousand pieces, upon the hard stones, and perhaps lose your whole collection. But two or three of these jars carefully packed in a basket, so as not to be easily broken, would perhaps, furnish as handy a collecting apparatus as you could extemporize at the sea shore.

MOUNTING AND PRESERVING.

For "floating out" your "Sea Mosses," as it is called, you should have a pair of pliers, a pair of scissors, a stick like a common cedar "pen stalk," with a needle driven into the end of it, or, in lack of that, any stick carefully sharpened; two or three large, white dishes, like "wash bowls," botanists drying paper, or common blotting-paper, pieces of cotton cloth, old cotton is the best; and the necessary cards or paper for mounting the plants on.

You will use the pliers in handling your plants in the water. The scissors you will need for trimming off the superfluous branches of plants which are too bushy to look well, when spread upon the paper, and to cut away parasites. The needle should be driven point first, a considerable distance into the stick, so as to make it firm, and

* From *Sea Mosses*—by A. B. Hervey—S. E. Cassino, Boston.

allow you to use the blunt end of it in arranging the finer details of your plant on the paper. For drying paper, of course, you can use common newspapers, by putting many thicknesses together; and a great many, no doubt, will do that. But sheets of blotting paper will be found much more satisfactory; twenty-five of them cut into quarters would probably be all you would use, and those you could easily take in your trunks. What will be found cheaper and still more serviceable, if you are going to mount a large number of plants at once, is a quantity of botanist's "drying paper." It can be had of the "Naturalists' Agency," 32 Hawley street, Boston, Mass., for, I believe, $1.25 per 100 sheets; probably also of other sellers of Naturalists' supplies in all the large cities on both sides of the continent. It is a coarse, spongy, brown felt paper, cut into sheets 12 x 18 inches, and has a fine capacity for absorbing moisture. For convenience, the cotton cloths should be made the same size as the drying paper used. Some collectors, who do not care to mount a great number of specimens at once, but want to have them very smooth and fine, when dry, use no drying paper at all, but in the place of it, have thin smooth pieces of deal, got out a foot or so square and one-quarter or one-third of an inch thick; upon these they spread one or more layers of cotton and lay the plant on them and put as many more over it; the cotton absorbs the moisture and the boards keep the pressure even and the papers and the plants straight and smooth throughout. For "mounting paper" each one must use his own taste. Many prefer cards cut of uniform size; they can be had at almost any paper store or job printing office made to order. Four and a half by six and a half inches, is a neat and convenient size. But if you want to mount several hundred or several thousand spceimens, in the course of a season, so as to have some to give to your friends, and to make up a number of books or albums, to sell at Church or Charity fairs, then perhaps the expense will be an item worth considering. In that case you will find it cheaper to buy a few quires of good 26 or 28 pound demy paper, unruled of course. The paper is in unfolded sheets 16 x 21 and will cut into convenient sizes for mounting any plants ordinarily collected. By halving it you have sheets 8 x 21, or 10½ x 16 inches. By quartering, the sheets are 8 x 10½ inches; halving these you get an octavo sheet 5¼ x 8 inches, which is quite large enough for the majority of plants. One half of this will give a sheet 4 x 5¼ inches which will be the size most used; while the smallest plants look best on the half of these sheets, 2½ x 4 inches.

With your large white dishes filled near to the brim with sea water, or, if you are away from the ocean with water made artificially salt, take a few of your plants from the collecting case, and put them in one of the dishes. Here, handling them with your pliers, shake them out and clean them of any adhering sand or shells, trim away parasites and superfluous branches and generally make them ready for "floating out." Thence, transfer them to the other dish. Then take your card or your paper, selecting a piece large enough to give the plant ample room, and leave a margin of white all around, and having dipped it in the water put it quite under the floating plant, holding the paper with your left hand and managing it with your right. Now float the plant out over the paper and draw the root or the base of it up near the end of the paper next your hand, so that you can hold it down on the paper with the thumb of the left hand, the rest of the hand being under the paper in the water. Now, slowly lift the paper up to the surface and draw it out of the water in such a way that the water will flow off from it in two or three directions. This will spread the plant out somewhat evenly over the paper. But in many cases you will need to arrange the plants in their most natural and graceful position, and also take care that they do not get massed upon each other, and make unsightly heaps while others are left bare. They should be carefully arranged so as to make the most beautiful picture possible. In some fine and delicate plants, too much care cannot be bestowed, in having the remote branchlets all naturally disposed and spread out. This final work of arranging details, you will do with your needle while you hold the paper very near to the surface of the water with your left hand, so near, indeed, that there will be just water enough, and no more, above it to float the delicate parts which you are manipulating. Oftentimes it will be found convenient, after the paper with the plant on it has been removed from the water, to re-immerse a part of it at a time and re-arrange the several parts separately. But all this can easily be done, more easily than I can tell how to do it. A very little practice will give you the "knack" perfectly. And, indeed, these plants are by no means refractory, or hard to manage. They will do anything you can reasonably want them to, while you humor them by keeping them in their native element. In fact, you will commonly need to do no more with them, than to just help them to do what they are willing and disposed to do themselves. For if you will let them take on your paper the form and outline which they have by nature in the water, there will be nothing left to desire, for their color, form and movement all combine there to make them the loveliest and most graceful things that grow. When you have put the last finishing touches upon the "floating" process and your "Sea Moss" is adjusted on your paper so as to be "a thing of beauty and a joy forever," then you want to lay the paper upon some inclined surface—any smooth board will do—to drain away the superfluous water. Thence it is to be transferred, in a few moments, to the press, for drying.

This is made in the following manner: Laying down one of the above described sheets of blotting paper, botanists' "drying paper" or boards of muslin-covered deal, you lay your paper with the plant on it upon this, the plant up. Cover the board or drying paper all over with "floated" specimens in the same way. Over all, and lying directly upon the plants spread your piece of muslin. Upon this put another sheet of the paper, or board, and upon this again a layer of plants, then a piece of the muslin, more paper, plants, muslin, and so on until you have disposed of all your collection, or so much of it as you care to mount. Upon the last layer of plants put a final sheet of paper, and over all a stout board as large as the drying paper. Upon this lay some heavy weights—stones will be as handy as anything at the seaside. I should put on, I think, about fifty pounds of them if I were using botanist's drying paper, which has a good deal of give in it. With the use of boards, unless there are a good many thicknesses of muslin, it would not do to weight it so heavily, or some of the plants would be crushed beyond recognition. I use the drying paper and always have two boards, one for the bottom and one for the top of my press. Then when I have made the pile complete, I can put it aside in some convenient corner out of the way, and set the stones to work bearing down upon it, a business for which they seem to have some conspicuous and weighty gifts.

Some botanists recommend that the drying paper be removed in the course of five or six hours, and the cloths and papers again in twenty-four hours. This will, perhaps, be the best if anyone has plenty of time. But my practice has always been to let them lie twenty-four hours and then give them a change of both cloths and papers, being careful in removing the cloths so as not to lift the plants from the mounting paper.

The second time in the press they should be subject to a harder pressure, seventy-five or one hundred pounds of stone being not too much. In twenty-four hours more most of them will be quite dry and ready to be put into your herbarium, album, or whatever you use for the final disposition of them. Those that are not perfectly dry should be put back in the press with dry papers and cloths for another day's stay.

When the plant is perfectly dry and removed from the press you should, before putting it away and forgetting these facts, write on the back of the paper the exact date and place of collecting.

People often ask me what I use to make the plants stick so firmly to the paper, supposing, evidently, that it is necessary to have some kind of gum or mucilage for that purpose. I have to answer that I have for most of them to use nothing whatever; that there is sufficient gelatinous mat'er in the body of the plant to make it perfectly adhere to the paper without other aid. And the reason for putting the muslin over the plants in the process of pressing and drying is, that they may not stick to the drying paper which is above them, the muslin not adhering to the plants at all except in some few cases.

But a considerable number of "Sea Mosses" do not adhere to paper well. They either have not gelatinous matter enough in them or will not give it out to glue their bodies to the paper. Various devices are resorted to in these cases. Sometimes the plant, after being dried in the press in the usual way, is simply strapped down with slips of gummed paper. Sometimes they are fastened down with some kind of adhesive substance, after being dried, gum tragacanth being the best for this. Others take them and float them out a second time in skimmed milk and after wiping off the milk from the paper, from the plants, except directly under the plants, put them in the press to dry again, when, it is said, they stay. I have never tried this method. A friend of mine who is famous for the artistic way in which she always "lays out" her "Sea Mosses" tells me that for these forms which lack what the Phrenolcgist might call "adhesiveness" she prepares from the "Irish Moss" *Chrondus crispus* a semi-fluid paste, into which she dips them before putting them on paper, and then carefully removes all of it from the paper and plant, except what is between the two and then put them in the press. By this means they are made to stick "like paper on the wall."

In preparing the coarser "Rockweed" and "Kelp" for the herbarium, another method will have to be persued. These will almost all turn very dark, or quite black, in the process of drying. I am accustomed to treat them by the following method: Taking them home, I spread them out in some shady place and let them lie for a few hours, perhaps twenty-four, perhaps less or more, until most of the water in them has evaporated, but not till they have become hard, stiff and brittle. Then I put them between sheets of drying paper and lay them in the press, and keep them there until the process of drying is complete. A little practice will be the only way by which you will be able to tell if they have been dried long enough in the open air. If you find them inclined to mould while kept in the press, you may be sure they are not dry enough, throw them away and get some new ones.

It is sometimes desirable to keep the treasures we have gathered from the sea unmounted, that we may carry them away to await a more convenient season for floating them out, or that we may send them to some friend or correspondent on the other side of the continent, or beyond the seas. It is, therefore, fortunate that all but the more delicate and perishable of these plants, may be dried rough, rolled up and kept any length of time, transported around the world, and then, when put in water again, will come out in half an hour, as fresh and bright and supple and graceful as they were when taken from their briny home. The friend just referred to assured me that even the *Callithamnia*, *Dasyæ* and the most delicate *Polysiphoniæ*, and such like plants, may be so treated by first shaking the wa'er out of them, and then thoroughly mingling them with dry seasand, and drying them rough in the usual way. She says the sand will adhere to the most delicate fibres and ramuli of the plant in such a way as to keep them separate and prevent their getting glued together, then, when they are afterwards soaked out, the sand will be disengaged, and the plant will be left as good as ever it was. Perhaps I ought to suggest that "soaking out" should always be done with salt water, unless you know you have only those plants which fresh water will not hurt. When I have had specimens of the "Rockweed," or "Kelp," sent to me "rough dried," I have found it best to prepare them for mounting, not by immersing them in water, and so get a great quantity of moisture into them, which would have to be expelled afterwards, with no little trouble, but by wrapping them about with wet towels; from these they would imbibe enough dampness to be manageable, and not enough to make them troublesome.

Before taking leave of this part of my subject I must permit myself to add a word to a point which botanists commonly think too little about, viz., the display of taste in the mounting of their plants. To the mere botanist a plant is a *specimen* of a given genus and species, interesting only for that fact. If it is a full grown typical form with fruit, all the better. Now, all are not botanists. Most of those who will read these pages will have an interest in these plants, to which the scientific interest will be secondary. I want to say then to them, look for the best things; get the whole plant when you can, but get and preserve the most perfect and beautiful plants. It is the rule with botanists to put but one species on each paper or card. I certainly advise disregarding this rule, unless you are mounting for scientific purposes altogether or chiefly. With numberless shades of red, which one group of "Sea Mosses" will give you, with the various kinds of green the other two will present, you will have an opportunity to display all the taste and skill you are master of. For in combining several different colors and forms on the same paper you may often produce the most brilliant results. A little practice will soon make you able to handle two or three plants at the same time in "floating them out" almost as readily as you can manage one. Then, again, you will find it possible with some of the more slender plants to work interesting and beautiful "designs" in the same way. Initial letters, even monograms, may not be beyond your reach with a little care and practice. Let the "Sea Mosses" contribute to the cultivation of every faculty and all possible means of pleasure for you.

For preserving your treasures after they are neatly mounted, pressed and dried, you have two courses open to you. You can take care of them as the botanist does by arranging them systematically in a herbarium, with covers of stout manilla paper, folded 10½ x 16 inches for each genus, and the species separated by white sheets of thinner cover, or you can provide yourself with blank books, made for the purpose, having the leaves cut to fit the sizes of paper or card which you mount your plants on, so as to slip the corners of the cards into the cuts. It is well in that case to provide a book with leaves large enough to hold two or four cards each. By following the directions here given I cannot doubt you will soon become a successful collector, and an expert in mounting and preserving "Sea Mosses."

ACCORDING to M. Chappuis (*Bull. Soc. Chim.*) the phosphorescence of phosphorus vapor by ozone. Phosphorus is not luminous in pure oxygen at 15°, and at the ordinary pressure, introduction of a trace of ozone causes luminosity; those substances which hinder the luminosity of phosphorus, *e. g.* turpentine oil, are substances which destroy ozone. If a little turpentine oil is brought along with phosphorus into a tube containing pure oxygen, and a small quantity of ozone is then passed in, the phosphorus exhibits its luminosity for a few moments only; M. Chappuis supposes that this is due to the combustion of phosphorus vapor by the ozone, and that the transiency of the phenomenon is explained by the rapid removal of the ozone by the turpentine oil.

THE ROTATORY POWER OF COMMERCIAL GLUCOSE AND GRAPE SUGAR. A METHOD OF DETERMINING THE AMOUNT OF REDUCING SUBSTANCE PRESENT BY THE POLARISCOPE.

BY PROF. W. H. WILEY.

From the Journal of the American Chemical Society, Vol. II.

In "the trade" the name of grape sugar is applied only to the solid product obtained from corn starch. On the other hand, the term "glucose" is given to the thick syrup made from the same material.

I shall use these words in their commercial sense.

INSTRUMENTS EMPLOYED.

I used in the following investigations two polariscopes made by Franz Schmidt and Haensch, Berlin. The readings of these instruments, after correction for displacement, agreed well together.

The one was the instrument ordinarily used, in which the purple ray is employed, and the quartz half moons give blue and red tints.

Both of these instruments are graduated to read 100 divisions, each equal to one per cent sugar with a solution containing 26.048 grms. pure cane sugar in 100 c.c. In addition to this scale the half shadow has another which gives the actual angular rotation.

This is especially convenient when the specific rotatory power of a substance is to be determined. The angular rotation, however, can be calculated for the former instrument.

For if we take the specific rotatory power of cane sugar at 73.8°, we have the following equation:

$$73.8 = \frac{a \times 100}{2 \times 26.048} \text{ whence } a = 38^\circ.45.$$

Each division on the cane sugar scale is therefore equal to 0°.3845 angular measure.

This quantity corresponds to the transition tint. It is different for the differently colored rays. In the half shadow polariscope, an instrument particularly adapted to persons afflicted with any degree of color-blindness, the mono-chromatic light coming from the sodium-Bunsen lamp passes through a crystal of acid potassium chromate. The ray thus produced is less rotatable than the "transition tint."

When the instrument gives 100 divisions on the sugar scale, it shows an angular rotation of only $34^\circ 42' = 34^\circ.7$. Our division, therefore, of the sugar scale, is equal to 0°.347 angular measure.

To determine the specific rotatory power of cane sugar for the sodium-acid potassium chromate ray, we use the following equation:

$$\text{Sp. rot. pr.} = \frac{34^\circ.7 \times 100}{2 \times 26.048} = 66^\circ.6.$$

To determine the specific rotatory power for any other substance which has been determined for the transition tint, we multiply by the factor 0.9024.

Thus, if we take the specific rotatory power for any other substance which has been determined for the transition tint, we multiply by the factor 0.9024.

Thus, if we take the specific rotatory power of dextrine for the transition tint at 139°, for the half shadow tint it will be $139^\circ \times 0.9024 = 125^\circ.4$.

These data rest upon the accepted formula:

$$(1)\ \theta = \frac{a}{\varepsilon.\ \delta.\ \lambda}$$

$$(2)\ \theta = \frac{a \times v}{\lambda \times w}$$

Here a = angular rotation.
θ = specific rotatory power.
ε = amount of substance in one grm. of the solution.
δ = specific gravity of solution.
λ = length of observation tube.
w = weight of substance in grms.

MATERIAL.

The glucose studied in the following examinations, was made by the Peoria Grape Sugar Company. I am under obligations to Mr. Allen, the superintendent, for many favors in connection with my work. The grape sugars were made in Buffalo.

ROTATORY POWER.

The average value of θ for the "half shadow ray" is nearly 85°. For the purple ray it is nearly 94°. It however varies extremely in different samples.

The following table will show the range of these variations.

TABLE I.

Showing variations of θ in different specimens of glucose and grape sugar, together with the specific gravities of the same.

No.	θ	Sp. Gr.	No.	θ	Sp. Gr.
1	91.50	1.406	11	89.36	1.416
2	91.50	1.407	12	87.73	1.422
3	98.10	1.440	13	89.77	1.417
4	79.93	1.414	14	70.84	1.463
5	75.47	1.414	15	69.40	1.463
6	83.97	1.417	16	87.67	1.412
7	82.75	1.416	17	109.99	1.427
8	86.41	1.415	18	93.17	1.431
9	84.11	1.416	19	89.75	1.409
10	87.19	1.417	20	91.31	1.421

From a study of this table it is seen that within small limits θ is independent of the specific gravity of the solution. Nos. 14 and 15 were grape sugar, and the specific gravity is much higher here than in the glucose, while the value of θ is much less.

Where the increase in density, however, is considerable, as in 3 and 17, there is also a marked increase in the value of θ, although this increase is not proportional to the increment of specific gravity. In masses of homogeneous nature and structure we should expect *a priori* that θ would always be proportional to the density of the body, *i. e.*, to the amount of optically active matter in a unit number of grammes.

It is thus seen without further argument that commercial glucoses are not optically homogeneous, even when made in the same factory and by processes which do not sensibly vary.

A further study of these optical reactions convinced me that the rotatory power of commercial glucose increased as the percentage of reducing substance diminished.

The following table shows the value of θ and the corresponding percentage of reducing matter as obtained by Fehling's solution.

TABLE II.

No.	θ	% Glucose.	No.	θ	% Glucose.
1	91.50	53.20	11	89.63	53.50
2	91.50	52.36	12	87.73	56.49
3	98.10	54.60	13	89.77	52.36
4	79.93	61.73	14	70.84	69.93
5	75.47	62.50	15	69.40	69.30
6	83.97	59.35	16	87.67	56.34
7	82.75	61.40	17	109.99	39.22
8	86.41	58.80	18	93.17	57.14
9	84.11	58.55	19	89.75	54.37
10	89.19	55.60	20	91.31	56.81

It will be seen by the above table that as the per cent

of reducing matter increases, the value of θ diminishes, and *vice versa*. Nos. 14 and 17 show extreme cases of this law. Nos. 3, 18 and 20, because of their high specific gravities, should not be included in the above generalization. Having thus established the law that the per cent of reducing matter is in general inversely as the value of θ, it is next proposed to investigate the relation between these two quantities, and determine whether it is constant or variable.

From Nos. 1 and 2, of table II, it is seen that for a value of $\theta = 91.50$, the percentage of reducing matter is 52.78. Let us say for convenience in calculation that $\theta = 91.50$ corresponds to reducing substance = 53 per cent. Let us consider next, some of the cases which the value of θ differs widely from 91.50. No. 17 of above table affords an example.

The difference is, 109.99—91.50 = 18.49. The difference in the per cent of reducing substance is 53—39.22 = 13.78. Thus an excess of the value of θ of 18.49 corresponds to a deficit of 13.78 in the percentage of reducing matter.

Therefore a variation of each degree in the value of θ is equivalent to 0.745 in the percentage of a reducing matter. By similar calculations with the other data furnished by the table, I have found, not including Nos. 3, 18 and 20, marked by the high specific gravity, that this number lies between 75 and 78.

I will give the calculation for the first of these numbers, and compare them with the numbers obtained by analysis.

TABLE III.

NUMBER.	Variation of Θ	% Glucose by 0.75 Factor.	% Glucose by Fehling's Sol.
1	0.00	53.00	53.20
2	0.00	53.00	52.36
3	—12.08	62.06	61.73
4	—16.03	65.03	62.50
5	— 7.53	58.64	59.35
6	— 8.75	59.57	61.40
7	— 5.07	56.81	58.80
8	— 7.44	58.58	58.55
9	— 4.30	56.21	56.60
10	— 2.14	54.62	53.50
11	— 3.77	55.82	56.49
12	— 1.73	54.29	56.18
13	—20.66	58.32	69.93
14	—22.10	69.56	69.30
15	— 3.83	55.88	56.09
16	+18.49	39.14	39.22
17	— 1.75	54.32	54.05
18	— 0.19	53.14	56.81
19	+ 6.60	47.15	54.60
20	+ 1.66	51.75	57.14

In the above table, Nos. 18, 19 and 20 are the three specimens with high specific gravity. We will, therefore, exclude them from the discussion. In the other numbers the percentage of reducing matter, as calculated from the reading of the polariscope, falls short of the amount obtained by the alkaline copper test ten times, and by an average of 1.018. It exceeds that amount seven times with an average of 0.75. We thus see that the polariscope will enable us to compute the reducing matter present in a glucose with a probable error of less than one per cent. This is quite accurate enough for practical purposes.

Perhaps a larger number of determinations should be made before constructing a formula for determining the amount of reducing in substance a "straight" glucose. The following formulæ, however, are given provisionally, subject to some slight correction derived from more extended data.

We may have three cases:

1. The value of Θ = 91.50
2. " " < 91.50
3. " " > 91.50

In the first case the percentage of reducing substance in a glucose, if not far from 1.410 sp. gr., will be nearly 53.

In the second case the required percentage may be found by the following formula, in which a = difference between the value of θ and 91.50, and g = per cent reducing required—

$$g = 53 + 0.75\,a \text{ or } 0.78\,a.$$

In the third case we have

$$g = 53 - 0.75\,a \text{ or } 0.78\,a.$$

In order to make the principle of more general application, I have modified the calculations so as to apply the formula directly to the cane sugar scale of the instrument.

To this end, for instruments using 26.048 grammes for 100 divisions, it is convenient to use only 10 grms. of the glucose. If 26.048 grms. are employed, the neutral point is thrown entirely beyond the limit of the scale. Ten grammes is the quantity which has been employed in the following table.

The average reading of the sugar scale for ten grammes is about 50.

In the following table will be found the results of the experiments.

TABLE IV.

NUMBER.	Scale.	% Reducing Substance by Calculation.	% Same by Cu. Test.	Difference.
1	52.65	53.43	53.20	+0.23
2	52.65	53.43	52.36	+1.07
3	46.07	61.66	61.73	—0.07
4	43.05	64.90	62.50	+2.40
5	48.04	58.75	59.35	—0.60
6	47.70	59.63	61.40	—1.77
7	49.80	57.00	58.80	—1.80
8	48.45	58.56	58.55	+0.01
9	50.26	56.45	55.60	+0.85
10	51.50	54.88	53.50	+1.30
11	50.57	56.04	56.49	—0.45
12	51.74	54.58	56.18	—1.60
13	40.83	68.21	69.93	—1.72
14	40.00	69.25	69.80	—0.05
15	50.53	56.09	56.34	—0.27
16	63.80	39.50	39.22	+0.28
17	51.73	54.37	54.05	+0.32
18	52.63	53.46	56.81	
19	56.53	48.59	54.60	
20	53.70	52.10	57.14	

The above calculations were made from the following data.

Starting with Nos. 1 and 2, and discarding small fractions, we find that 53 divisions of the cane sugar scale correspond to 53 per cent of reducing matter nearly.

By a method of calculation entirely similar to that employed in determining the reducing matter from the fluctuations of Θ, I have found that a variation of one degree in the sugar scale corresponds to an inverse variation of nearly 1.25 per cent of reducing substance.

We may have as in the previous calculation three cases.

1st. The reading of the scale = 53
2d. " " " " > 53
3d. " " " " < 53

In the first case 53 = 58 per cent nearly.

In the second case, placing a for the reading of the scale, we have

$$g = 53 - (a - 53)\ 1.25$$

In the third case we have

$$g = 53 + (53 - a)\ 1.25$$

In seven of the first seventeen cases the percentage of reducing substance calculated by the above formula, exceeded that given by the copper test, and by a mean amount of 0.539.

In ten of them it fell short, and by a mean amount of 0.938. This method, therefore, can be relied upon to give results which do not vary from the copper test except by a small amount.

Not much more in the way of accuracy can be claimed for the copper test itself.

In Nos. 18, 19 and 20 we have again the cases where the high specific gravities vitiate the results of the calculation.

CORRECTION FOR SPECIFIC GRAVITY.

I next proceeded to find out a method for correcting the reading of the polariscope for variations, caused by changes in the specific gravity of the specimens. First I determined the percentage of water in glucose of different specific gravities; following are the results:

I.

Sp. gr. = 1.440
Weight taken = 5.515. in Pt. dish.
Loss = 0.35, at 170°, 2 hours.
Per cent H_2O = 0.35 ÷ 5.515 = 6,37.

II.

Sp. gr. = 1.431
Weight taken = 5.86
Loss = 0.53, 170°, 2 hours.
Per cent H_2O = 0.53 ÷ 5.89 = 9.05.

III.

Sp. gr. = 1.409
Weight taken = 4.038
Loss = 0.622, 170°, 3 hours.
Per cent H_2O = 15.40

IV.

Sp. gr. = 1.416
Weight taken = 4.425
Loss = 0.525, 170°, 2 hours.
Per cent H_2O = 11.93

V.

Sp. gr. = 1.417
Weight taken = 8.639
Loss = 1.091, 170°, 3 hours.
Per cent H_2O = 12.70

VI.

SOLID GRAPE SUGAR.

Sp. gr. = 1.463
Weight taken = 7.215, 170°, 3 hours.
Loss = 0.61
Per cent H_2O = 9.29

These data are scarcely sufficient to establish a rule for correction for variations in specific gravity, but it appears from them that the formulæ will not vary much from the following:

The rule, 53 divisions = 53 per cent, seems applicable to samples in which the percentage of H_2O is 12 to 14, and of which the sp. gr. is from 1.409 to 1.414. For each variation of 0.001 in the specific gravity, the percentage of H_2O varies about 0.3.

Thus if we take the two extreme cases, viz.: 6.37 and 15.14 per cent of H_2O, we find the corresponding specific gravities to be 1.440 and 1.409, a difference of 0.031.

The difference in the percentage of water is 9.03. The quotient of 0.0903 ÷ 0.031 = 3 nearly.

Let us apply these data to the correction of Nos. 18, 19 and 20 in table IV. I give below these numbers and also their corrections.

TABLE V.

NUMBER.	Scale.	% Reducing Substance by Calculation.	Same Corrected.	Same by Cu. Sol.
18	52.63	53.46	55.83	56.81
19	56.53	48.59	55.17	54.60
20	53.70	52.10	56.55	51.14

The above corrections were based on the supposition that 53 divisions of the scale correspond to 53 per cent reducing matter, when the sp. gr. = 1.409, and the percentage of water 15.

We may therefore construct the following provisional formulæ for estimating the correction to be applied to the reading of the scale when the sp. gr. of the specimen varies much from 1.409.

Let a = reading of scale.
" a' = corrected reading.
" ε = sp. gr. of the sample.

Then $a' = a - 3a(\varepsilon - 1.409)$, when the sp. gr. is greater than 1.409, and $a' = a + 3a(1.409 - \varepsilon)$, when ε is less than 1.409.

I next propose to undertake some investigations to show the nature and number of the optically active principles present in glucose.

THE UNITY OF NATURE.

BY THE DUKE OF ARGYLL.

X.

THE ORIGIN OF RELIGION CONSIDERED IN THE LIGHT OF THE UNITY OF NATURE.

(Concluded.)

IN the beginning of this chapter I have observed how little we think of the assumptions which are involved in putting such questions as that respecting the origin of Religion. And here we have come to a point in our investigations at which it is very needful to remember again what some of these assumptions are. In order to do so let us look back for a moment and see where we stand.

We have found the clearest evidence that there is a special tendency in religious conceptions to run into developments of corruption and decay. We have seen the best reasons to believe that the religion of savages, like their other peculiarities, is the result of this kind of evolution. We have found in the most ancient records of the Aryan language proof that the indications of religious thought are higher, simpler, and purer as we go back in time, until at last, in the very oldest compositions of human speech which have come down to us, we find the Divine Being spoken of in the sublime language which forms the opening of the Lord's Prayer. The date in absolute chronology of the oldest Vedic literature does not seem to be known. Professor Max Müller, however, considers that it may possibly take us back 5000 years.[1] This is probably an extreme estimate, and Professor Monier Williams seems to refer the most ancient Vedic hymns to a period not much more remote than 1500 B. C.[2] But whatever that date may be, or the corresponding date of any other very ancient literature, such as the Chinese, or that of the oldest Egyptian papyri, when we go beyond these dates we enter upon a period when we are absolutely without any historical evidence whatever, not only as to the history of Religion, but as to the

[1] Hibbert Lectures, p. 216.
[2] "Hinduism," p. 19.

history and condition of Mankind. We do not know even approximately the time during which he has existed. We do not know the place or the surroundings of his birth. We do not know the steps by which his 'knowledge "grew from more to more." All we can see with certainty is that the earliest inventions of Mankind are the most wonderful that the race has ever made. The first beginnings of human speech must have had their origin in powers of the highest order. The first use of fire and the discovery of the methods by which it can be kindled; the domestication of wild animals; and above all the processes by which the various cereals were first developed out of some wild grasses—these are all discoveries with which in ingenuity and in importance no subsequent discoveries may compare. They are all unknown to history—all lost in the light of an effulgent dawn. In speculating, therefore, on the origin of these things, we must make one or other of two assumptions—either that Man always had the same mental faculties and the same fundamental intellectual constitution that he has now, or that there was a time when these faculties had not yet risen to the level of Humanity, and when his mental constitution was essentially inferior.

On the first of these assumptions we proceed on the safe ground of inquiry from the known to the unknown. We handle a familiar thing; we dissect a known structure; we think of a known agency. We speculate only on the matter of its first behavior. Even in this process we must take a good deal for granted—we must imagine a good deal that is not easily conceivable. I we try to present to our own minds any distinct image of the first Man, whether we supposed him to havef been specially created or gradually developed, we shall soon find that we are talking about a Being and about a condition of things of which science tells us nothing, and of which the imagination even cannot form any definite conception. The temptation to think of that Being as a mere savage is very great, and this theory underlies nine-tenths of all speculations on the subject. But, to say the very least, this may not be true, and valid reasons have been adduced to show that it is in the highest degree improbable. That the first Man should have been born with all the developments of savagery is as impossible as that he should have been born with all the developments of civilization. The next most natural resource we have is to think of the first Man as something like a child. But no man has ever seen a child which never had a parent, or some one to represent a parent. We can form no picture in our mind's eye of the mental condition of the first Man, if we suppose him to have had no communication with, and no instruction from, some Intelligence other than his own. A child that has never known anything, and has never seen example, is a creature of which we have no knowledge, and of which therefore we can form no definite conception. Our power of conceiving things is, of course, no measure of their possibility. But it may be well to observe where the impossibilities of conception are, or may be, of our own making. It is at least possible that the first Man may not have been born or created in the condition which we find to be so inconceivable. He may have been a child, but having, what all other children have, some intimations of Authority and some acquaintance with its Source. At all events, let it be clearly seen that the denial of this possibility is an assumption; and an assumption too which establishes an absolute and radical distinction between childhood as we know it, and the inconceivable conditions of a childhood which was either without Parents, or with Parents who were comparatively beasts. Professor Max Müller has fancied our earliest forefathers as creatures who at first had to be "roused and awakened from mere staring and stolid wonderment," by certain objects "which set them for the first time musing, pondering, and thinking on the visions floating before their eyes." This is a picture evidently framed on the assumption of a Fatherless childhood—of a Being born into the world with all the innate powers of Man, but absolutely deprived of all direct communication with any Mind or Will analogous to his own. No such assumption is admissible as representing any reasonable probability. But at least such imaginings as these about our first parents have reference to their external conditions only, and do not raise the additional difficulties involved in the supposition that the first Man was half a beast.

Very different is the case upon the other of the two assumptions which have been indicated above. On the assumption that there was a time when Man was different in his own proper nature from that nature as we know it now—when he was merely an animal not yet developed into a Man—on this assumption another element of the unknown is introduced, which is an element of absolute confusion. It is impossible to found any reasoning upon data which are not only unknown, but are in themselves unintelligible and inconceivable. Now it seems as if many of those who speculate on the origin of Religion have not clearly made up their minds whether they are proceeding on the first of these assumptions or on the second; that is to say, on the assumption that Man has always been, in respect to faculty, what he now is, or on the assumption that he was once a beast. Perhaps, indeed, it would be strictly true to say that many of those who speculate on the origin of Religion proceed upon the last of these assumptions without avowing it, or even without distinctly recognizing it themselves. It may be well, therefore, to point out here that on this assumption the question cannot be discussed at all. We must begin with Man as Man, when his development or his creation had made him what he is; not indeed as regards the acquisitions of experience or the treasures of knowledge, but what he is in faculty and in power, in the structure and habit of his mind, in the instincts of his intellectual and moral nature.

But, as we have also seen at the beginning of this chapter, there are two other assumptions between which we must choose. Besides assuming something as to the condition and the powers of the first Man, we must also make one or other of two assumptions as to the existence or non-existence of a Being to whom his mind stands in close relation. One is the assumption that there is no God; and then the problem is, how Man came to invent one. The other is that there is a God; and then the question is, whether He first formed, and how long He left, His creature without any intuition or revelation of Himself?

It is really curious to observe in many speculations on the origin of Religion how unconscious the writers are that they are making any assumption at all on this subject. And yet in many cases the assumption distinctly is that, as an objective reality, God does not exist, and that the conception of such a Being is built up gradually out of wonderings and guessings about "the Infinite" and "the Invisible."

On this assumption I confess that it does not appear to me to be possible to give any satisfactory explanation of the origin of Religion. As a matter of fact, we see that the tendency to believe in divine or superhuman Beings is a universal tendency in the human mind. As a matter of fact, also, we see that the conceptions which gather round this belief—the ideas which grow up and are developed from one consequence to another respecting the character of these superhuman Personalities and the relations to mankind—are beyond all comparison the most powerful agencies in molding human nature for evil or for good. There is no question whatever about the fact that the most terrible and destructive customs of barbarian and of savage life are customs more or less directly connected with the growth of religious superstitions. It was the perception of this fact which inspired the intense hatred of Religion, as it was known to

him, which breathes in the memorable poem of Lucretius. In all literature there is no single line more true than the famous line—"Tantum religio potuit suadere malorum." Nor is it less certain, on the other hand, that the highest type of human virtue is that which has been exhibited in some of those whose whole inspiration and rule of life has been founded on religious faith. Religious conceptions have been historically the centre of all authority, and have given their strength to all ideas of moral obligation. Accordingly, we see that the same hatred which inspired Lucretius against Religion because of its power for evil, now inspires other men against it because of its power for good. Those who wish to sever all the bonds which bind human society together, the State, the Church, the Family, and whose spirits are in fierce rebellion against all Law, human or divine, are and must be bitter enemies of Religion. The idea must be unendurable to them of a Ruler who cannot be defied, of a Throne which cannot be overturned, of a Kingdom which endureth throughout all generations. The belief in any Divine Personality as the source of the inexorable laws of Nature is a belief which enforces, as nothing else can enforce, the idea of obligation and the duty of obedience.

It is not possible, in the light of the unity of Nature, to reconcile this close and obvious relation between religious conceptions and the highest conditions of human life with the supposition that these conceptions are nothing but a dream. The power exercised over the mind and conduct of Mankind, by the belief in some Divine Personality with whom they have to do, is a power of having all the marks that indicate an integral part of the system under which we live. But if we are to assume that this belief does not represent a fact, and that its origin is any other than a simple and natural perception of that fact, then this negation must be the groundwork of all speculations on the subject, and must be involved, more or less directly, in every argument we use. But even on this assumption it is not a reasonable explanation of the fundamental postulates of all Religion—namely, the existence of superhuman Beings—to suppose that the idea of personality has been evolved out of that which is impersonal; the idea of Will out of that which has no Intelligence; the idea of life out of that which does not contain it.

On the other hand, if we make the only alternative assumption—namely, that there is a God, that is to say, a Supreme Being, who is the Author of creation,—then the origin of man's perception of this fact ceases to have any mystery other than that which attaches to the origin of every one of the elementary perceptions of his mind and spirit. Not a few of these perceptions tell him of realities which are as invisible as the Godhead. Of his own passions his perception is immediate—of his own love, of his own anger, of his own possession of just authority. The sense of owing obedience may well be as immediate as the sense of a right to claim it. Moreover, seeing the transcendent power of this perception upon his conduct, and, through his conduct, upon his fate, it becomes antecedently probable, in accordance with the analogies of Nature and of all other created Beings, that from the very first, and as part of the outfit of his nature, some knowledge was imparted to him of the existence of his Creator, and of the duty which he owed to Him.

Of the methods by which this knowledge was imparted to him, we are as ignorant as of the methods by which other innate perceptions were implanted in him. But no special difficulty is involved in the origin of a perception which stands in such close relation to the unity of Nature. It has been demanded, indeed, as a postulate in this discussion, that we should discard all notions of antecedent probability—that we should take nothing for granted, except that Man started on his course furnished with what are called his senses, and with nothing more. And this demand may be acceded to, provided it be well understood what our senses are. If by this word we are to understand nothing more than the gates and avenues of approach through which we derive an impression of external objects—our sight, and touch, and smell, and taste, and hearing—then, indeed, it is the most violent of all assumptions that they are the only faculties by which knowledge is acquired. There is no need to put any disparagement on these senses, or to undervalue the work they do. Quite the contrary. It has been shown in a former chapter how securely we may rest on the wonder and on the truthfulness of these faculties as a pledge and guarantee of the truthfulness of other faculties which are conversant with higher things. When we think of the mechanism of the eye, and of the inconceivable minuteness of the ethereal movements which that organ enables us to separate and to discriminate at a glance, we get hold of an idea having an intense interest and a supreme importance. If adjustments so fine and so true as these have been elaborated out of the unities of Nature, whether suddenly by what we imagine as Creation, or slowly by what we call Development, then may we have the firmest confidence that the same law of natural adjustment has prevailed in all the other faculties of the perceiving and conceiving mind. The whole structure of of that mind is, as it were, revealed to be a structure which is in the nature of a growth—a structure whose very property and function it is to take in and assimilate the truths of Nature—and that in an ascending order, according to the rank of those truths in the system and constitution of the Universe. In this connection of thought too great stress cannot be laid on the wonderful language of the senses. In the light of it the whole mind and spirit of Man becomes one great mysterious retina for reflecting the images of Eternal Truth. Our moral and intellectual preceptions of things which, in their very nature, are invisible, come home to us as invested with a new authority. It is the authority of an adjusted structure—the mental organization of which has been molded by what we call natural causes—these being the causes on which the unity of the world depends.

And when we come to consider how this molding, and the molding of the human body, deviates from that of the lower animals, we discover in the nature of this deviation a law which cannot be mistaken. That law points to the higher power and to the higher value in his economy of faculties which lie behind the senses. The human frame diverges from the frame of the brutes, so far as the mere bodily senses are concerned, in the direction of greater helplessness and weakness. Man's sight is less piercing than the eagle's. His hearing is less acute than the owl's or the bat's. His sense of smell may be said hardly to exist at all when it is compared with the exquisite susceptibilities of the deer, of the weasel, or of the fox. The whole principle and plan of structure in the beasts which are supposed to be nearest to him in form, is a principle and a plan which is almost the converse of that on which his structure has been organized. The so-called man-like Apes are highly specialized; Man on the contrary is as highly generalized. They are framed to live almost entirely on trees, and to be dependent on arboreal products, which only a very limited area in the globe can supply. Man is framed to be independent of all local conditions, except indeed those extreme conditions which are incompatible with the maintenance of organic life in any form. If it be true, therefore, that he is descended from some "arboreal animal with pointed ears," he has been modified during the steps of that descent on the principle of depending less on senses such as the lower animals possess, and more and more on what may be called the senses of his mind. The unclothed and unprotected condition of the human body, the total abscence of any organic weapon of defense, the want of teeth adapted even for prehension, and the same want of power for similar purposes in the hands and fingers—these are all changes and departures from the mere animal type which stand in obvious relation to the mental

powers of Man. Apart from these, they are changes which would have placed the new creature at a hopeless disadvantage in the struggle for existence. It is not easy to imagine—indeed, we may safely say that it is impossible to conceive--the condition of things during any intermediate steps in such a process. It seems as if there could be no safety until it had been completed—until the enfeebled physical organization had been supported and reinforced by the new capacities for knowledge and design. This, however, is not the point on which we are dwelling now. We are now speculating on the origin of Man. We are considering him only as he is, and as he must have been since he was Man at all. And in that structure as it is, we see that the bodily senses have a smaller relative importance than in the beasts. To the beasts theses sense tell them all they know. To us they speak but little compared with all that our spirit of interpretation gathers from them. But that spirit of interpretation is in the nature of a sense. In the lower animals every external stimulus moves to some appropriate action. In Man it moves to some appropriate thought. This is an enormous difference; but the principle is the same. We can see that, so far as the mechanism is visible, the plan or the principle of that mechanism is alike. The more clearly we understand that this organic mechanism has been a growth and a development, the more certain we may be that in its structure it is self-adapted, and that in its working it is true. And the same principle applies to those other faculties of our mental constitution which have no outward organ to indicate the machinery through which their operations are conducted. In them the spirit of interpretation is in communication with the realities which lie behind phenomena—with energies which are kindred with its own. And so we come to understand that the processes of Development or of Creation, whatever they may have been, which culminated in the production of a Being such as Man, are processes wholly governed and directed by a law of adjustment between the higher truths which it concerns him most to know, and the evolution of faculties by which alone he could be enabled to apprehend them. There is no difficulty in conceiving these processes carried to the most perfect consummation, as we do see them actually carried to very high degrees of excellence in the case of a few men of extraordinary genius, or of extraordinary virtue. In science the most profound conclusions have been sometimes reached without any process of conscious reasoning. It is clearly the law of our nature, however, that the triumphs of intellect are to be gained only by laborious thought, and by the gains of one generation being made the starting-point for the acquisition of the next. This is the general law. But it is a law which itself assumes certain primary intuitions of the mind as the starting-point of all. If these were wrong, nothing could be right. The whole processes of reasoning would be vitiated from the first. The first man must have had these as perfectly as we now have them, else the earliest steps of reason could never have been taken, the earliest rewards of discovery could never have been secured. But there is this great difference between the moral and the intellectual nature of Man, that whereas in the work of reasoning the perceptions which are primary and intuitive require to be worked out and elaborately applied, in morals the perceptions which are primary are all in all. It is true that here also the applications may be infinite, and the doctrines of Utility have their legitimate application in enforcing, by the sense of obligation, whatever course of conduct Reason may determine to be the most fitting and the best. The sense of obligation in itself is, like the sense of logical sequence, elementary, and, like it, is part and parcel of our mental constitution. But unlike the mere sense of logical sequence, the sense of moral obligation has one necessary and primary application which from the earliest moment of Man's existence may well have been all-sufficient. Obedience to the will of legitimate Authority is, as we have seen in a former chapter, the first duty and the first idea of duty in the mind of every child. If ever there was a man who had no earthly father, or if ever there was a man whose father was, as compared with himself, a beast, it would seem a natural and almost a necessary supposition that, along with his own new and wonderful power of self-consciousness, there should have been associated a consciousness also of the presence and the power of that Creative Energy to which his own development was due. It is not possible for us to conceive what form the consciousness would take. "No man hath seen God at any time." This absolute declaration of one of the Apostles of the Christian Church proves that they accepted, as metaphorical, the literal terms in which the first communications between Man and his Creator are narrated in the Jewish Scriptures. It is not necessary to suppose that the Almighty was seen by His first human creature walking in bodily form in a garden "in the cool of the day." The strong impressions of a spiritual Presence and of spiritual communications which have been the turning-point in the lives of men living in the bustle of a busy and corrupted world, may well have been even more vivid and more immediate when the first "Being worthy to be called a man" stood in this world alone. The light which shone on Paul of Tarsus on the way to Damascus may have been such a light as shone on the father of our race; or the communication may have been what metaphysicians call purely subjective, such as in all ages of the world do sometimes "flash upon that inward eye which is the bliss of solitude." But none the less may they have been direct and overpowering. The earliest and simplest conception of the Divine Nature might well also be the best. And although we are forbidden to suppose the embodiment and visibility of the Godhead, we are not driven to the alternative of concluding that there never could have been anything which is to us unusual in the intimations of His presence. Yet this is another of the unobserved assumptions which are perpetually made—the assumption of an uniformity in Nature which does not exist. That "all things have continued as they are since the beginning" is conceivable. But that all things should have continued as they were since before the beginning is a contradiction in terms. In primeval times many things had then just been done of which we have no knowledge now. When the form of Man had been fashioned and completed for the first time, like and yet unlike to the bodies of the beasts; when all their organs had been lifted to a higher significance in his; when his hands had been liberated from walking and from climbing, and had been elaborated into an instrument of the most subtle and various use; when his feet had been adapted for holding him in the erect position; when his breathing apparatus had been set to musical chords of widest compass and the most exquisite tones; when all his senses had become ministers to a mind endowed with wonder and with reverence, and with reason and with love—then a work had been accomplished such as the world had not known before, and such as has never been repeated since. All the conditions under which that work was carried forward must have been happy conditions—conditions, that is to say, in perfect harmony with its progress and its end. They must have been favorable, first, to the production and then to the use of those higher faculties which separated the new creature from the beasts. They must have been in a corresponding degree adverse to the incompatible with the prevalence of conditions tending to reversion or to degradation in any form. That long and gradual ascent, if we assume it to have been so,—or, as it may have been, that sudden transfiguration,—must have taken place in a congenial air and amid surroundings which lent themselves to so great a change. On every conceivable theory, therefore, of the origin of Man, all this seems a necessity of thought.

But perhaps it seems on the Theory of Development even more a necessity than on any other. It is of the essence of that theory that all things should have worked together for the good of the Being that was to be. On the lowest interpretation, this "toil co-öperant to an end" is always the necessary result of forces ever weaving and ever interwoven. On the higher interpretation it is the same. Only, some Worker is ever behind the work. But under either interpretation the conclusion is the same. That the first man should have been a savage, with instincts and dispositions perverted as they are never perverted among the beasts, is a supposition impossible and inconceivable. Like every other creature, he must have been in harmony with his origin and his end—with the path which had led him to where he stood, with the work which made him what he was. It may well have been part of that work—nay, it seems almost a necessary part of it—to give to this new and wonderful Being some knowledge of his whence and whither—some open vision, some sense and faculty divine.

With arguments so deeply founded on the analogies of Nature in favor of the conclusion that the first Man, though a child in acquired knowledge, must from the first have had instincts and intuitions in harmony with his origin and with his destiny, we must demand the clearest proof from those who assume that he could have had no conception of a Divine Being, and that this was an idea which could only be acquired in time from staring at things too big for him to measure, and from wondering at things too distant for him to reach. Not even his powers could extract from such things that which they do not contain. But in his own Personality, fresh from the hand of Nature,—in his own spirit just issuing from the fountains of its birth,—in his own Will, willing according to the law of its creation,—in his own desire of knowledge,—in his own sense of obligation,—in his own wonder and reverence and awe,—he had all the elements to enable him at once to apprehend, though not to comprehend, the Infinite Being who was the Author of his own.

It is, then, with that intense interest which must ever belong to new evidence in support of fundamental truths that we find these conclusions, founded as they are on the analogies of Nature, confirmed and not disparaged by such facts as can be gathered from other sources of information. Scholars who have begun their search into the origin of Religion in the full acceptance of what may be called the savage theory of the origin of Man—who, captivated by a plausible generalization, had taken it for granted that the farther we go back in time, the more certainly do we find all Religion assuming one or other of the gross and idolatrous forms which have been indiscriminately grouped under the designation of Fetishism—have been driven from this belief by discovering to their surprise that facts do not support the theory. They have found, on the contrary, that up to the farthest limits which are reached by records which are properly historical, and far beyond those limits to the remotest distance which is attained by evidence founded on the analysis of human speeeh, the religious conceptions of men are seen as we go back in time to have been not coarser and coarser, but simpler, purer, higher—so that the very oldest conceptions of the Divine Being of which we have any certain evidence are the simplest and best of all.

In particular, and as a fact of typical significance, we find very clear indications that everywhere Idolatry and Fetishism appear to have been corruptions, whilst the higher and more spiritual conceptions of Religion which lie behind do generally even now survive among idolatrous tribes as vague surmises or as matters of speculative belief. Nowhere even now, it is confessed, is mere Fetishism the whole of the Religion of any people. Everywhere, in so far as the history of it is known, it has been the work of evolution, the development of tendencies which are deviations from older paths. And not less significant is the fact that everywhere in the imagination and traditions of Mankind there is preserved the memory and the belief in a past better than the present. "It is a constant saying," we are told, "among African tribes that formerly heaven was nearer to man than it is now; that the highest God, the Creator Himself, gave formerly lessons of wisdom to human beings; but that afterwards He withdrew from them, and dwells now far from them in heaven." All the Indian races have the same tradition; and it is not easy to conceive how a belief so universal could have risen unless as a survival. It has all the marks of being a memory and not an imagination. It would reconcile the origin of Man with that law which has been elsewhere universal in creation—the law under which every ceature has been produced not only with appropriate powers, but with appropriate instincts and intuitive perceptions for the guidance of these powers in their exercise and use. Many will remember the splendid lines in which Dante has defined this law, and has declared the impossibility of Man having been exempt therefrom:—

> Nell' ordine ch'io dico sono accline
> Tutte nature per diverse sorti
> Più al principio loro, e men vicine;
> Onde si muovono a diversi porti
> Per lo gran mar dell' essere; e ciascuna
> Con istinto a lei dato che la porti.
> * * * * *
> Nè pur le creature, che son fuore
> D'intelligenzia, quest'arco saetta,
> Ma quelle c'hanno intelletto ed amore.[3]

The only mystery which would remain is the mystery which arises out of the fact that somehow those instincts have in Man not only been liable to fail, but that they seem to have acquired apparently an ineradicable tendency to become perverted. But this is a lesser mystery than the mystery which would attach to the original birth or creation of any breature in the condition of a human savage. It is a lesser mystery because it is of the essence of a Being whose Will is comparatively free that he should be able to deviate from his appointed path. The origin of evil may appear to us to be a great mystery. But this at least may be said in mitigation of the difficulty, that without the possibility of evil there could be no possibility of any virtue. Among the lower animals obedience has always been a necessity. In Man it was raised to the dignity of a duty. It is in this great change that we can see and understand how it is that the very elevation of his nature is inseparable from the possibility of a Fall. The mystery, then, which attaches to his condition now is shifted from his endowments and his gifts to the use he made of them. The question of the origin of Religion is merged and lost in the question of the origin of Man. And that other question, how his Religion came to be corrupted, becomes intelligible on the supposition of wilful disobedience with all its consequences having become "inherited and organized in the race." This is the formula of expression which has been invented or accepted by those who do not believe in original instincts or intuitions, even when these are in harmony with the order and with the reasonableness of Nature. It may well therefore be accepted in a case where we have to account for tendencies and propensities which have no such character—which are exceptions to the unity of Nature, and at variance with all that is intelligible in its order, or reasonable in its law.

If all explanation essentially consists in the reduction of phenomena into the terms of human thought and into the analogies of human experience, this is the explanation which can alone reconcile the unquestionable corruption of human character with the analogies of Creation.

---

[3] "Paradiso," canto i. 110-120.

For the present I must bring these papers to a close. If the conclusions to which they point are true, then we have in them some foundation-stones strong enough to bear the weight of an immense, and, indeed, of an immeasurable, superstructure. If the Unity of Nature is not a unity which consists in mere sameness of material, or in mere identity of composition, or in mere uniformity of structure, but a unity which the mind recognizes as the result of operations similar to its own; if man, not in his body only, but in the highest as well as in the lowest attributes of his spirit, is inside this Unity and part of it; if all his powers are, like the instincts of the beasts, founded on a perfect harmony between his faculties and the realities of creation; if the limits of his knowledge do not affect its certainty; if its accepted truthfulness in the lower fields of thought arises out of correspondences and adjustments which are applicable to all the operations of his intellect, and all the energies of his spirit; if the moral character of Man, as it exists now, is the one great anomaly in Nature—the one great exception to its order and to the perfect harmony of its laws; if the corruption of this moral character stands in immediate and necessary connection with rebellion against the Authority on which that order rests; if all ignorance and error and misconception respecting the nature of that Authority and of its commands has been and must be the cause of increasing deviation, disturbance, and perversion, then, indeed, we have a view of things which is full of light. Dark as the difficulties which remain may be, they are not of a kind to undermine all certitude, to discomfit all conviction, and to dissolve all hope. On the contrary, some of these difficulties are seen to be purely artificial and imaginary, whilst many others are exposed to the suspicion of belonging to the same class and category. In some cases our misgivings are shown to be unreasonable, whilst in many other cases, to say the least, doubt is thrown on Doubt. Let destructive criticism do its work. But let that work be itself subjected to the same rigid analysis which it professes to employ. Under the analysis, unless I am much mistaken, the destroyer will be destroyed. That which pretends to be the universal solvant of all knowledge and of all belief, will be found to be destitute of any power to convict of falsehood the universal instinct of Man, that by a careful and conscientious use of the appropriate means he can, and does, attain to a substantial knowledge of the Truth.

ELEMENTS OF COMET (*b*), 1881.

(Communicated by Rear Admiral JOHN RODGERS, Superintendent U. S. Naval Observatory.)

The following elements have been computed by Prof. Frisby, U. S. N., from observations made with the Transit Circle at the Naval Observatory:

Time of perihelion passage, June 16, .37001.

π	=	265°	31′	15.″4
☊	=	270	58	27

SATURDAY, AUGUST 27, 1881.

THE CINCINNATI MEETING OF THE AMERICAN ASSOCIATION FOR THE ADVANCEMENT OF SCIENCE.

The thirtieth meeting of this Society was held at Cincinnati, on the 17th of August and following days, and adjourned on the 23rd.

The meeting opened with some discouraging features, due principally to the marked absence of many of the most prominent members of the Association. Among the absentees we noticed retiring President Lewis E. Morgan, of Rochester; Professor Spencer F. Baird, Professor O. C. Marsh, of Yale; Professor Asaph Hall, of Washington; Professor W. B. Rogers, of Boston; Professor Burt G. Wilder, of Cornell; Professor Simon Newcomb, of Washington; Professor George F. Barker, of Philadelphia; Professor Alexander Graham Bell, of Washington, and Professor Alexander Agassiz, of Cambridge.

It is agreeable to record that in spite of these desertions, which in most cases were unavoidable or due to sickness, the Cincinnati meeting has been in many respects most successful, showing that the "*esprit de corps*" of the great body of the Association is at a high standard and requires no fostering spirit to maintain its vitality.

The following registration shows the attendance of members at the annual meeting since 1869:

1869—Salem	244
1870—Troy	188
1871—Indianapolis	196
1872—Dubuque	164
1873—Portland	195
1874—Hartford	224
1875—Detroit	165
1876—Buffalo	215
1877—Nashville	176
1878—St. Louis	134
1879—Saratoga	256
1880—Boston	997

At the recent Cincinnati meeting the attendance of members was about 550, which compares most favorably with all previous years, excepting the last at Boston, which from various circumstances was a phenomenal year of success.

The growing popularity of the Association, or the increased interest of the masses in scientific matters, is shown by the registration of 400 new names on the roll of the Association, the majority of whom resided in Ohio, Indiana and Kentucky.

An agreeable feature of this meeting was the exhibition of scientific apparatus by those engaged in such manufactures.

Messrs. Beck, Bausch and Lomb, Bullock, Queen & Co., and Sexton for Gundlach showed exhibits, which made it evident that microscopists can command all they desire from the optician, provided the one essential of dollars and cents are within their reach, and even in this respect improvements have been made, which have greatly reduced the expenses of microscopists.

The following gentlemen acted as officers of the association on this occasion.

CINCINNATI, 1881.

President.—George J. Brush, of New Haven, Connecticut.

Vice President, Section A.—William Harkness, of Washington, D. C.

Vice President, Section B.—E. T. Cox, of San Francisco, Cal.

Chairman of Permanent Subsection of Chemistry.—G. C. Caldwell, of Ithaca, N. Y.

Chairman of Permanent Subsection of Microscopy.—A. B. Hervey, of Taunton, Mass.

Chairman of Permanent Subsection of Anthropology.—Garrick Mallery, of Washington, D. C.

Chairman of Permanent Subsection of Entomology.—John G. Morris, of Baltimore, Md.

Permanent Secretary.—F. W. Putnam, of Cambridge, Mass.

General Secretary.—C. V. Riley, of Washington, D. C.

Secretary of Section A.—E. T. Tappan, of Gambier, O.

Secretary of Section B.—Charles S. Minot, of Boston, Mass.

Secretary of Permanent Subsection of Chemistry.—Alfred Springer, Cincinnati, O.

Secretary of Permanent Subsection of Microscopy.—W. H. Seaman, of Washington, D. C.

Secretary of Permanent Subsection of Anthropology.—J. G. Henderson, of Winchester, Ill.

Secretary of Permanent Subsection of Entomology.—B. Pickman Mann, of Cambridge, Mass.

Treasurer.—William S. Vaux, of Philadelphia, Pa.

Nearly two hundred papers, described in the following list, were entered to be read.

TITLES OF PAPERS.

1. Magnetic survey of Missouri.—*Francis E. Nipher.*
2. On the effect of prolonged stress upon the strain in timber.—*R. H. Thurston.*
3. Numerical elements of the orbits of the seven Electrical Vortices, to whose motions atmospheric storms are principally due, with the processes by which they have been derived, and examples given of the application of the formula by which their positions on the surface of the earth can be computed for any given time.—*Thomas Bassnett.*
4. Universal Energy of light.—*Pliny Earl Chase.*
5. A new system of interest, discounts, etc.—*James W. Robinson.*
6. The constitution of the "Atom" of science.—*Mrs. A. B. Blackwell.*
7. Cañons, as I have seen them, with some thoughts as to their origin.—*Wm. Bross.*
8. The unification of geological nomenclature.—*Richard Owen.*
9. Recent discoveries, measurements, and temperature observations made in Mammoth Cave, Ky.—*H. C. Hovey.*
10. A remarkable case of retention of heat by the Earth.—*H. C. Hovey.*
11. Coal dust as an element of danger of mining; shown by the late explosion in the Albion Mines, in Nova Scotia.—*H. C. Hovey.*
12. The successful administration of nitrous-oxide for dental and surgical operations.—*C. P. Howland.*
13. An Iso-picraminic acid.—*Charles W. Dabney, Jr.*
14. Development of Sugar in Maize and Sorghums.—*Peter Collier.*
15. A revision of the anatomy of the ethmoid bone in the mammalia.—*Harrison Allen.*
16. The life unit in plants.—*Byron D. Halsted.*
17. On Bopyrus manhattensis from the gill-cavity of Palæmonetes vulgaris Stimpson.—*Carl F. Gissler.*
18. The uncivilized mind in the presence of higher phases of civilization.—*Otis T. Mason.*
19. The stone images and idols of the mound-builders.—*Wm. McAdams.*
20. Some remarkable relics from mounds in Illinois.—*Wm. McAdams.*
21. Stone implement showing glacier marks.—*Wm. McAdams.*
22. The occurrence of Cretaceous fossils near mouth of Illinois river.—*Wm. McAdams.*
23. Mound-builders' skeleton.—*Watson C. Holbrook.*
24. Stone implements in the drift.—*Watson C. Holbrook.*
25. Prehistoric hieroglyphics.—*Watson C. Holbrook.*
26. A contribution to Croll's theory of secular climatal changes.—*W. J. McGee.*
27. Influence of forests upon streams.—*David D. Thompson.*
28. Alchemy, the cradle of Chemistry. Illustrated by lantern views.—*H. Carrington Bolton.*
29. The great primordial force.—*H. R. Rogers.*
30. "Mixed" or "New Process" sugars. With methods and results of analysis.—*H. W. Wiley.*
31. Amylose. Its nature and method of manufacture. Its optical properties.—*H. W. Wiley.*
32. Relation of reducing power as measured by Fehling's solution to the rotatory power of commercial glucose and grape sugar.—Second paper.—*H. W. Wiley.*
33. On a new material suitable for stop-cocks and stoppers for reagent bottles,—*H. W. Wiley.*
34. The stereoscope, and vision by optic divergence.—*W. Le Conte Stevens.*
35. The nitrogenous constituents of grasses.—*Clifford Richardson.*
36. Mineralogical Notes.—*Benjamin Silliman.*
37. On the influence of the structure of the nerve-fibres upon the production and conduction of nerve-force.—*H. D. Schmidt.*
38. The recurrence of faunas in the Devonian Rocks of New York.—*H. S. Williams.*
39. Note on some Fish remains from the Upper Devonian of New York.—*H. S. Williams.*
40. Note on specimens of Ptilophyton and associated fossils collected by Dr. H. S. Williams, in the Chemung Shales of Ithaca, N. Y.—*J. W. Dawson.*
41. Composition and quality of American Wines.—*Henry B. Parsons.*
42. On Dibromiodacrylic and Chlorbromiodacrylic Acids.—*C. F. Mabery* and *Rachel Lloyd.*
43. On Chlortribrompropionic Acid.—*C. F. Mabery* and *H. C. Weber.*
44. Alhazen's Problem: its history and bibliography, together with various solutions of it.—*Marcus Baker.*
45. Is the law of repetition the Dynamic Law underlying the Science of Chemistry?—*Miss Virginia K. Bowers.*
46. A study of blood during a protracted fast.—*Lester Curtis.*
47. A contribution to the study of Bacterial Organisms, and commonly found on exposed mucus surfaces, and in the alimentary canal of healthy individuals.—*Geo. M. Sternberg.*
48. Suggestions for improvement in the manufacture of glass, and new methods for the construction of large telescopic lenses.—*G. W. Holley.*
49. On the electrical resistance and co-efficient of expansion of incandescent platinum.—*E. L. Nichols.*
50. On recent deep-sea soundings in the Gulf of Mexico and Caribbean Sea, by the U. S. Coast Survey.—*J. E. Hilgard.*
51. Symmetrical method of Elimination in Simple Equations, by the use of some of the principles of Determinants.—*Jas. D. Warner.*
52. A Musical Local-telegraph alphabet.—*William Boyd.*
53. An Improved Sonometer.—*W. Le Conte Stevens.*
54. A new and improved freezing Microtome.—*Thomas Taylor.*
55. A new and Improved Freezing apparatus for use in Surgical and Dental Practice, being a substitute for the ether spray.—*Thomas Taylor.*
56. Bacteria and Micrococci, and their relations to plant culture.—*Thomas Taylor.*
57. Electricity, Magnetism, Gravitation. Their phenomena considered as the manifestation of one force.—*S. S. Parsons.*
58. The Berea Grit of Ohio.—*Edward Orton.*
59. The Gold-bearing drift of Indiana.—*Geo. Sutton.*
60. On the amount of Glacial erosion in Ohio, Indiana and Illinois, with some deductions therefrom.—*E. W. Claypole.*
61. On the Discovery of an Archemediform Tenestellid in the Upper Silurian Rocks of Ohio.—*E. W. Claypole.*
62. Life-history of the Buckeye Stem-borer. *Sericoris instrutana* Clem.—*E. W. Claypole.*
63. Some needed reforms in the use of Botanical Terms.—*Charles R. Ridler.*
64. Digital differentiation.—*A. J. Howe.*
65. The excavation of the Grand Cañon of the Colorado River.—*C. E. Dutton.*
66. On the cause of the Arid climates of the Far West.—*C. E. Dutton.*
67. Evolution and its place in Geology.—*Edward S. Edmunds.*
68. A Short study of the Features of the Region of Lower Great Lakes, during the Great River Age; or notes on the Origin of the Great Lakes of North America.—*J. W. Spencer.*
69. On the inhabitants of N. E. Siberia, commonly called Chukchis and Namollo.—*W. H. Dall.*
70. A Lawgiver of the Stone Age.—*Horatio Hale.*
71. *Ilex cassine*, the Black Drink of the Southern Indians.—*John G. Henderson.*
72. Was the antelope hunted by the Indians on the prairies of Illinois?—*John G. Henderson.*
73. Agriculture and Agricultural Implements of the Ancient Inhabitants of the Mississippi Valley.—*John G. Henderson.*
74. Houses of the Ancient Inhabitants of the Mississippi Valley.—*John G. Henderson.*
75. Comparative Differences in the Iroquis Group of Dialects.—*Mrs. Erminnie A. Smith.*
76. Typical thin sections of the rocks of the cupriferous series in Minnesota.—*N. H. Winchell.*
77. The limited biological importance of synthetic achievements in Organic Chemistry.—*Albert B. Prescott.*
78. On a mesal cusp of the deciduous mandibular canine of the domestic cat, Felis domestica.—*Burt G. Wilder.*

79. Remarks on the Classification and Distribution of Producti.—*S. H. Trowbridge.*
80. Note on a comparison of Newcomb's Tables of Uranus and Neptune, with those of the same planets by Le Verrier.—*D. P. Todd.*
81. The Saroscope: Register of eclipses traced from Eden's prime, 3939 B. C.—*A. W. Brown.*
82. Pentachloramyl formate.—*Alfred Springer.*
83. On the features of Equivalence to Chemical Elements, shown by electricity and heat.—*Samuel J. Wallace.*
84. On a sign of logical connection in Equations.—*Samuel J. Wallace.*
85. On an abbreviation in writing a long series of figures, and its use in calculations.—*Samuel J. Wallace.*
86. Retarded Development in Insects.—*C. V. Riley.*
87. New Insects Injurious to American Agriculture.—*C. V. Riley.*
88. The Egg-case of Hydrophilus triangularis.—*C. V. Riley.*
89. On the Oviposition of Prodoxus decipieus.—*C. V. Riley.*
90. The Cocoon of Gyrinus—*C. V. Riley.*
91. Ozark Highlands.—*G. C. Swallow.*
92.—On the disposition of color—markings of domestic animals.—*Wm. H. Brewer.*
93. On the ancient Japanese bronze belts.—*Edw. S. Morse.*
94. On changes in Mya and Lunatia since the deposition of the New England Shell-heaps.—*Edw. S. Morse.*
95. On worked shells in New England Shell-heaps.—*Edw. S. Morse.*
96. Natural and industrial history of the White Pine in Michigan.—*Wm. Hosea Ballou.*
97 Experiments to determine the comparative strength of globes and cylinders of the same diameter and thickness of sides.—*S. Marsden.*
98 On a convenient method of expressing micrometrically the relation between English and metric units of length on the same scale.—*Wm. A. Rogers* and *Geo. F. Ballou.*
99. Evidence of atomic motion within liquid molecules, as based upon the speed of chemical action.—*R. B. Warder.*
100. On a new method of applying water power of small head to effect the direct compression of air to any required high pressure.—*H. T. Eddy.*
101. A preliminary investigation of two causes of lateral deviation of spherical projectiles based on the kinetic theory of gases.—*H. T. Eddy.*
102. Phenomena of growth in plants.—*D. P. Penhallow.*
103. On the life duration of the Heterocera (moths).—*J. A. Lintner.*
104. On the action of Pilocarpin in changing the color of the human hair.—*D. W. Prentiss.*
105. On a simple method of measuring faint spectra.—*Wm. Harkness.*
106. On the methods of determining the solar parallax, with special reference to the coming transit of Venus. —*Wm. Harkness.*
107. The sources of the nitrogen of plants.—*W. O. Atwater.*
108. The chemistry of fish and invertebrates.—*W. O. Atwater.*
109. The quantitative estimation of nitrogen.—*W. O. Atwater.*
110. The quantitative estimation of Chlorine.—*W. O. Atwater.*
111. Historic Notes on Cosmic Physiology.—*T. Sterry Hunt.*
112. Upon the use of the Induction Balance as a means of determining the location of leaden bullets imbedded in the human body.—*Alexander Graham Bell.*
113. Upon a new form of electric probe.—*Alexander Graham Bell.*
114. The best method of mounting whole chick embryos.—*Charles Sedgwick Minot.*
115. Note on whether man is the highest animal.—*Charles Sedgwick Minot.*
116. Note on the segmentation of the vertebrate body.—*Charles Sedgwick Minot.*
117. The motion of roots in germinating Indian Corn—*W. J. Beal.*
118. Exhibition of some archæological specimens from Missouri.—*S. H. Trowbridge.*
119. Animal myths of the Iroquois.—*Mrs. Erminnie A Smith.*
120 A remarkable invasion of northern New York by a Pyralid Insect (*Crambus vulgivagellus*).—*J. A. Lintner.*
121. On the wave-lengths of the principal lines of the Solar Spectrum.—*T. C. Mendenhall.*
122. How does the bee extend its tongue.—*A. J. Cook.*
123. The Syrian Bees.—*A. J. Cook.*
124 Carbolic acid as a preventive of Insect Ravages.—*A. J. Cook.*
125. A new self-registering Mirror Barometer.—*John R. Paddock.*
126. On the length of life of Butterflies.—*W. H. Edwards.*
127. On certain habits of Heliconia charitonia.—*W. H. Edwards.*
128. Notes on experimental Chemistry.—*Albert B. Prescott.*
129. Additional facts on the fertilization of Yucca.—*Thomas Meehan.*
130. On the Interpretation of of Pictographs by the application of Gesture-signs.—*W. J. Hoffman.*
131. On the great outburst in Comet *b* of 1881, observed at the Cincinnati Observatory.—*Ormond Stone.*
132. An alleged abnormal peculiarity iu the history of Argynnis myrina.—*W. H. Edwards.*
133. Some new forms of apparatus for the chemical laboratory.—*G. C. Caldwell.*
134. Time service, Carleton College Observatory.—*W. W. Payne.*
135. Note on the theory of the flight of elongated projectiles. —*H. T. Eddy.*
136. On the mechanical Principles involved in the flight of the boomerang.—*H. T. Eddy.*
137.—On a convenient form of slide case.—*Robt Brown, Jr.*
138. A filtration evaporation balance.—*H. Carmichael.*
139. The liquifaction of glass in contact with water at 250° c. —*H. Carmichael.*
140. A new Radiometer.—*H. Carmichael.*
141. A new differential Thermometer.—*H. Carmichael.*
142. On some relations of Birds and Insects.—*S. A. Forbes.*
143. Comparison of Maya dates with those of the Christian Era.—*Cyrus Thomas.*
144. A new theory of the formation of Hail.—*Leonard Waldo.*
145. Method of determining the value of the Solar Parallax from meridian observations of Mars.—*J. R. Eastman.*
146. Numbers of cometary orbit relative to perihelion distance.—*H. A. Newton.*
147. Phonetics of the Káyowe language.—*Albert S. Gatschet.*

The next annual meeting of the Association will take place at the City of Montreal under the Presidency of Dr. J. W. Dawson, Principal of McGill College. The election of Dr. Dawson will be a welcome announcement in all scientific circles, and the meeting for 1882 will doubtless be one of the most memorable in the annals of the Association.

We commence this week with the publication of a series of the papers read at the Cincinnati meeting or abstracts prepared by the authors. Those who have not forwarded their communications are requested to do so as soon as convenient. We shall be willing to prepare suitable illustrations, if a request for the same is made at once, to afford time for their preparation.

REPORT ON THE GEOLOGY AND RESOURCES OF THE BLACK HILLS OF DAKOTA. By HENRY NEWTON, E. M., and WALTER P. JENNEY, E. M., Washington, D. C., 1880.

The report on the Black Hills issued six years after the death of its leading observers, to whose name at least it may prove an appropriate monument, comprises the geology, palæontology, mineral resources, lithology and related subjects of interest of that boss of rocks whose circular uplift commands the outstretched plains of central Dakota.

To the *fames sacra auri* may at least be attributed one important service in this connection, as it was a transient disturbance with the Indian settlers, caused by the appearance of gold hunters on their domain, that immediately led to the survey.

The Black Hills had been assigned to the Sioux, and this unauthorized irruption raised the question how far the United States Government might permit a violation of their contract with the Indians, and how much benefit in mineral wealth would accrue to the new explorers and settlers if their incursions were tolerated. To answer more especially this latter question, and to make substantial contributions to general knowledge, the United States Government instituted a survey of this interesting and unknown country, and to Messrs. Jenney, and Newton, was intrusted its management and direction, under the auspices of the Department of the Interior.

After six months spent in this wild and inhospitable region, members of the survey returned, richly provided with means for a more deliberate examination of its character, and scientific aspects in the laboratories and cabinets of the east.

A delay—one of the innumerable hitches incident to congressional apathy or pre-occupancy—in the appropriation of monies for the printing of their report, invited Mr. Newton to revisit the hills in the spring of 1877 to complete his observations, mend or extend his theories, and here he contracted typhoid fever, of which he died—a loss to science, to society and education.

The work begun under his vigorous and intelligent supervision naturally halted, and although many of its various parts were long since completed, it is only now that in a compiled form they appear in print.

Mr. Gilbert edited the work and undertook the difficult and thankless task of deciphering, compacting and evolving from the *disjecta membra* of Mr. Newton's notes, the part devoted to the discussion of the geology, physical and stratigraphical of these hills. It is not difficult to detect the mind and pen of the author of the "Geology of the Henry Mountains," and whether or not the essay would form an exact reproduction of Mr. Newton's views, it is itself a valuable monograph, instructive and suggestive.

The Black Hills cover an area of 850 square miles, rising from the level and uninhabited wastes about them to an altitude at their highest point of nearly 8000 feet, thickly covered with dense and primeval forests of pine, whose condensed shadows from afar hides all else, and for long marches distinguishes these highlands to the approaching traveller.

The Black Hills, briefly, are an uplift of conformable strata, displaying their consecutive beds in symmetrical succession, from a central axis or elevation, disintegrated and channelled, sculptured and modified by subærial and aqueous erasion. The simplicity and perfection of their stratigraphical structure render them comparatively easy of exposition, and make them a capital example of primary sedimentation, possibly to become classic in future illustrations of geological principles.

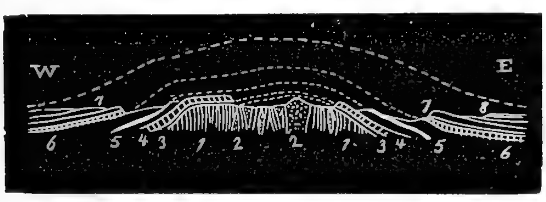
The formations, as they are crossed from the centre of the group outward to the circumference, and similarly disposed on every side—*i. e.*, sloping inward to the centre—are the archæan, Potsdam sandstone, carboniferous, shales and limestone, red beds—Trias, Jura—cretaceous and then beyond, upon the plains Tertiary. The central area is a diversified region abounding in park-like expanses, wild and rugged chasms, peaks, isolated pyramids, picturesque gorges, table-lands and a net-work of enfilading streams pouring outward east and west to swell the waters of the Cheyenne and Belle Fourche rivers. This is the archæan area or axis, upon whose flanks repose the higher strata, and in whose gulches and stream beds were found the traces of gold which first brought these hills to scientific notice. This axis lies generally north and south, is slightly arcuate, with its convexity pointing eastward, and is composed of schists, quartzites, gneiss rock, granite, trachytic intrusions and associated metamorphic slates. The granite and quartzites form salient ridges, and the trachyte sharp peaks in the landscape. Next out-cropping underneath the carboniferous is the Potsdam, unconformably bedded upon the upturned edges of archæan slates, carrying characteristic fossils and made up of basal conglomerate, sandstone locally altered around trachytic cones to quartzite, and calcareous beds. This rock has undergone extensive removal along with

the carboniferous strata which surmounts it; indeed, according to the results of the survey, has been removed from the entire uncovered archæan nucleus. Here a remarkable gap occurs; the next succeeding formation is the carboniferous, and we pass from the primordial at one step to the end of the palæozoic strata, with the striking omission of the Silurian and Devonian systems. We are then told that the carboniferous limestone overlies *conformably* this lower rock—a statement hardly credible—that its hard and resistant strata rise in conspicuous relief like an amphitheatric wall around the included and debased archæan area, with a talus of *debris* composed of its own and Potsdam fragments, piled upon its sides. Beyond the mural escarpments of the carboniferous, a trough-like valley encircles the latter formation like a moat, the bottom of which is formed of the Red Beds, probably Trias or Jura. These consist of marls and clays, sandstone or limestone bands, whose soft material has been easily and largely removed. Beyond this again, and rising from it in steep cliffs, the mechanical basis of the cretaceous is met—the Dakota Sandstone—forming the foot hills which encircle as a final group this geological unit. Beyond again stretches the plains of tertiary strata.

The history of the Black Hills, as written by this survey, is this: A low archæan area primarily, whose erasion and degradation has furnished the sands, and fragments of which the Potsdam sandstones, conglomerate, and quartzites have been formed, has been finally overlaid upon submergence with a regular but unconformable sheet of Potsdam rock. The dome thus made has been lifted from the water and for the long time from the Potsdam to the Lower Carboniferous remained dry land, not even subjected—an extraordinary statement—to considerable denudation. Then the carboniferous sea flowed over all and deposited its even floor of limestone over the Potsdam, which two, most regularly superimposed, now form the walls of the archæan inclosure, from which they have been removed by erasion.

The Triassic and Jurassic followed, surmounting the carboniferous with beds of marl and clays, and adding their accumulations to the rising mound of strata.

Lastly, the cretaceous sealed in the column of deposits so that the ideal dome assumed the form of the adjoined section after upheaval.



IDEAL CROSS-SECTION OF THE BLACK HILLS.

1. Archæan Schists.
. Granite.
3. Potsdam.
4. Carboniferous.
5. Red Beds.
6. Jura.
7. Cretaceous.
8. Tertiary.

Then the uplift occurred which brought these heavy beddings upward in a flat-topped oval displacement, a highland from which, by a process of enormous denudation, the cretaceous and the Jura and Red Beds have been pared away, their slanting beds and monoclinals now surrounding the hills. The carboniferous and Potsdam have also disappeared from the large area on the east side of the dome, where the archæan schists are exposed, and in time will retreat further and further, uncovering new portions of the azoic terrain. The carboniferous now forms the surface rock of the wide western plateau, and is deeply cut by a net-work of anastomosing cañons. A bird's-eye view of the whole presents the aspect of an overturned colossal pastry, with its bottom crust on one side badly gnawed away. In this place it would be impossible to discuss the serious questions which arise in reference to this exposition. Its guarantee is in the field work and observations of its authors, and it certainly presents a geological chapter of extreme interest.

Prof. Whitfield's important contributions in the palæontology form a striking feature in the report. Mr. Jenney reports, after a detailed examination of the mineral resources of the country, that "the Black Hills are pre-eminently a gold-producing region." Mr. Caswell contributes a chapter on the lithology of the Black Hills.

Very much of general scientific interest is found throughout this handsome volume, and the United States Government have, in its publication, added one more honor to its deserved eminence amongst nations re-organizing science, and added one more debt to the increasing sum due to it from all scientific students.

L. P. GRATACAP.

WASHINGTON, 1880.

THE GREAT PRIMORDIAL FORCE.*

By HENRY RAYMOND ROGERS, M. D., Dunkirk, N. Y.

The law of "*Conservation of Force*" having received the full and unqualified endorsement of all true scientists, is to-day the basis of all physical philosophy and the key to the explanation of all physical phenomena. No view of force can henceforth be accepted which is incompatible with it.

It may be said to be the product of the last half century, its origin being obscure and uncertain. Its earlier conceptions evinced but little promise of the grand future that awaited it, and its advancement, like that of all fundamental truths, has been exceedingly slow. It must be confessed that to-day, even, our knowledge of its provisions is but *rudimentary*. In the way of applying it to the explanation of the mysteries of nature's varied phenomena but little has yet been done. We are confident that whenever this immutable law shall be properly applied, a new era will have dawned upon physical science.

Another fundamental principle of recent discovery has been developed *pari passu* with that mentioned, and in importance is only secondary to it, viz:—the "Unity of Force,"—the correlation of all the forces. It has been demonstrated that all forms of force are resolvable into one another, it is therefore manifest that whatever name, or designation, we may give to these varied forms, but one essence pervades and animates them all. Instead of many independent forces, set forth in an irrational, contradictory, and mostly complicated philosophy, actually there exists *One Great Primordial Force*; simple in its character, competent to explain all physical phenomena, and in harmony with the nature of things. It is the force that rules the universe of matter,—innumerable star-suns and minutest atoms alike; and, for its realm, it has the vast bewildering space and all the cosmical bodies which occupy its depths.

This force is real and *substantial*. "Conservation of force proves as certainly as it proves anything, that all force is substantial. Nothing can be conserved, or preserved, unless it is something that exists, and it seems to be an axiomatic truth that nothing can exist unless it be a substance of some kind. If force in one form is convertible into force of another form, then all force in whatever form it may be exerted is substance, since it is impossible to conceive of the conversion of one thing into another thing, and neither thing be anything substantial. Our inability to take cognizance of the constituents, or corpuscles of a force, is no valid reason to a thoughtful

* Read before the A. A. A. S., Cincinnati, 1881.

mind why such force should not be regarded as a real substance—as literally and truly an entity, as is the air we breathe."

The two fundamental principles having been ascertained, our acquaintance with the essential nature of the primordial force depends upon the use we make of our positive knowledge of the specific operations of the several forms of force, as now, for the first time, we are enabled to understand and interpret them. Since we are just beginning to appreciate the great law of conservation of force and the great fact of the unity of all the forces, a better reading of physical phenomena is rendered possible. By these data we plainly read that this force is *electric* in its constitution. We claim that the electric theory is a factor in the explanation of all the phenomena.

We are able to perceive that a great celestial battery is in operation, to which the primordial force owes its perpetual development; a battery differing from our own magneto, and dynamo-electric batteries only in scale of operation. It has the same essential constitution, and *modus operandi.* Quite like the battery of man's construction, the celestial battery requires the co-operation of two elements, either of which, acting independently, is incapable of producing force, but acting in concert, the two develop all known forces of the universe. These two elements which have never yet been adequately associated in the interpretation of the phenomena of gravity, heat, light, etc, are *motion* and *magnetism;* the motions of the celestial spheres, and the magnetic constituent of each celestial sphere. True, the scientific world has vaguely conceived of the development of power through the agency of celestial motions, but it has failed to formulate any *exact philosophy* of the manner in which those motions should develop actual force. Such a philosophy is accessible.

It is known that the earth is a vast magnet, having a magnetic axis nearly corresponding to its geographical axis, and terminating in a *positive,* or northern pole, and in a *negative,* or southern pole. But the earth's inherent magnetic force must remain purely *potential,* or *static,* and without the ability to act, or to move, except through the co-operation of a separate and independent force, whereby this static magnetism may be converted into active, vital currents. From our experience with the electric battery, we know that motion, and change of polarity, are capable of producing vital, active force, from force inert and dormant. In the celestial, as in the terrestial battery, motion and change of polarity are prerequisite to the awakening of inert, dormant force, into vital, active force.

That electricity may be obtained from magnetism by motion, or that magnetism, conjoined with motion, may be made the source of electricity, is well understood. So, by their unceasing rotation the magnetic sun and earth furnish both the needed motions, and the incessant change of polarity, which are requisite to the completion of the celestial battery. Thus, through the medium of revolving celestial armatures, acting upon celestial magnets, *statics* are converted into *dynamics,* on a scale commensurate with the demands of the universe; and that dream of the ages, *perpetual motion,* is found a realized fact in nature.

All space being pure vacuum, distance is virtually annihilated, and all the spheres are brought relatively into close proximity, Mercury, 37,000,000 of miles from the sun, and Neptune 2,800,000,000 of miles, stand alike in their relation with the great central orb. This condition is thus favorable to such "*action at a distance,*" as is found *indispensable* to the inter-communications going on between the bodies which constitute the universe of matter. The fact of instantaneous action at a distance, and without a medium of transmission, though questioned, is demonstrated in the action of gravity.

Through the operation of the celestial battery a great current of force is incessantly in motion from the sun to the earth. Both the law of conservation, and the law of magnetic action, demand that a current of equal proportion shall as incessantly return from the earth, to the sun; —the one current cannot for a moment exist without the other. Were this return current interrupted, the light of the sun would instantaneously cease, all life would become extinct, and, the power of cohesion being suspended, the earth and everything thereon would return to their original elements, and vanish into space. In this action, and retro-action, we find a grand magnetic circuit between the earth and sun, through the operation of which the earth's portion of the primordial force is utilized. The same conditions which exist between the sun and earth, as described, exist also between every satellite and its primary, and between the star-suns of the universe.

SOLOMON was wiser in some respects than the scientists of the present day. He says that "The wind returneth again according to his *circuits.* All the rivers run into the sea, yet the sea is not full; unto the place from whence the rivers come, thither they return again." Science recognizes the immense movement of force from the sun to the earth,—but has she made sufficient account of the fact that the earth is not full? Has she recognized the fact that back to the sun again, in some form or other, the rivers of energy must return in ceaseless circuit? And yet, the law of conservation demands it, and the electrical theory satisfies the demand.

The various manifestations, or affections, of the primordial force which receive the appellation of the great physical forces have their fullest and clearest explanation through the interpretation given by the electrical theory.

GRAVITY CONSIDERED AS AN AFFECTION OF THE PRIMORDIAL FORCE.

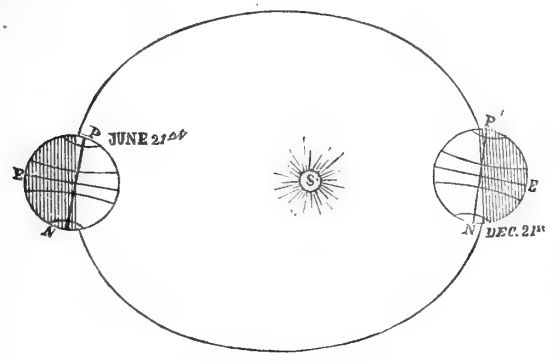
Science has strangely neglected to examine the field which gives best promise of an ultimately satisfactory explanation of this phenomena.

According to the present popular philosophy, "gravity acts directly as the mass, and inversely as the square of the distance." FARADAY says, "The received idea of gravity appears to me to ignore entirely the principle of the conservation of force, and, by the terms of its definition, if taken in an absolute sense, 'varying inversely as the square of the distance' to be in direct opposition to it."

If gravity acts directly as the mass, then surely, as the sun's mass is *constant,* and the earth's mass is also *constant,* the force of attraction should at all times remain invariable, and the earth's orbit should consequently be a true circle, instead of an ellipse. If gravity acts inversely as the square of the distance, then the earth at aphelion could not without the aid of some other force or interfering cause, be returned to perihelion, but the lessening attraction would permit it to move on indefinitely into space.

The electrical theory, however, suggests a more rational, clear, and satisfactory philosophy, and makes provision for the elliptical orbit of the members of the solar system. In order that the earth's orbit, for example, should be elliptical, the mutual attraction existing between the sun and the earth must necessarily increase and diminish with mathematical exactness and regularity. To such *regularly varying attraction,* and to no other cause, can the ellipticity be due. Attraction is greatest about the 21st of December when the two bodies are nearest each other, and least about the 21st of June, when they are relatively the most distant. Whether the attraction between the sun and earth shall be greater, or shall be less, depends altogether upon their relative position. Thus when the earth's south-pole presents nearest the sun, the attraction between the two bodies is the greatest, and when the earth's north-pole so presents,

attraction is least. Why should this variation in position produce such a variation in attraction? In the light of the electrical theory the following explanation is confidently advanced:



On the 21st of December the *positive* sun, (S.) and the *negative* south-pole of the earth's magnetic axis (N.) are in closest relation to each other, and the north-pole, (P.) is out of the field, therefore the opposing conditions, viz: the *positive* sun, and the *negative* portion of the earth, represented by the south-pole, acting in concert, produce attraction between the two bodies, according to the electrical law that *unlikes* attract each other. At that date the centre of the great electric sun-current strikes the earth at a point 23½ degrees south of the equatorial line, and from thence moves in the direction of its mass towards, and along the earth's natural magnetic axis; in this instance, towards the north. This northerly movement of the electric mass is *concurrent* with the earth's magnetic axis, and the force of attraction between the two bodies is thereby increased to its maximum.

On the 21st of June precisely opposite conditions exist: the *positive* sun, and the *positive* north-pole, are in closest relation to each other, and the south-pole is out of the field; attraction between the two bodies is consequently at that date lessened, and this in accordance with the electrical law that *likes* repel each other. And, too, the centre of the great sun-current strikes the earth at a point 23½ degrees north of the equator, and its mass moves in a southerly direction. The direction of this electrical movement is *contrary* to the earth's natural magnetic axis, and the force of attraction between the two bodies is further lessened; consequently at that date they are found at their greatest distance apart,—viz: several millions of miles more distant than on the 21st of December.

On the 20th of September, and the 20th of March, the sun is equidistant from the earth's two polar extremities, and the centre of the great sun-current strikes the earth at the equator in a direction at right-angles with the earth's magnetic axis. The electrical conditions are thus balanced, and the earth at those periods is equally distant from the sun.

The degree of ellipticity of each planetary orbit is due to the inclination of its axis: if the axis is at right angles with the plane of the ecliptic, the poles must be equidistant from the sun, and attraction and repulsion thus become equalized, and the orbit must necessarily be circular. Had the axis of the earth been perpendicular to the plane of the ecliptic, the sun would always have appeared to move in the equator, the days and nights would have been equal, and there could have been no change in the seasons.

The extent of ellipticity in any orbit is governed by the amount of axial divergence from such right-angle.

As a further demonstration of the ability of the electrical theory to account for the grand phenomena of the universe, we will apply it to the philosophy of the earth's axial motions. Electricity and Magnetism are regarded by scientists at the present day as virtually identical. The correlation of heat and magnetism is apparently as pronounced, as witness certain natural phenomena which bear directly upon this point. The tropical plant, the *phytolacca electrica*, is known to produce marked electrical effects; a touch of a twig gives to the hand as vivid a shock as that of a Rumkorff battery. At the distance of seven or eight paces, the influence of the plant is manifested through a compass needle, the closer the proximity, the more marked are the demonstrations; and if the compass is placed in the centre of the bush, the movement of attraction previously shown by the needle is changed into that of rapid rotation. The intensity of the phenomena varies with the time of day. At two o'clock P.M. it attains its maximum, and at night its magnetic powers are scarcely perceptible. It is thus demonstrated that at precisely the same hour, viz: two o'clock P.M. *heat* intensity, and *magnetic* intensity are *co-incident*. From this hour each diminishes, and from the morning until two o'clock P.M. each increases in the same proportion. The hour of the least magnetic effect, or the most *negative* condition, is shown by the following phenomenon to occur at a period of time opposite to that of its maximum, or *positive* condition, viz: two o'clock A.M. It is the experience of miners whose lives are passed in the depths of the earth, that between twelve and two o'clock in the night, if there is a loose stone or bit of earth in the mine it is sure to fall. Says a miner of many years experience: "About this time it seems that everything begins to stir, and soon after twelve o'clock, although the mine has been as still as the tomb before, you will hear particles of rock and dirt come tumbling down, and if there is a caving piece of ground in the mine it is sure to give way."

From these and such like familiar suggestions on the part of nature we may infer that the portion of the earth which is at any given time specially under the action of the great sun-current, becomes *electro-positive*, the maximum intensity occurring at two o'clock P.M. During the night the magnetic condition changes, and is at two o'clock A.M. most *electro-negative*. Thus at two o'clock P.M. the sun on the one hand, and that portion of the earth on the other hand, being in like electrical conditions, viz: *electro-positive*, mutually repel each other, and the consequent *push* moves the earth in revolution. The revolving earth turning eastward, is continually carrying its *negative* condition of the night into the field of the *positive* sun, a mutual attraction therefore takes place with its consequent *pull* upon that side; and thus is generated the process of an incessant attraction on the east side, and of repulsion on the west side, giving to the earth its axial motion.

Gravity may therefore legitimately be claimed as purely an electrical phenomenon.

The words of the grand old FARADAY now stand forth in lines of light, viz: Gravity, surely this force must be capable of an experimental relation to electricity, magnetism, and the other forces, so as to bind it up with them in reciprocal action, and equivalent effect.

SUN HEAT, *as an Affection of the Great ONE-FORCE.*

The demonstrations of our senses, as well as the teachings of all the ages, lead us to attribute to the sun the possession of a most dazzling brilliancy, an unlimited amount of heat. So it certainly appears. Yet the simple fact that the earth receives its heat through the agency of the sun, is not conclusive evidence that the sun is itself hot. On the contrary, it is well known that heat rapidly diminishes in the direction of the sun, and that at the altitude of considerably less than three miles lies the line of perpetual frost, the temperature of space progressively lowering beyond that point. The space therefore which separates the earth from the sun, 93,000,000 of miles in extent, is inconceivably cold; its intensity is variously estimated at from *minus* a few hundred degrees, (Fahr.) to

minus 18,000,000 of degrees. It seems incredible that scientists who possess the knowledge of these facts can entertain the thought, or attempt to maintain the theory, that heat comes from the sun, *as heat*, through such a distance, and such a medium. And, if not coming as heat, then the previously existing philosophies of the functions of the sun are *fundamentally erroneous*.

Science at the present time admits of four different explanations of the production of sun heat, viz: (1.)combustion of cosmical substances falling into the sun; (2.) arrest of motion of substances thus supposed to fall into the sun; (3.)contraction of the solar mass; and (4.) dissociation of compound bodies in the sun's substance. Each of the foregoing hypotheses stands in direct opposition to the inexorable law of conservation of force. Each recognizes the presence of a vast flood of heat, light, and force incessantly issuing from the great solar mass, and proceeding therefrom with inconceivable velocity to the earth. Yet neither of them makes provision for the retro-acting, or returning current, which under the law of conservation, becomes indispensable. Each assumes the actual and indispensable presence of heat at the sun, as an element in the solar economy. But inasmuch as heat cannot come from the sun *as heat*, there really exists at the sun no necessity for the enormous production there, such as these hypotheses demand. The prodigious destruction of material claimed to be involved in the production of heat at the sun, and the expenditure of an inconceivable amount of force in projecting the same in all directions, and to inconceivable distances into space, are uncalled for, and therefore irrational. Upon the electrical theory, no such extravagant and irrational processes are needful.

A true understanding of the great physical phenomena of our earth depends upon a correct knowledge of the constitution of its atmosphere. There is a more vital element than clouds, vapors, gases. This constituent is magnetic in its character, and may be designated as *static*, from its habit in equilibrium, and also in contradistinction from the vast *active* current which fills the space between the sun and the earth. In all scientific formulæ of its constitution, this principle as a real entity has been ignored. The fact that the atmosphere is a vast magnetic reservoir, that it is the most magnetic of all earthly bodies except iron, nickel, and cobalt, is well understood; yet there appears to have been no suspicion of the grandeur and importance of its functions in the earth's physical economy. As constituted, the atmosphere is peculiarly adapted to co-operate with the sun in this economy.

In fact it is the medium and instrument of all the sun's terrestrial operations. Prepared by such knowledge of the constitution of the atmosphere, we can better comprehend the philosophy of the action of the great sun-current so incessantly moving earthward.

By means of the dynamo-electric machine, it is demonstrated that motion or magnetism, (or both,) is converted into heat and light; so does not analogy suggest that the grand motions of the heavenly spheres are by the same principle converted into sunlight, and sun-heat; thus making unnecessary the measureless and ceaseless destruction of material that is demanded by the present theory? Our atmosphere supplies the conditions represented by the "carbon point," and the "platinum coil," in practical electricity. A current invisible, without manifestation, passes through space, as electricity through wires, until, meeting the resistance and favorable conditions of our atmosphere, there occur those wonderful and important phenomena, heat, and light. No particle of either heat or light need therefore come as such from the sun to the earth, the current being wholly invisible and cold in its passage. For a practical demonstration of such transmission of a current, we are much indebted to experiments made by Prof. MAHLON LOOMIS, of WASHINGTON, D. C. Without any visible means of transmission, he succeeded in sending the magnetic current from one mountain top to another twenty miles distant.

In the light tenuous atmosphere of the summits of lofty mountains, the human body often experiences the fiercest effects of sun-heat, and the pyrheliometer of POUILLET also records such effects for the reason that the body and the instrument become *objects of resistance* to the current, and a local heat is thus developed, which is far greater than that of the light atmosphere surrounding, which offers no such resistance. It is hardly necessary to add that the greater heat always manifested on the surface of the earth beneath is owing to the fact of a denser medium, and a consequent greater resistance.

The battery of mundane construction—our best aid and interpreter in the reading of universal phenomena—while it is the developer of heat, light, and power, is itself neither luminous, hot, nor magnetic. To explain the effects of the sun, therefore, there is not the least reason to infer that it is itself luminous, or even warm. Potential action generated in a dark, cold body may produce great heat, light, and attraction, at a distance from the seat of activity, and what is thus wrought artificially, in a small way, may surely be done naturally, and in a tremendous fashion, by the grand forces of the sun.

SUNLIGHT.

The same process develops sunlight. If lines be drawn from the sun to the earth, tangent to both, these lines will enclose a tapering space, the sun at the big end, the earth at the small end, and the space between a truncated cone; this space may be designated the solar cone or cone-space. Within this space incessant circulation is going on, and all the phenomena of gravity, heat, light, are produced through their reciprocal activity. The field of encounter between the forces of the sun and earth is our atmosphere, and in the collision light is generated. Being thus conditioned upon the atmosphere, light and heat cannot be found in space beyond the lines of the solar cone.

It is to be observed that light rapidly diminishes in the direction of the sun, even as we have seen to be the case with heat. Beyond the lower portion of the atmospheric mass, there is no dazzle; and the human eye in looking upon the great orb is not dazed. Thus the exceeding brilliancy which characterizes the sun's rays, so far from being a phenomenon located in the sun itself, as is the popular, and even the scientific conception, is actually confined to the lower strata of our atmosphere.

If light were transmitted to us from the sun in perfect intensity, the entire vault of heaven must appear as luminous as our sun.

The sun is therefore not the manufacturing place and distributing reservoir of *actual* light and heat; it is rather the source from whence the whole solar system is supplied with the *invisible*, *potential* light and heat, which become developed where it is required. The great central orb may therefore be regarded as like unto the earth, on its surface, and in its surroundings, viz: a dark, cool, habitable body.

OTHER RECOGNIZED FORMS OF FORCE.

All other recognized forms of force have their best explanation in the same theory.

It may be necessary to caution against a natural misconception which is fruitful in seeming objections against the theory advanced. Let it be understood then, that man's machinery must always work to disadvantage when made to illustrate the operations of nature. The machine itself is an inert thing, a dead weight interposed, the working of which requires the expenditure of force. In nature's operations, on the contrary, without labor or friction, one form of force under proper conditions transmutes itself into another form, there being no loss of force in the change. We must recognize the fact of an unimpaired energy in the universe, the fact that force is never lost nor wasted.

The Great Primordial force owes its genesis to the initial impulse which set all spheres in motion in vacuous space. To this universal principle, not only all physical force, but new life itself is due.

HUMBOLDT says: "It is indeed a brilliant effort, worthy of the human mind, to comprise in one organic whole the entire science of nature, from the law of gravity to the formative impulse in animated bodies."

That the earth, and the sun, and all the heavenly bodies, are possessed of the mysterious magnetic energy, and consequently exert a powerful magnetic influence over each other, has long ago been conceived by such men as HERSCHEL, HUMBOLDT, FARADAY; and is the faith of scientists to-day. But when we have arrived at such a conclusion, it is impossible for us to stop short, and not make the necessary deductions therefrom. Mighty magnets, when involved in mighty motions, must produce mighty currents and mighty effects. It is not for nothing that these powers and conditions exist. If we admit the premises, we must not ignore the conclusions that are necessitated. Provision must be made for the outcome of every admitted fact in science.

Therefore, it is with assurance that we urge the electric theory, and maintain that the burden of proof rests with those, who, admitting the elements of motion and magnetism, have yet made no provision whatever for their keeping.

Besides, there are two other principles already alluded to—the conservation of force, and the unity of all the forces—with respect to which it may be demanded, to what other result do they lead, and can they lead, in all reason and logic, than to the admission of the grand fact of a Great Primordial Force.

THE TIDAL EVOLUTION OF THE MOON.

On Saturday, June 4th, in the Museum Buildings, Trinity College, Dr. Ball, Astronomer Royal for Ireland, delivered an interesting and instructive lecture on recent discoveries in astronomical science. Dr. Ball said that from the variety of topics which might fairly be dealt with in his lecture he would select three, and in making this selection he had been mainly guided by the relative importance of different astronomical problems. He had also endeavored to exercise his choice so that his lecture should, as far as possible, refer to the various branches of astronomy. Having dealt with two branches of his subject, Dr. Ball described "Darwin's Theory of the Tidal Evolution of the Moon." It had, he said, been the triumph of modern gravitational astronomers to indicate the changes which must be going forward in a system devoid of rigidity. It was at all events easy to show that the tendency of these changes lay in one direction, and this was the most important point for consideration. Everyone was aware of the daily movements of the sea, which were called the tides. Most people were aware that the movements of the waters were caused by the attraction of the sun and the moon. Let them ponder therefore on the tides, as they seemed to give a clue to some of the profoundest of nature's secrets. He had heard that the port of Dublin was gradually being improved by the deepening of the bar. He had heard that the deepening of the bar had been attributed to the judicious action of the Port and Docks Board. But what the board had chiefly done was to call into requisition the scouring power of the tide, which, as he was informed, was gradually reducing or bearing away the bar. The tide was therfore accomplishing, at the bar of Dublin, the same kind of work as could be accomplished by men or by steam-engines. In other words, the tide was here doing a useful work that could otherwise only be done by the expenditure of energy. It was the same elsewhere. The tides were doing work useful or the reverse, and expending energy in so doing. Where did the energy come from? It could not be created. It could only come from the store of energy available for such purposes in the solar system. The reserve energy whence the tides drew the supplies they were daily consuming consisted partly in the daily rotation of the earth on its axis. The earth was like a mighty flywheel which would absorb a prodigious amount of energy in setting it in motion, and which would give out that energy before it would be brought to rest. The rotation of the earth on its axis was a vast but not inexhaustible storehouse of energy, on which the tides could draw for thousands of years. Energy also existed in the solar system in many other forms, some of which could also be rendered available for the tides. So far as was known, the total amount of energy could not be increased. The important question was—Can that total ever be diminished? The tides were diminishing it every day. The small oceanic tides were not the sole source of the expenditure. The solid body of the earth itself must be subject to tides; still more must the fluid or gaseous members of our system be subjected to tides. All tides involved friction, and all friction involved loss of energy. Here, then, was the great discrepancy between the theory of Lagrange and the actual condition of our system. Lagrange's calculations assumed that the total energy of the solar system was constant, but the actual fact was that the energy was slowly diminishing. The tracing of tidal evolution was chiefly due to the labors of Mr. G. H. Darwin, son of the celebrated naturalist. The influence of the tides had already been recognized as the cause of the same face of the moon being always bent on the earth. Whether the tides were merely oceanic, or whether they were actual bodily tides, the results remained much the same. At the present time the moon revolved around the earth in a month: the earth revolved on its axis in a day. The tides produced in the earth by the moon must act to reduce the rate of the earth's rotation. The effect of the tides on the earth was to lengthen the day. The day was gradually lengthening, but this change could not take place without a reactionary change on the moon. The change undergone by the moon was perhaps a little difficult to understand, as it depended on some by no means simple dynamical principles. The friction of the tides consumed the energy of the system. It turned a large portion of that energy into heat, which was then radiated off into space to be forever lost. But the friction of the tides could not alter the moment of momentum of the system. As the earth became gradually slower and slower in its rotation its moment of momentum decreased, yet for this to happen the moment of momentum of the moon should increase. It followed mathematically that as the tides gradually made the earth rotate more and more slowly, the moon must be getting farther and farther away from us. At the end of a million years from the present time the day will be more than one day of twenty-four is now; and in one million years hence the moon will move round the earth at a greater distance than she does now, and the length of the month will be correspondingly increased. In the far distant future therefore, we are to look for an increased length of month. The length of day will, however, increase much faster than the length of the month, until at length the duration of the day equals that of the month. When this time arrives the moon will have moved out to a distance half as great again as it is at present, and the length of the month will have increased to two months. Our day will then have increased from twenty-four hours up to nearly two months. and as the moon continues to to show the same face to us, we are destined to turn the same face on the moon. Were the earth and the moon the only bodies in the universe, such a state of things might go on forever. The sun, however, will produce tides in the earth which will again modify their movements. He had said that the moon was gradually receding farther and farther from the earth, and that the

length of the day was increasing—getting gradually longer and longer. But how long has this been going on? Yesterday was shorter than to-day. The day which Homer had was shorter than our day, but not indeed to any appreciable extent. There can be no doubt, however, that a million years ago the day was appreciably shorter than the day is at present. He wished to conduct them back to an exceedingly remote period, to a critical epoch in the history of the earth. That epoch must have been more than fifty millions of years ago, but how much more he could not tell. At that extremely remote time the day was greatly less than it is at present. It was only, indeed, a fraction of its present amount, being only from two to four hours long. He would trace back the moon to the same remote epoch to which he had conducted the earth. The tides in the earth are forcing the moon gradually away from us at present. The moon was therefore formerly nearer to us than it is now. Millions of years ago the orbit of the moon was much less than it is at present. The time of the moon's revolution was much smaller and the moon must have been quite close to the earth, and whirled round the latter in a period of from two to four hours equal to the period of the earth's revolution on its axis. Such, then, is the primeval condition of things to which the tracing of tidal evolution conducted. Antecedent to this critical epoch they could hardly go with any degree of certainty. After explaining Darwin's theory in reference as to the supposed rupture of the earth at a very remote period of time, and the consequent formation of the moon, the lecturer proceeded to speak of the surprise with which astronomers realized that the small interior satellite of Mars revolved on its axis in less than a third of the time —nearly 24 hours—which the primary occupied in revolving on its own axis. He also spoke of the tremendous forces in action at remote periods when tides rose to a height of a thousand or two thousand feet, scouring rocks and carrying enormous quantities of matter to the sea, and when that action caused so much comparatively rapid manufacture of strata.

MR. DARWIN ON DR. HAHN'S DISCOVERY OF FOSSIL ORGANISMS IN METEORITES.

Dr. Hahn's discovery, of which an elaborate account was given in No. 50 of SCIENCE, has stirred up a lively discussion of this highly interesting subject. Dr. Hahn has taken steps to enable Prof. von Quenstedt, the renowned Tübingen geologist, and all others who expressed the desire to examine his microscopic preparations. It is understood that all those who have availed themselves of the opportunity thus offered have become convinced of the genuineness of Dr. Hahn's discovery.

It is very interesting to note the position taken by the greatest of living evolutionists in this controversy, if it can still be called such. Charles Darwin, on receipt of Dr. Hahn's work, wrote to him:

" . . . It seems to be very difficult to doubt that your photographs exhibit organic structure . . . ," and furthermore:

" . . . your discovery is certainly one of the most important."

Not content with the mere presentation of his work, Dr. Hahn visited the veteran zoologist and brought his preparations to him for inspection.

No sooner had Mr. Darwin peered through the microscope on one of the finest specimens when he started up from his seat and exclaimed:

" Almighty God! what a wonderful discovery! Wonderful!"

And after a pause of silent reflection he added:

" Now reaches life down!"

The latter remark no doubt refers to the proof furnished by Dr. Hahn's discovery that organisms can reach our planet from celestial space. It is an acknowledgment of the relief Mr. Darwin must have felt in not being forced to a belief in a primeval "*generatio equivoca*."

As was suggested in the paper referred to, "the Richter-Thomson hypothesis of the origin of life on the earth has become a tangible reality!" R.

AN AFTERNOON ON PASSAIC RIVER.

On the 25th day of last month the editor, in company with his former colleague on the *Quarterly*, Mr. J. L. Wall, escaped from the city and made a trip to the town of Belleville, on the Passaic River. A row-boat was engaged, and we proceeded to collect specimens from along the shores. Not many species of algæ were found, nor was there any great variety of animal forms, but the water-plants, so hardy and useful in aquaria, the *Anacharis Canadensis* and *Vallisneria spiralis*, were abundant. Reaching over into the shallow water, it was an easy matter to obtain perfect plants of *Vallisneria* with good roots, and we collected a number of them. The *Anacharis* grows so readily without roots that the more fresh looking stems were carried home without regard to the roots. An old can was made use of to carry home some of the river mud, in which to plant the *Vallisneria*. The mud was placed in the bottom of a tall specie jar, the roots of the plant were properly embedded, and the jar filled with water. The next morning, after the water was cleared by settling, the mud was covered with a layer of clean sand, which tends to prevent riling of the water by a slight disturbance. All the leaves of the *Vallisneria* were removed, so that a new growth might start in the aquarium. It is probable that we will thus obtain some vigorous plants of *Vallisneria* for use during the coming winter. The *Anacharis* was simply thrown into a large aquarium, where it will doubtless grow without further care. Rowing about slowly, a long, green, spiral filament was observed reaching up to the surface of the water. It was two or three feet in length, and bore a peculiar flower at the end. This was the female flower of *Vallisneria*, a very interesting object for study; it was quite a surprise to us, as the plant does not usually flower as early as July. Looking toward the shore, the water was covered with an innumerable quantity of white specs, which attracted our curiosity. Rowing up to them, we found that they were the male flowers of *Anacharis*. These are very curious flowers. The long, tubular perianth, sometimes two or three inches in length, reaches from the axil of a leaf to the surface of the water, and bears the stamens above. It would easily be mistaken for the flower-stem, but it is really the tubular perianth. These flowers were very abundant, so that the water appeared white with them. The pollen-grains were numerous, and could be seen floating about on the water in little clusters resembling snow-flakes. *Potamogeton* was abundant, in several forms, and the common arrow-plant, so named from the shape of the leaf, *Pontedaria cordata*, which is also good for large aquaria. This plant should be set in a flower-pot, with suitable soil in which to root, and then submerged, either wholly or in part.

Among the algæ, two species of Oscillaricaceæ were found quite actively moving *Oscillaria tenius* and *littoralis*, and *Lyngbya majuscula*. The most interesting specimen of all, however, was a species of *Ulothrix*, a very common, filamentous, green algæ, in which the cells are about as long as they are wide. It was interesting because when we examined it, at about seven o'clock the next morning, the process of giving off swarm-spores had just begun. The entire contents of each cell in whole filaments, quickly formed into green, spherical masses, which began to move about in the confined space within the cells; soon the cell-walls ruptured, and the contents escaped as very active swarm-spores, somewhat elongated in form, and furnished with four long, whip-like appendages, or flagella, by means of which they could

swim about. They measured $5.\mu 8$ to 8μ (.00022 to .00033-inch in diameter). After a while they become attached to some object, lose their flagella, elongate and subdivide, forming new growths of *Ulothrix.—The American Monthly Microscopical Journal.*

SELENOGRAPHICAL.

For the purpose of comparing drawings of lunar objects, it is proposed to circulate at frequent intervals, among observers, a portfolio containing sketches and descriptions of various formations, which will ultimately be presented to the Selenographical Society. To cover expenses, an annual subscription of 2s. 6d. will be required. Among those who have already signified their intention of joining in the movement are Rev. F. B. Allison, Mr. W. R. Birt, Mr. T. P. Gray, Rev. R. S. Hutchings, and the Rev. Dr. Richards. Those who are willing to add their names to the above list are requested to communicate with the editor of "SCIENCE."

BOOKS RECEIVED.

SEA MOSSES. A Collector's Guide and an Introduction to the Study of Marine Algæ, by A. B. HERVEY, A.M. S. E. Cassino, Boston, 1881.

We welcome this excellent book, published at a seasonable moment, which will make it doubly appreciated by the public.

To the thousands who are now making a temporary home within the sound of the surf and who love the sea, seeking its presence for rest of spirit or health of body, the present work will be found a welcome companion and guide, opening up a new channel for the pleasant passage of leisure hours. No longer need the idler watch the incoming and outgoing of the tides with listless indifference, or be weary of the beating of sleepless waves, as they go tumbling among the rocks.

The author prepares the way for another pleasure which "this great and wide sea" can give us, besides that which she offers to our fancy and our dreams. In the contemplation and study of the exquisitely beautiful flora which she nurtures in her ample waters.

If you become acquainted with these plants, their beauty, delicacy and grace, and know their names, habits and history, you will admit the sea has added a new charm to your existence.

There may be no royal road to knowledge, but Mr. A. B. Hervey has certainly selected the shortest and most agreeable path by which the tyro may acquire a practical knowledge of the department of Cryptogamic Botany, included in the study of the most beautiful of Marine Algæ, the Sea Mosses.

The publishers have done justice to Mr. Hervey's work, and have produced a handsome printed book of nearly 300 pages, with twenty full-page colored illustrations of the most beautiful of the Sea Mosses, which will be found of great value to the student engaged in these studies.

No person of intelligence residing within reach of the sea, should remain without a copy of this work.

PROF. S. P. LANGLEY has made the following calculation:—A sunbeam one square centimeter in section is found in the clear sky of the Alleghany Mountains to bring to the earth in one minute enough heat to warm one gramme of water by 1° C. It would therefore, if concentrated upon a film of water 1-500th of a millimetre thick, 1 millimetre wide, and ten millimetres long, raise it $83\frac{1}{3}$ in one second, provided all the heat could be maintained. And since the specific heat of platinum is only 0.0032, a strip of platinum of the same dimensions would, on a similar supposition, be warmed *in one second* to 2603° C.—a temperature sufficient to melt it!

NOTES.

FAURE batteries are now made with flat plates, the rolling up of the sheets having been found to produce many cracks in the minium.

FROM exact experiments, M. Mascart finds that the intensity of current capable of producing in one second the electrolysis of the equivalent of a substance expressed in milligrammes is equal to 96.01 webers.

REMSEN has again investigated the action of finely-divided iron in inducing the formation of cyanide when nitrogen is passed over a hot mixture of carbon, iron, and an alkaline metal; he finds that freshly reduced iron induces a large formation of cyanide, but that iron after keeping for some time loses this power.

THE PHYSIOLOGICAL EFFECTS OF MATÉ.—Maté, or Paraguayan tea, is known to be extensively used in South America, and almost universally in Brazil, the common practice being to pour boiling water on some of the powder (consisting of ground leaves and twigs of certain species), then to suck the infusion through tubes provided with strainers. MM. d'Arsonval and Conty have recently inquired into the action of this substance, administering it to dogs, either by injecting into the veins or by introduction into the stomach, and they have observed a remarkable effect of it on the gases of the blood. It dimishes the carbonic acid and oxygen both of the arterial and of the venous blood to a large extent, sometimes a third or even half of the normal quantity. This action, which is less intense during digestion, and has no necessary relation to phenomena of excitation of the sympathetic nerve-system, is somewhat obscure as to its "mechanism," but its existence proves directly the importance and nutritive value of the aliment in question, which, consumed in such large quantities in South America, is almost unknown in Europe.

PROF. IRA REMSEN, of the Johns Hopkins University, Baltimore, has been lately experimenting as to whether the chemical behavior of a metal is in any way influenced by magnetic action, and has obtained some interesting results. The best effects were got by placing a shallow, thin iron vessel holding copper sulphate solution over the poles of a magnet. Out of the magnetic field the solution would deposit a uniform coating of copper, but in the field the lines marking the outlines of the poles were sharply distinguished as depressions in the deposit. In this case a permanent magnet was used capable of supporting 55 lbs. With an electro-magnet still more striking effects were observed. There was no deposit of copper on a narrow space marking the outline of the poles. Within this the deposit was fairly uniform, but outside the copper was deposited in irregular ridges running at right angles to the lines of force, and apparently coincident with the lines marking the equi-potential surfaces. By increasing the power of the electro-magnet, the action is intensified, and the area affected is broadened. The cause of the phenomenon has not yet been elucidated.

PROF. E. LOMMEL describes in *Wied. Ann.* a new polarising apparatus in which two plates of platinocyanide of magnesium, cut perpendicularly to the optic axis, are used as polariser and analyser, just as in the tourmaline pincette. Such a section of this crystal transmits a blue light, which, when the angle of incidence exceeds 2°, it is found to be perfectly polarised in the plane of incidence, and it therefore can be used, if tilted to that extent out of perpendicularity to the axis, as a polariser for a pencil of parallel blue rays. One curious point in respect to the behavior of thin film thus prepared is the following: Let ordinary non polarised light be looked at through the crystal while the latter is normal in the line of sight. A white central spot, perfectly circular in form, and non-polarised, is observed in the middle of a blue field, which is polarised at every point radially. The only other crystals which can be used for polarising pincettes are the tourmaline and herapathite (iodo-sulphate of quinine); the point of difference between these and the platino-cyanide of magnesium is that while the two former (which are negative crystals) absorb the ordinary ray, and must therefore be cut parallel to the optic axis, the latter absorbs the extraordinary ray, and must therefore be cut at right angles to the optic axis.

A CONTINUOUS registering thermometer for recording the temperature of the body has just been described by its inventor, M. Marey. It consists of a brass tube communicating with a Bourdon manometer, containing oil, and closed. Any change of temperature, by altering the internal pressure, makes the curved manometer tube curl more or less, and to it is fixed an index which registers the movements by inscribing them on a recording cylinder. The thermometric bulb may be at some distance from the inscribing apparatus, being connected by a flexible tube of annealed copper. Two such bulbs may be applied to different parts of the body, even to the interior. It is possible therefore to note the relation between the temperatures of the interior and exterior of the body. If we remember rightly, an analogous but more portable instrument was suggested some time ago by Mr. Donald Macalister, but we are not aware whether his instrument is yet before the public.

SUN SPOTS.

The following record of observations made by Mr. D. P. Todd, Assistant, has been forwarded by Prof. S. Newcomb, U. S. Navy, Superintendent Nautical Almanac Office, Washington, D. C.

TRIBUNE BUILDING, NEW YORK.

P. O. Box 3838

SATURDAY, SEPTEMBER 3, 1881.

The attempt to utilize compressed air as a motive power for street cars in cities, appears to have been most unsuccessful. About four years since, a company was organized in New York city for the purpose of building street cars on the pneumatic system, capable of replacing those drawn by horse power, and about the early part of April, 1878, a passenger car propelled by compressed air was running on the Second avenue, New York, between 63d and 93d streets.

The experiment was considered perfectly satisfactory for a first attempt, as the cars performed their work admirably; and the public press and various eminent engineers considered the problem solved. There was, however, an essential element of success that was wanted, which appeared insignificant at the time, but which proved fatal to the whole scheme. This was a failure on the part of the engineers to design machinery which should be constant in its working, requiring little attention from the driver.

It was supposed that in building future composite pneumatic engine cars these defects could be remedied. But when the six cars built on this principle were placed on trial, the same trouble was experienced, and the experiment was abandoned, causing a considerable pecuniary loss to the promoters of the company.

The Pneumatic Tramway Engine Company, undaunted by past losses and failures, have renewed their efforts, and have recently constructed a pneumatic traction engine, which we understand will be immediately placed on trial on one of the New York elevated railroads. The successful working of Electric Railway Engines has probably increased the difficulties of those who are advocating the use of compressed air as a motive power. In the absence of smoke, odor, noise and cinders, both the electric and compressed air systems have many advantages over steam for elevated railroads, and the question of economy wiil probably decide which system shall be finally accepted. At the present moment all the advantages appear to be in favor of the electric railways for use within city limits, and it is probably a mere matter of time, for all the New York elevated railroads to be running their trains by this system.

THE STATE AND HIGHER EDUCATION.*

By Professor N. H. Winchell.

The incentive to the following address appears to have been certain remarks made officially by President John of Hamline University, who considered that "higher education should not be under the control of the State," and that the design of the State Colleges has been a conspicuous and universally acknowledged failure.

In the first part of the paper Professor Winchell presents an historical sketch of the circumstances, the result of which was "that the State finds itself in the conduct of systematic education."

After tracing the progress of education in Europe he states:

Thus we find that none of the old universities, except when under the control of the government, and sometimes not even then, have been willing to modify their curricula in compliance with the demands and spirit of the age. If they have done it, as more lately at Oxford University, it is only after the force of public sentiment has been able to batter down the walls of prejudice and conceit with which they have been surrounded. During this whole conflict throughout Europe the Church, in its various forms, but particularly the Roman church, instead of being the champion and refuge of free thought and free knowledge, has been the most powerful obstacle to its progress, and has persistently opposed every movement to introduce the means for disseminating useful knowledge among the people. The heat of the conflict is passed. The tide has set in the right direction. The old universities perceive the triumph of modern science. European governments are unanimously striving for the establishment of modern schools of science on the broadest foundations, and equipping them with the fullest appliances.

Now let us turn to America, and inquire how this history has been mirrored on our institutions of higher learning.

In the first place the church colleges that arose in this country prior to 1824, or even later, were modeled after the mediæval universities of Oxford and Cambridge, so far as they expanded into the dimensions of a university. For the most part they were simply colleges of classical lore, with but one course of study, aiming specifically. at first, to educate young men for the clerical profession. As they were born of the English universities, so they inherited their mediæval narrowness and bigotry. As the early church had grappled with Copernicus and Galileo, and had been worsted, so the later church would grapple with everything that bore a resemblance to or intimation of any new fangled notions of nature. Although the world had made wonderful strides in human knowledge, the colleges shut their eyes and ears to the change. The age demanded education in the great industries that characterize modern society, but could get only that of the age of Elizabeth. As modern science and civilization began to buzz about their doors, they drew themselves within their shells, affrighted, like snails. Having none of the elements of the

* Delivered before the Minnesota Academy of Natural Sciences, Jan. 12, 1881.

new light within them, they were literally enslaved to themselves and could not escape. They began to sink in public esteem. Their graduates failed conspicuously in competition in all the affairs of life with self-made men. Finally, in view of this disparity between the demand and supply of industrial and scientific instruction in America, a far-seeing and generous business man, Stephen Van Rensselaer by name, came forward with private means, and became the first to endow, in America, a "school of theoretical and applied science." This was done in 1824, and it is located at Troy, New York. Twenty years later the first voluntary effort was made within one of the old church colleges of America to regulate the curriculum so as to conform to the new demands, aud although pushed by one of the ablest educators of America, Francis Wayland, in his own institution, and with his own denomination, at Brown university, the movement ended in a conspicuous defeat of the "new education." After the successful establishment of the Troy Polytechnic Institute, the example of Van Rensselaer was followed in Connecticut by Joseph E. Sheffield in the founding of the Sheffield Scientific school, which became attached to, but by no means recognized as co-ordinate with, the old line course in Yale college. This was in 1860. In 1847, soon after the failure of Dr. Wayland at Brown University, Abbot Lawrence endowed the Lawrence Scientific school at Harvard college.

About this time the legislature of the new States of the West began to express the sentiments of the people. In Illinois conventions met in 1851 to consider such means as might be deemed expedient to further the interests of an agricultural community, and to take steps toward the establishment of an agricultural college. They met not as Presbyterians, or Methodists, or Romanists, but as an agricultural community. The next year petitions were sent to Congress for the endowment of industrial universities in each State. In 1850 the agricultural college of Michigan was provided for by the State constitution, and went into operation in 1855. The scientific course of the University of Michigan was ordered by the State legislature in 1851. In 1858 Iowa appropriated money for a model farm and an agricultural college. In Kentucky, under the guide of Regent Bowman, an institution, chartered in 1858, had been established for "diffusing education among the industrial classes." In Pennsylvania an agricultural college was established in 1854, and in Maryland in 1856. In New York, as early as 1837, a project for establishing an agricultural college at Albany was entered upon and a site was selected. This resulted in failure. It was revived in 1844, and again failed through the death of a liberal friend of the enterprise; but in 1856 the State Agricultural Society of New York induced the legislature to appropriate $40,000 for a college of agriculture. This institution was established at Ovid, and died when the war of the rebellion broke out in 1861. The People's College, at Havana, N. Y., intended entirely for the industrial classes, was at first offered the national agricultural land grant of New York State, but failing to comply with the conditions imposed by the legislature, this fund was passed to Cornell University at Ithaca. These institutions, all established prior to the year 1862, when Congress passed and the President approved the great educational land grant law had come into existence in compliance with the demands of modern civilization, and not at the instance of the church colleges, but often in the face of obstacles and discouragements thrown in their way by the church schools. But President John says that the "facilities of higher education existed in this country, and met all demands, before State colleges were thought of." With the single exception of Yale College and Hamline University at Red Wing, which established a so-called "Scientific Department," the former in 1846 and the latter in 1857, not one of the church colleges, so far as I have been able to learn, showed the first symptom of knowing, much less recognizing, the difference in educational need between the age of Bacon and that of Lincoln.

The soil, therefore, was all ready for the seed. The bill introduced by Mr. Morrill of Vermont was vetoed by conservative Buchanan. Passed again at the instance of Mr. Wade, with only seventeen opposing votes, it was signed by President Lincoln on the 2d of July, 1862. It has been said that times of war witness the birth of great ideas and the initiation of great enterprises. It is true that in the United States, with the establishment, through rivers of blood, of the national idea, was also established the idea of higher education by the State as one of the justifiable means, in a republic, of self-defence and self-perpetuation.

This is all passed now, nearly two decades ago. If we proceed to inquire what has been its effect, we shall be able to answer another of President John's surprising statements. Is the design of the law establishing these industrial colleges by Congress, "a conspicuous and universally acknowledged failure?"

One of the first effects of this land grant by Congress was an awakening in the church colleges, then existing, to the value of the public domain as an educational agency. This was so rapid, and so great, that some of them succeeded in capturing the whole fund almost before the people knew it had been given to them. In others, along with a compliance with the terms of the act, the State demanded representation on the controlling board; but in most cases the church colleges were passed by, and new institutions were founded by the various States, though still, in many cases, combined with some other State or private fund.

In the second place, this law, which has so positively been pronounced a failure, brought into existence up to 1876, about forty schools of agriculture and mechanic arts, often styled national schools of science. These have come into existence since 1862—except in three States where similar institutions had already been endowed by State funds. In some cases also the fund was applied by the State legislatures to rejuvenate weakly scientific institutions, or further endow those that were flourishing. In the meantime, since 1862, the various churches of the United States had founded, up to 1876, 106 denominational schools. Some of these are based on broad foundations, and, like Hamline University, offer the student the most complete scientific as well as classical and literary culture. While the national schools of science are mainly confined to their own sphere—the primary intent of the law creating them—the new church schools cover all the fields of knowledge. It cannot certainly be unjust to them to compare their patronage by the youth of the country, with that received by the State schools. This, perhaps, will throw some light on the question of their asserted failure.

The 106 denominational colleges, established between 1862 and 1876, both inclusive, as reported by the Commissioner of Education, are found to be giving instruction to 13,757 students, including all departments, preparatory and undergraduate, in all branches of knowledge, from theology to chemistry and engineering, giving them an average of 130 students for each institution. Of these students, 9,066 are reported as in the preparatory (or secondary) grade of study, an average of 85 for each institution; and 4,691 are reported in undergraduate studies—an average of 44 for each institution.

Taking the same authority for the statistics of the forty State schools of agriculture and mechanic arts, and including only those students that are strictly in those departments, wherever a pre-existing college received the congressional grant, we find 4,891 students, which gives an average of 122 for each institution. Of these, 631 are reported in preparatory (or secondary) courses, and 4,260 in the undergraduate courses of study. This gives the state schools an average of 16 in the prepara-

tory classes and 106 in the higher classes. Thus it can be seen that, as institutions of higher learning, the attendance on the new church colleges is but 41 per cent of that on the State colleges. Hence, if the law of congress which called into existence these State colleges be a failure, how much greater the failure of that sectarian spirit which called these 106 denominational colleges into existence.

Another remarkable effect of this movement toward popularizing higher education in America was the renovation and elevation of the church colleges, then existing, and the establishment of numerous others with much broader and a more liberal scope of instruction. This of itself has resulted in immense benefit to education, as well as to the church in America. This effect is as important as the creation of the State schools themselves. The church has always been the principal agent of higher education, at least in the United States, and the recognition, by these institutions, of the great underlying truths of nature, and of the ministration of her laws to the daily comfort of man, is an epoch in the history of the nineteenth century, which, in its effects on the race, will exceed all other achievements of the "new education." It will contribute not only to the spread of science, but also to the spread of Christianity, particularly among those intelligent classes of the people who have been hostile to it, or indifferent, because of the attitude of the Christian church toward the truths of modern science. If the church once recognizes the fact that every enlightened nation is in arms against its supine adherence to mediæval education, and condescends to place itself in harmony with the truths of creation as well as revelation, one of the greatest obstacles to the evangelization of the world will be removed. It is easy to see that the material aspects of modern civilization are rapidly penetrating unchristian and uncivilized nations, outstripping the church in evangelizing them. How much better it would be if the two agencies could go harmoniously together into the same field, co-operating to accomplish the same end.

What has been said, so far, relates to the past. A few matters of fact have been stated. They pertain to the title, by which the State received, and holds, the educational structure which she has occupied. But President John not only disputes the title, but also the right of the State to occupy this field. We admit that force does not always coincide with right, and that, although nine points in the law are established when peaceful possession is proven, the tenth point may have the right on its side. Let us enquire, then, if there be a consistent reasonableness in the State's attempting and continuing to do this work. We shall not attempt here the justification of the State in establishing and maintaining primary and secondary schools. It is not demanded. In passing, however, we will except President John's definition of the duty of the State to educate. He fixes it at the "limit of necessity to preserve its own existence." So let it be. We shall recur to it again. But, specifically, as relates to higher education, the leading objections that have been urged are the following: (1) The personality of the State. President Elliot has fully presented this objection. It is foreign to the free spirit of American republicanism to witness the controlling influence and authority of the State in social and educational affairs. It smacks of the divine right of kings, and is a reminder of the despotism of Europe, two centuries ago. Now all this may be an objection in monarchical governments, but it seems rather strange that any promising educator in republican America should forget that here the people are the State. There is no kingly personality interfering with the domestic and social institutions of the community. The authority that controls is the aggregate will of the community. The chief right of the State's power is to conserve this aggregate will. Such an expression of the will of the people is voluntaryism in the discharge of its highest organic function, and is not "paternal government." (2) Again it is objected to State education, that it tends to uniformity, and not to variety, reducing all pupils to the same pattern, and smothering the aspirations of genius which spurns conventionalities and revels in the gratification of its own idiosyncrasies. This objection is more valid in the lower schools than in the higher. In the higher schools it is very questionable if the institutions of the church would be as lenient with idiosyncrasies in pupils, as those of the State. Judging from the past it would be folly for a student with an idiosyncrasy of genius to flee to a church college for its indulgence. We cannot see how this objection applies more fully in State colleges than to church colleges. In fact it is one of the necessary sacrifices which an individual has to make, when he becomes one of an organized community. He receives the benefits of combined effort in all directions, and he has to surrender the personal freedom to act in certain directions in which his action would transgress the aggregate good of the community. The schools are for the average pupil—both State schools and church schools—and he with an idiosyncrasy will look in vain for a place to disport himself. (3). It is urged again that it is not economical. Because, forsooth, a sectarian zeal demands denominational colleges, and "cannot conscientiously accept this service of the State," and will maintain colleges of its own, therefore the State cannot rightfully duplicate these institutions and tax the denominations for their maintenance. Not to mention the brevity of the time elapsed since the sects were willing to "do the same kind of work" as the State University, it is enough to reply that this argument applies against all State organization for education. The Roman Catholic insists on maintaining his own hospitals, and objects to taxation for public schools. The Atheist opposes the public tax because in these schools is taught the idea of a God, the Jew because the New Testament is read, or the Protestant because it is not. This argument against the public schools may be applied with equal reason against the State's management of the deaf and mute. At least, certain medical fraternities might use it because they cannot "conscientiously" endorse nor accept the methods of treatment practised by the State. (4). But the fourth objection, after all, is the chief one urged by the opponents of State schools—they do not correctly indoctrinate the student in matters of religious dogma. It is said that "the State by self-imitation cannot teach religion." This assertion the State accepts, and would fain leave it to the proper agent, yet the State is not therefore "prohibited by statutory limitation from throwing the least safeguard around the minds of our youth," which is one of the surprising inferences of President John. The State in its educational operations will always be governed by the aggregate sentiment of the people. Those fundamental ideas of religion, which are accepted by all sects, the State institutions will be compelled to teach. If, peradventure, for a time they happen to lapse from this high duty, the will of the community will sooner or later be restored. They are creatures of the people. They will teach what the people can agree on shall be taught. While they must not teach sectarian dogma, they must not become centres of atheism nor of infidelity. If they did either, they would not long survive. Like the schools of Switzerland, they are based on the "principles of Christianity and democracy." The special, political and denominational application of these broad platforms is left to party politics, and to various sects.

We venture the assertion, however, that when the true kernel of this objection is found, it will not consist in a fear of the non-inculcation of these truths by the State, but in a jealousy of the sects, one against the other. Education by the church has been considered essentially the training of the youth and doctrines of the

catechism. Though greatly extended in scope, it is still animated by the same cardinal principle. Each sect must defend itself by teaching its own dogmas to the youth, and, though every State college were to be abolished, there would be still as great a reason for maintaining all the denominational colleges. How long it would be before they would degenerate to the condition of mere sectarian propaganda, as before the revival, no one can say, but there would be a strong tendency in that direction. Freed from the competition of State colleges, their zeal in the teaching of science would soon lag. Not having ready access to the public means and resources of instruction, such as the State archives, maps, authorities, explorations, surveys, statistics, and to the avenues by which the State knows and readily regulates the great industries of the people, the church colleges would very soon see that there is an actual incongruity in their assuming to direct the scientific and industrial education of the people. It is the chief business of the church to look after the spiritual well-being of the people and not to fit them to carry forward the complicated machinery of modern civilization. Religion is the lubricator of this vast system, and the church is the agent by which it is applied. When the church departs from this sphere, she forsakes the true idea of the primitive church. When she leaves her spiritual kingdom and assumes to direct in the construction of steam engines, in the handling of theodolites and compasses, in the management of cotton-gins, in the measurement of the angles of crystals, and the distances to the stars, she may very reasonably be held to be out of her sphere. She has the privilege, of course, of doing all these things, and there was a time when she had good reason to do them, and was urged to do them, as the only capable agent; but that time has passed, and it can hardly be considered to be her duty to do them in the nineteenth century, when other agents equally capable have arisen, endowed with that special duty and function.

One of the boasted advanced steps of the nineteenth century is the separation of the church and State. In the mere manipulation of the governmental machine this is fully realized in the United States, and in much of continental Europe. But the administration of the laws is not the State, nor, indeed, is the making up of the laws, nor both of these united. True statesmanship surveys the whole body politic. It foresees and often institutes national enterprises. It watches the external and also the internal influences that move the masses; it takes advantage of the shifting markets for the domestic products. It notes the rise and decline of the various industries. It applies stimulants when needed and repression when necessary. In short, the State is an all-prevading, energizing, regulating, far-seeing organization of the people; the culminating expression of the modern democracy. It is this machinery, which in our day is very closely connected with the appliances of modern science, which is not free from the church, but which the church assumes still to direct. Instead, we claim that it is the right and duty of the State itself to look after its own interests, and especially its highest interests, and to take measures to qualify citizens not only to read their ballots, but to discharge all the duties of high citizenship. There is no limit to this duty short of the necessity of the State, as has already been admitted. That which constitutes a State—"high-minded men"—is its necessity, and that it is the duty of the State to provide, to the end that its multifarious industry may be under the guide of the highest statesmanship.

THE French Government has appointed a committee, presided over by Rear Admiral Bourgeois, to study the different applications of electricity to navigation.

THE Society of Telegraph Engineers and Electricians will hold a meeting in Paris on September 21.

MAGIC MIRRORS*.

BY M. BERTIN.

[Translated from the French by Marchioness Clara Lanza.]

LADIES AND GENTLEMEN:—The term Magic was formerly applied to those metallic mirrors employed by sorcerers, necromancers, astrologers and charlatans, and by means of which spirits were invoked and the future predicted. These mirrors, transmitted from antiquity to the middle ages, were used to a very great extent about the sixteenth century, and up to two hundred years ago they were constantly seen in Europe. Now they are found nowhere except in the far East. We are able to furnish any amount of information about this strange superstition, but it is not of these mirrors that I intend to speak.

There is another kind of magic mirror, so-called because it produces effects apparently marvelous but real. History will tell you nothing, however, about these mirrors, and they are not even mentioned in any book of physics. Their appearance in Europe is quite recent, and as they are exceedingly rare, there is not often an opportunity presented for observing them. It is of this scientific curiosity that I shall talk to you this evening.

These mirrors are an uncommon variety of metallic ones. The latter you know were the first invented by man. The Greeks and Romans had no other kind, except a few specimens of glass mirrors made at the factory in Sidon. But glass when not quicksilvered does not make a good mirror, and it was not until the thirteenth century that quicksilver was employed for the purpose. Up to that date metallic mirrors alone were used, and even now some uncivilized nations employ and mannfacture no other kind.

The Chinese and Japanese, for instance, are an example†. Since they have been in constant communication with European nations, however, they have partially adopted our glass mirrors and send us their metal ones as objects of curiosity. Chinese mirrors are exceedingly rare, so rare, in fact, that there is not one to be had in Paris. This leads me to think that they are no longer manufactured. Japanese mirrors, on the contrary, are very common. This is perhaps owing to the fact that in Japan the mirror is not only a necessary article for the toilet, but also an object of national worship. The primitive religion of the country, which is still embraced by the aristocracy and called *Synthism*, worships the goddess of the sun as its principal divinity, and the Emperors of the nation are supposed to be her descendants. This goddess invented the metallic mirror, and presenting it to her son bade him preserve it religiously. In the palace of Mikado, therefore, the mirror chamber is as carefully attended to as that of the Emperor himself, and often receives greater attention. In the temples of *Synthism* the only object of worship is a mirror, kept in a box covered with several wrappings of silk. Although this religion has been abandoned by the greater portion of the people, who have since become Buddhists, the mirror, nevertheless, has always remained a precious article. The ladies keep it raised upon a tall easel, which brings the glass upon a level with their eyes when they stand upon tip-toe. When they wish to remove it they hold it carefully by the handle, sometimes thrusting the latter into a piece of split bamboo.

These mirrors are of bronze of various sizes and shapes, but always portable. One side is polished and amalgamated. It is also generally convex, so that the images reflected look somewhat distorted. The other side is flat or slightly concave and is always ornamented by figures

* Alecture delivered before the *Association Scientifique de France*.

† This statement is not altogether correct. The Chinese manufacture glass mirrors, and very seldom, if ever, use metallic ones any more.

in relief of more or less perfect workmanship. Japanese mirrors usually are more beautiful than the Chinese.

Here, gentlemen, are a few. I cannot pass them among you, but I can show them to you perfectly well by means of the magic lantern. This one is the copy of a mirror brought from Japan by Professor Dybowski. This second one belongs to General Teissier. The designs are of the reverse or unpolished side.

Among these mirrors there are a few of a lesser thickness, which possess a remarkable property. Although they reflect ordinary images in a diffused light, if a ray of sunlight falls across the polished surface and is reflected upon a white screen, the ornamentation upon the reverse side will be transported to the screen. This is what we call a magic mirror.

The first that appeared in Europe came from China. The Chinese, in fact, have known of them for a very long time. One of their historians who flourished in the eleventh century of our era, mentions them with admiration. Another writer, who lived in the year 1300, gave us a supposed explanation of the phenomenon. The Chinese Encyclopedia contains an article upon the subject, which has been translated by our great sinologue, Stanislas Julien. These mirrors have always been rare, but persons who have lived in China assure me that they can sometimes be found in Chinese curiosity shops.

We are not sure that the mirrors were ever purposely made. It is probable, on the contrary, that they are merely the result of imperfect fabrication. In regard to the Japanese this is absolutely certain, for magic mirrors are unknown in Japan. Neither the manufacturer nor the person who sells them has any idea of their peculiar property. European *savants*, however, have found magic mirrors from Japan many times. In 1832 M. Prinsep described one in the *Journal de la Société Asiatique*, which he had discovered in Calcutta. In 1877 Mr. Atkinson, Professor in the Imperial University of Jeddo, observed that numbers of Japanese mirrors produced magical effects. This attracted the attention of M. Ayrton, Professor in the Engineering School in the same city, who immediately began to investigate the matter. After examining five or six hundred he affirmed that three or four out of every hundred were magic.

Partially magic mirrors ought to be very common, and I am quite sure if I had been permitted to examine the Japanese collections in Paris, I should have found several. I am indebted to General Teissier for two beautiful mirrors that he brought from Japan. One of them is decidedly magic. I will have an electric light thrown across it and then upon the screen. You will see a part of the design upon the back appear.

Although we can furnish no written testimony concerning these mirrors, several learned men however, especially those who had traveled extensively, knew all about them. In the year 1830 Humboldt came all the way from Berlin to Paris, in order to show the Academy of Sciences a mirror which he believed to be magic. The experiments were made at the Observatory. Unfortunately there are no traces of them to be found in the scientific reviews of the period, but we know that the whole affair was a *fiasco*. Our illustrious chemist, M. Dumas, who was one of the investigators, affirms that Humboldt's mirror could not be considered magic in any sense of the word.

The first magic mirror that appeared in Europe was owned by M. Monchez, the Director of the Observatory in Paris. On his return from China he brought with him several mirrors, one of which was magic and had been sold as such. This mirror was presented to the Academy of Sciences on the 22d of July, 1844.

In 1847 a second one appeared belonging to the collection of the Marquis de la Grange. Stanislas Julien gave a detailed description of this one, in which he stated that the reflection obtained was identical with the reverse of the mirror, but that the latter was not in relief. This mirror, therefore, should not have been magic at all, or if it was, all our modern theory would be upset. Many attempts have been made to find this mirror, but up to the present time the search has proved fruitless.

A third magic mirror was presented to the Academy in 1847 by Person, Professor of Physics in Besançon. Person's report consists of twenty-five lines only, but it is extremely important, as it contains the whole theory of magic mirrors, which, until then was unknown.

Finally, in 1853, Maillard presented the Academy with a fourth mirror, which was not magic to any great extent. It is now in the Collège de France. I have held it in my hands, examined it carefully, and I can assure you that it is an exceedingly bad specimen. A great deal of imagination must be possessed by any person who can call the effects of this mirror magic.

This, gentlemen, was the last, and the excitement about magic mirrors began gradually to subside. Nothing more was heard of them till the year 1878, when MM. Ayrton and Perry, both professors in the Engineering School, at Jeddo, presented the Royal Society of London with several magic mirrors which they had brought from Japan. For the first time, technical observations were made concerning the construction of these mirrors. As to the mirrors themselves, the effects produced by them were truly marvellous. We were unable, however, to form any correct judgment upon them until last year, when M. Ayrton brought four to Paris. The experiments made by him proved very successful, and were witnessed by me with great interest.

Since then, the fame of magic mirrors has revived with double intensity.

A few days after M. Ayrton's séance I received a visit from my old pupil M. Dybowski, Fellow of the Academy of Physical Science, who returned from Japan after a professorship of more than two years at the University of Jeddo. Of course, you all know that after the revolution of 1869, Mikado's government founded large scientific schools in the capital. Unfortunately, they no longer "import" professors from Europe, but content themselves with such pupils as we turn out.

Like all Japanese, M. Dybowski was ignorant of the existence of magic mirrors. He brought with him, however, as curiosities, four mirrors of antique manufacture, which are called *Temple mirrors* in Japan, and considered to be superior to modern ones, as the fabrication has grown exceedingly defective of late, owing, probably, to the competition of European mirrors. We experimented together with these four specimens, one of which was found to be magic in a slight degree. This mirror has been the starting-point of all our subsequent progress. Of course, this was naturally the consequence of a sound theory, which, however, was not immediately established.

The oldest on record is that given by a Chinese author of the thirteenth century. According to him, "the cause of the phenomenon is due to the use of fine and coarse copper. If, in manufacturing the mirror, the image of a dragon is produced in relief upon the reverse, a similar dragon is engraved upon the polished side. This last is concealed by filling up the lines of the engraving with copper. The metal is then incorporated with a purer quality of copper, while the mirror is submitted to the action of fire. Finally, the surface is polished and washed over with amalgam." The author, however, does not seem to see that if the difference in the reflective power of the two qualities of copper was sensible enough to make the phenomenon appear, this variation must necessarily disappear under the application of the amalgam.

Brewster's theory does not differ notably from the Chinese explanation. He says the polishing effaces the engraving and renders it invisible in a diffused light, leaving upon the metal, however, variations of density and reflective power, which makes the image quite visible

when exposed to the sun. But Brewster was not aware that the surface of the mirrors was amalgamated, and we may safely say that he was wrong to attempt a solution of the mystery, without ever having seen a magic mirror.

Nevertheless, before rejecting his idea completely, let us seek to verify it. I myself have had an engraving made upon copper, then caused it to be effaced. When it was no longer visible in a diffused light, it was, unfortunately no longer visible when exposed directly to the sun. Perhaps I went badly to work, and very likely a more careful and delicate operator might have succeeded better. We might have explained in this way the effects of an extraordinary mirror mentioned by M. Ayrton, which, instead of reproducing the image engraved upon the reverse, disclosed to the astonished spectators the grotesque features of a Buddhist saint.

Brewster's theory, fortunately, was not known in France when public attention was directed upon magic mirrors. I say fortunately, because his opinion, being that of a celebrated man, might have led us astray. The first French physician who examined a magic mirror, Person, immediately discovered the true solution of the problem. In the first place, he found that the polished surface of the mirror was not perfectly convex, but only so in certain parts, corresponding with the lines of the figure upon the reverse. In the portions corresponding to the relief, it was almost flat. Rays of light reflected upon the convex parts diverge, and produce but a faint image. On the contrary, rays reflected upon the flat portions retain their parallelism, and produce an image which is very intense. This is why the ornaments in relief appear brilliant upon a dark background.

This irregularity of the surface depends of course upon the method of fabrication. When taken out of the cast, the mirror presents the appearance of a flat disk. Before being polished it is scratched in every sense of the word with a pointed instrument, to which it naturally offers more resistance in the thick parts than in the thin. This operation makes it at first slightly concave, and by the elastic reaction of the metal it becomes convex. This convexity is more sensible in the thin places than in those corresponding to the relief of the design. The mirror is finally polished with a whet-stone, then with charcoal, which must frequently destroy the irregularities which produce the magical effect. The surface thus becomes perfectly smooth, but generally one or two cavities can be found. The manufacturer fills these in with balls of copper which he has ready prepared and of all dimensions, and which he afterwards rubs and polishes until he thinks they are invisible to the naked eye. An expectation, however, which is but imperfectly realized, generally speaking. The entire surface is then rubbed by hand with an amalgam composed of equal portions of mercury and tin.

Such are the details of the manufacture of magic mirrors. It is easy to see that they quite agree with Person's explanation, but the latter has one objection. How, it will be asked, can the surface of the mirror be irregular without this being apparent in the images it reflects in a diffused light?

However, this objection is removed when we come to consider the facts attentively.

A mirror with a perfectly regular surface is an exceedingly rare object. Here, for instance, is a flat, metallic mirror employed in astronomical observations. The reflections it gives are very good.

Here also is a silver plaque which reflects in a manner equally perfect. If however, it is made to reflect an electric light, we can see clearly that the surface is not uniform, for we are able to perceive, so to speak, every blow of the hammer which it received during the process of manufacture. Here is one of those little round mirrors which we buy for a few pennies at the bazaars. It is excellent and extremely serviceable if you desire to comb your beard, but detestable if you wish it to reflect light.

By means of these examples you can easily see that all our common mirrors are irregular and reflect light imperfectly, although forms can be reflected by them very well. These are true magic mirrors, only the image reflected is as irregular as the mirror itself, while that of the Japanese mirror is regular like the curves of the surface which produces it.

But are we quite certain that the flat and the convex parts of an irregular mirror reflect a sufficiently variable amount of light to make them quite distinct, one from the other. Let us see:

Here is a convex mirror, the summit of which has been planed off, making a flat mirror in the middle of a convex one. I will now reflect it upon the the screen by means of an electric light. You see the central portion is a very brilliant disk which shows that the flat mirror reflects the cylindric portion. Around it is a black circle in which there is no light at all. This is the space between the cylinder and a sort of funnel which contains the light reflected by the convex mirror. This light forms around the black circle a grayish ring of feeble intensity and quite distinguishable from the white central disk. The difference would be much more marked if the two lights were closer together.

Here I have another mirror which is flat. To the middle of it has been attached a convex lens. The whole has then been silvered. A reflecting light you see, shows us upon the screen, a large spot nearly black surrounded by a brilliant ring which has another ring around it of a gray color. The centre and the rings about it are produced by the reflection upon the central convex lens, across which comes the cylinder formed by the reflection upon the flat mirror.

The variation in intensity of the two reflections is enormous, particularly in the centre, which only appears black by contrast. For, of course, there is just as much light upon the central disk as upon the edges. We know that it is really luminous for we can cast upon it the shadow of an opaque body.

It has been, I hope, clearly demonstrated to you, therefore, that the curves upon the surface of the mirror produce inequalities of marked intensity when reflected. You have, however, a perfect right to remain in doubt as to Person's theory, because in all magic mirrors, these irregularities are very faint, being almost invisible to the naked eye. Although Person has endeavored to sustain his theory by direct observations upon the surface of his mirror, it was necessary to support it still further by means of new experiments.

An Italian *savant*, M. Govi, has undertaken this task, and in 1864 and 1865 presented two papers upon the subject to the Academy of Turin.

The first one contains several experiments made for the purpose of upholding Person and utterly demolishing Brewster. But Brewster was determined not to give in, and after having translated M. Govi's article for the *Scientific Review*, he followed it up with a quantity of remarks and objections which he certainly never would have made had he ever been fortunate enough to hold a magic mirror in his hands.

The stupidity of the illustrious Scotch physician had a very good result, for it incited M. Govi to seek new proofs and obtain a surer ground than ever for his opinion. In this way he conceived the idea of making the most important and most curious experiment which had yet been seen in regard to metallic mirrors. He thought that by heating the mirrors on the back, the warmth would take effect sooner upon the thin parts than upon the thick; that the former would become more convex, and thus the magic property would increase in such mirrors as already possessed it in some degree, and might possibly be produced in those which were not magic.

Here is General Teissier's mirror—you have already seen that it was slightly magic—I shall now have it heated

by means of a gas light placed behind it, and you will immediately see that the magical effects become more intense. It develops by degrees and produces nearly all the forms and images which are on the back, quite perfectly. You observe that the great quantity of small figures which are in but slight relief are not visible, while all the others of pronounced relief are clearly brought out. This fact is an important one. It shows us that we must look for magic mirrors only among those having ornaments in decided relief upon their backs. You must also know that they are not to be found among very thick mirrors. The experiment is still more successful with this Japanese toilet mirror.

The first experiments, after reading M. Govi's papers, were made by M. Ayrton and myself, as we desired to verify the investigation of the Italian *savant* before publishing them, and at the same time study thoroughly this very interesting subject, hoping that we might be able, perhaps, to reproduce the mirror in France instead of importing them from the extreme East. You must bear in mind that we had but one mirror at our disposition and that one but slightly magic. It belonged to M. Dybowski. We began by heating it as I shall show you presently. Here is the natural mirror which is hardly magical at all. You see the effect is produced in proportion to the amount of heat employed. Heat applied to several other Japanese mirrors bought in Paris or borrowed from collectors produced a magical effect upon them all.

These experiments were repeated by us very often. But it was not long before we discovered the inconveniences of the heating method. First of all, as it is extremely difficult to preserve an equal degree of warmth upon the entire surface. The image is rarely perfectly regular; then the mirror itself is somewhat altered. The reverse becomes covered with a bronze iridescence while the surface loses its polish because the heat destroys the amalgam which covers it, the mirror loaned to me was in a frightful condition when I returned it, but it was finally put in order again. The spots upon the back were removed by a coating of slightly acidulated water, and the amalgamation replaced by nickel plating which made a more perfect and durable polish. Before giving it back to its owner, however, we had numerous copies made from it, and it was one of these which I showed you a few moments since.

The disadvantages of heating made us wonder if the same effect could not be produced by a different method, and we thought of pressure. M. Duboscq solved the problem by means of this box. You see it is not thick, and is of the precise diameter of the mirror which is attached to the upper part by an iron ring and one of India rubber. The under portion is closed and provided with a spout and plug which it connects with the little hand pump well known as the Gay-Lussac. This pump inhales on one side, and exhales on the other. If we attach an India rubber tube to the spout, on the exhaling side the movement of the piston will compress the air behind the mirror. We will now try it.

The mirror becomes more convex and the image widens. The thin portions protrude more than the others and the magical effect grows more and more pronounced. It will be quite complete when the pressure attains two atmospheres. We have it now! You see, the effect is perfect. It is certainly much finer than anything M. Ayrton has shown us, although his experiments astonished us so much.

We can also produce an inverse effect, by attaching the rubber tube to the inhaling spout. The action of the pump will remove the air beneath the mirror, which will become less convex and you see the luminous disk contract. The thin portions corresponding to the outlines of the design will yield more than the others, become less convex and perhaps concave. They will reflect more light and we may see a new image appear which will be the exact reverse of the preceding. That is to say, that the parts in relief will appear black upon a white ground. This is a *negative* form of the first, in which we saw the relief traced in white upon a black surface.

M. Deboscq made many other experiments, one of which I will relate to you before I conclude.

I wished to go still further. I wished to have a cast taken of the mirror while it is magic, and make a galvano-plastic deposit in the mould so that we might have a magic surface instead of a mirror. We tried this three times. The plaster moulding was very successful and the surface magic, but the galvano-plastic deposit was a complete failure. If any one here among my audience can give me any advice upon the subject I would be most grateful.

Gentlemen, I hope sincerely I have been able to interest you in this new subject of magic mirrors. If I have succeeded in making my meaning throughout, clear to you, these mirrors will no longer be a mystery, and you will have seen once more how Science, by slow but sure efforts, is finally able to explain and reproduce phenomena, which at first sight seemed miracles, always provided that the phenomena are real and not mere phantoms of human credulity.

RECENT SURGICAL CASE.

The following case, which, in some respects, is similar to that of President Garfield's, may be read with interest for the purpose of comparison. The man was sent to St. Michael's Hospital, Newark, N. J., where his case was considered hopeless at the date of his entry. We are indebted to Dr. H. C. H. Herold for a copy of the following report:

George Freund, age 36, Germany, ex-policeman.—Admitted to hospital July 4th, suffering from bullet wound of chest. The wound was produced by a 22-inch calibre pistol, and situated an inch and three-quarters below and half an inch to the left of the left nipple. When seen half an hour after admission his pulse, temperature and respiration were all normal. On examining his lungs the percussion note was normal. On auscultation, rales were heard over both lungs, resulting from chronic bronchitis. He is subject to attacks of asthma. Heart sounds normal. Ordered one-quarter of a grain of morphine every two hours until sleep was obtained.

July 5.—Morning. Passed a very restless night, not seeming to feel the effects of the morphine. Temperature, 102; pulse, 120; respiration, 32, and very labored. It was ascertained on examination that he was suffering from an asthmatic attack. He has had no spitting of blood and no sign of any lung trouble. Ordered grains x of iodide of potash, three times a day. July 5.—Evening. Complains of great pain in the vicinity of the wound, extending toward the stomach. Temperature, 102; skin feeling to the hand cold and covered with a clammy sweat. Pulse, 80; quite feeble and compressible, intermitting at every second beat. Respiration, 30; not labored, having recovered from his asthmatic attack.

July 6.—Passed a very restless night; one-eighth grain of morphia given every two hours; temperature, 103; pulse, 110; respiration, 40; labored and sighing; slight hemorrhage from wound; all pain left him.

July 7.—Passed a quiet night, sleeping very well; only one-eighth grain of morphia administered; temperature, 101; pulse, 106; respiration, 18; slight hemorrhage from wound; expectoration of a sputa which looks very much like laudable pus.

July 8.—Slept quite well, taking one-eighth grain of morphia; complains of some pain in vicinity of wound; hemorrhage from wound ceased; has taken no food since admission, being sustained by stimulants, beef tea, milk, etc.; temperature, 102; pulse, 115, quite strong, intermitting at every fifth beat; respiration, 26.

July 9.—Very comfortable night, taking only one-

eighth grain of morphia; wound discharging laudable pus; temperature, 101½; pulse, 110; respiration, 24.

July 10.—Restless night, no morphia being given. Wound still discharging healthy pus. Temperature, 101½; pulse, 110; respiration, 26.

July 11.—Temperature, 101; pulse, 110; respiration, 24.

July 12.—Temperature, 102; pulse, 110; respiration, 22. Ordered digitalis.

July 13.—Temperature, 100½; pulse, 100; respiration, 22. Urine containing traces of albumen. Solid food taken and retained.

July 14.—Temperature, 101; pulse, 108; respiration, 20.

July 15.—Temperature, 100½; pulse, 95; respiration, 22.

July 16.—Temperature, 100½; pulse, 100; respiration, 22.

July 17.—Temperature, 101; pulse, 100; respiration, 23.

July 18.—Temperature, 101; pulse, 100; respiration, 22.

July 19.—Very restless night. Temperature, 101½; pulse, 130; respiration, 34. Complains of pain in the region of the heart.

July 20.— Temperature 101½; pulse, 120; respiration, 34.

July 21.—Temperature, 101; pulse, 112; respiration, 32.

July 23.—Restless night, troubled much by a short, hacking cough; wound entirely healed. Temperature, 100¾; pulse, 106; respiration, 32. Vomited his breakfast.

July 24.—Passed a restless night notwithstanding the free use of bromide. Temperature, 103; pulse, 130; respiration, 38. Still troubled with cough, which distresses him greatly; cannot retain solid food. Stimulants freely given.

July 25.—Slept better, but cough still troubles him; breathing labored. Temperature, 100¾; pulse, 65; respiration, 39; muscular twitching of hands and feet.

July 26.—Much more comfortable this morning. Temperature, 100½; pulse, 92; respiration, 40; digitalis discontinued.

July 27.—Temperature, 99; pulse, 58; respiration. 36.

July 28.—Temperature, 98½; pulse, 56; respiration, 30.

July 29.—Temperature, 99; pulse. 60; respiration. 32.

July 30.—Delirious during the night, attempted to get out of bed. Temperature, 99½; pulse, 52; strong and full; respiration, 28.

July 31.—Temperature 99½; pulse, 68; respiration, 32. Delirious during night. Bromides given freely.

August 1.—Temperature, 100; pulse, 52; strong and full; respiration, 34.

August 2.—Temperature, 98½; pulse, 51; respiration. 30. Delirious during night.

August 3.—Temperature, 98½; pulse, 108; respiration, 22. Troubled very much with attacks of coughing.

August 4.—Temperature, 98½; pulse, 100; respiration, 24.

August 5.—Temperature, 98½; pulse, 96; respiration, 24.

August 6.—Temperature, 100; pulse, 96; respiration, 20.

August 7.—Temperature, 99; pulse 94; respiration 19.

August 8—Temperature, 98¾; pulse, 88; respiration, 22; sleeps well; appetite, good.

August 9.—Temperature, 98½; pulse, 90; respiration, 20.

August 13.—Temperature, pulse and respiration have remained the same as on August 9. The patient for the first time to-day since his injury has been allowed to get up and dress.

August 18.—Doing well since last report. Walks around the wards; eats and sleeps well, the bullet remaining in his body.

ON THE GERM THEORY.*

By Prof. Pasteur.

"The subject of my communication is vaccination in relation to chicken cholera and splenic fever, and a statement of the method by which we have arrived at these results—a method the fruitfulness of which inspires me with boundless anticipations. Before discussing the question of splenic fever vaccine, which is the most important, permit me to recall the results of my investigations of chicken cholera. It is through this inquiry that new and highly important principles have been introduced into science concerning the virus or contagious quality of transmissible diseases. More than once in what I am about to say I shall employ the expression virus-culture, as formerly, in my investigations on fermentation, I used the expressions, the culture of milk ferment, the culture of the butyric vibrion, etc. Let us take, then, a fowl which is about to die of chicken cholera, and let us dip the end of a delicate glass rod in the blood of the fowl with the usual precautions, upon which I need not here dwell. Let us then touch with this charged point some *bouillon de poule*, very clear, but first of all rendered sterile under a temperature of about 115° centigrade, and under conditions in which neither the outer air nor the vases employed can introduce exterior germs —those germs which are in the air, or on the surface of all objects. In a short time, if the little culture vase is placed in a temperature of 25° to 35°, you will see the liquid become turbid and full of tiny microbes, shaped like the figure 8, but often so small that under a high magnifying power they appear like points. Take from this vase a drop as small as you please, no more than can be carried on the point of a glass rod as sharp as a needle, and touch with this point a fresh quantity of sterilized *bouillon de poule* placed in a second vase, and the same phenomenon is produced. You deal in the same way with a third culture vase, with a fourth, and so on to a hundred, or even a thousand, and invariably within a few hours the culture liquid becomes turbid and filled with the same minute organisms.

"At the end of two or three days' exposure to a temperature of about 30° C. the thickness of the liquid disappears, and a sediment is formed at the bottom of the vase. This signifies that the development of the minute organism has ceased—in other words, all the little points which caused the turbid appearance of the liquid have fallen to the bottom of the vase, and things will remain in this condition for a longer or shorter time, for months even, without even the liquid or the deposit undergoing any visible modification, inasmuch as we have taken care to exclude the germs of the atmosphere. A little stopper of cotton sifts the air which enters or issues from the vase through changes of temperature. Let us take one of our series of culture preparations—the hundredth or the thousandth, for instance—and compare it in respect to its virulence with the blood of a fowl which has died of cholera; in other words, let us inoculate under the skin ten fowls, for instance, each separately with a tiny drop of infectious blood, and ten others with a similar quantity of the liquid in which the deposit has first been shaken up. Strange to say, the latter ten fowls will die as quickly and with the same symptoms as the former ten; the blood of all will be found to contain after death the same minute infectious organisms. This equality, so to speak, in the virulence both of the culture preparation and of the blood is due to an apparently futile circumstance. I have made a hundred culture preparations—at least, I have understood that this was done—without leaving any considerable interval between

* "International Medical Congress." London, 1881.

the impregnations. Well, here we have the cause of the equality in the virulence.

"Let us now repeat exactly our successive cultures with this single difference, that we pass from one culture to that which follows it—from the hundredth to, say, the hundred and first, at intervals, of a fortnight, a month, two months, three months or ten months. If, now, we compare the virulence of the successive cultures, a great change will be observed. It will be readily seen from an inoculation of a series of ten fowls that the virulence of one culture differs from that of the blood and from that of a preceding culture when a sufficiently long interval elapses between the impregnation of one culture with the microbe of the preceding. More than that, we may recognize by this mode of observation that it is possible to prepare cultures of varying degrees of virulence. One preparation will kill eight fowls out of ten, another five out of ten, another one out of ten, and another none at all, although the microbe may still be cultivated. In fact, what is no less strange, if you take each of these cultures of attenuated virulence as a point of departure in the preparation of successive cultures and without appreciable interval in the impregnation, the whole series of these culures will reproduce the attenuated virulence of that which has served as the starting point. Similarly, where the virulence is null it produces no effect. How, then, it may be asked, are the effects of these attenuating virulences revealed in the fowls? They are revealed by a local disorder, by a morbid modification more or less profound in a muscle, if it is a muscle which has been inoculated with the virus. The muscle is filled with microbes which are easily recognized, because the attenuated microbes have almost the bulk, the form, and the appearance of the most virulent microbes.

"But why is not the local disorder followed by death? For the moment let us answer by a statement of facts. They are these: the local disorder ceases of itself more or less speedily, the microbe is absorbed and digested, if one may say so, and little by little the muscle regains its normal condition. Then the disease has disappeared. When we inoculate with the microbe, the virulence of which is null, there is not even local disorder, the *naturæ medicatrix* carries it off at once, and here, indeed, we see the influence of the resistance of life, since this microbe, the virulence of which is null, multiplies itself. A little farther, and we touch the principle of vaccination. When the fowls have been rendered sufficiently ill by the attenuated virus which the vital resistance has arrested in its development, they will, when inoculated with virulent virus, suffer no evil effects, or only effects of a passing character. In fact, they no longer die from the mortal virus, and for a time sufficiently long, which in some cases may exceed a year, chicken cholera cannot touch them, especially under the ordinary conditions of contagion which exist in fowl-houses. At this critical point of our manipulation—that is to say, in this interval of time which we have placed between two cultures, and which causes the attenuation—what occurs? I shall show you that in this interval the agent which intervenes is the oxygen of the air. Nothing more easily admits of proof. Let us produce a culture in a tube containing very little air, and close this tube with an enameller's lamp. The microbe in developing itself, will speedily take all the oxygen of the tube and of the liquid, after which it will be quite free from contact with oxygen. In this case it does not appear that the microbe becomes appreciably attenuated, even after a great lapse of time. The oxygen of the air, then, would seem to be a possible modifying agent of the virulence of the microbe of chicken cholera—that is to say, it may modify more or less facility of its development in the body of animals. May we not be here in presence of a general law applicable to all kinds of virus? What benefits may not be the result? We may hope to discover in this way the vaccine of all virulent diseases; and what is more natural than to begin our investigation of the vaccine of what we in French call charbon, what you in England call splenic fever, and what in Russia is known as the Siberian pest, and in Germany as the Milzbrand.

"In this new investigation I have had the assistance of two devoted young *savants*—MM. Chamberland and Roux. At the outset we were met by a difficulty. Among the inferior organisms, all do not resolve themselves into those corpuscle germs which I was the first to point out as one of the forms of their possible development. Many infectious microbes do not resolve themselves in their cultures into corpuscle germs. Such is equally the case with beer yeast which we do not see develop itself usually in breweries, for instance, except by a sort of scissiparity. One cell makes two or more, which form themselves in wreaths; the cells become detached, and the process recommences. In these cells real germs are not usually seen. The microbe of chicken-cholera and many others behave in this way, so much so that the cultures of this microbe, although they may last for months without losing their power of fresh cultivation, perish finally like beer yeast which has exhausted all its aliments. The anthracoid microbe in artificial cultures behaves very differently. In the blood of animals, as in cultures, it is found in translucid filaments more or less segmented. This blood or these cultures freely exposed to air, instead of continuing according to the first mode of generation, show at the end of forty-eight hours corpuscle germs distributed in series more or less regular along the filaments. All around these corpuscles matter is absorbed. as I have represented it formerly in one of the plates of my work on the diseases of silkworms. Little by little all connection between them disappears, and presently they are reduced to nothing more than germ dust.

"If you make these corpuscles germinate, the new culture reproduces the virulence peculiar to the thready form which has produced these corpuscles, and this result is seen even after a long exposure of these germs to contact with air. Recently we discovered them in pits in which animals dead of splenic fever had been buried for twelve years, and their culture was as virulent as that from the blood of an animal recently dead. Here I regret extremely to be obliged to shorten my remarks. I should have had much pleasure in demonstrating that the anthracoid germs in the earth of pits in which animals have been buried are brought to the surface by earthworms, and that in this fact we may find the whole etiology of disease, inasmuch as the animals swallow these germs with their food. A great difficulty presents itself when we attempt to apply our method of attenuation by the oxygen of the air to the anthracoid microbes. The virulence establishing itself very quickly, often after twenty-four hours in an anthracoid germ which escapes the action of the air, it was impossible to think of discovering the vaccine of splenic fever in the conditions which had yielded that of chicken-cholera. But was there, after all, reason to be discouraged? Certainly not; in fact, if you observe closely, you will find that there is no real difference between the mode of the generation of the anthracoid germ by scission and that of chicken-cholera. We had therefore reason to hope that we might overcome the difficulty which stopped us by endeavoring to prevent the anthracoid microbe from producing corpuscle germs, and to keep it in this condition in contact with oxygen for days, and weeks, and months. The experiment fortunately succeeded.

"In the ineffective (*neutre*) *bouillon de poule* the anthracoid microbe is no longer cultivable at 45° C. Its culture, however, is easy at 42° or 43°, but in these conditions the microbe yields no spores. Consequently it is possible to maintain in contact with the pure air at 42° or 43° a *mycélienne* culture of bacteria entirely free of germs. Then appear the very remarkable results which follow. In a month or six weeks the culture dies—that

is to say, if one impregnates with it fresh *bouillon*, the latter is completely sterile. Up to that time life exists in the vase exposed to air and heat. If we examine the virulence of the culture at the end of two days, four days, six days, eight days, etc., it will be found that long before the death of the culture the microbe has lost all virulence, although still cultivable. Before this period it is found that the culture presents a series of attenuated virulences. Everything is similar to what happens in respect to the microbe in chicken cholera. Besides, each of these conditions of attenuated virulence may be reproduced by culture; in fact, since the charbon does not operate a second time (*ne récidive pas*), each of our attenuated anthracoid microbes constitutes for the superior microbe a vaccine—that is to say, a virus capable of producing a milder disease. Here, then, we have a method of preparing the vaccine of splenic fever. You will see presently the practical importance of this result, but what interests us more particularly is to observe that we have here a proof that we are in possession of a general method of preparing virus vaccine based upon the action of the oxygen and the air—that is to say, of a cosmic force existing everywhere on the surface of the globe.

"I regret to be unable, from want of time, to show you that all these attenuated forms of virus may very easily, by a physiological artifice, be made to recover their original maximum virulence. The method I have just explained of obtaining the vaccine of splenic fever was no sooner made known than it was very extensively employed to prevent the splenic affection. In France we lose every year, by splenic fever, animals of the value of twenty million francs. I was asked to give a public demonstration of the results already mentioned. This experiment I may relate in a few words. Fifty sheep were placed at my disposition, of which twenty-five were vaccinated. A fortnight afterward the fifty sheep were inoculated with the most virulent anthracoid microbe. The twenty-five vaccinated sheep resisted the infection; the twenty-five unvaccinated died of splenic fever within fifty hours. Since that time my energies have been taxed to meet the demands of farmers for supplies of this vaccine. In the space of fifteen days we have vaccinated in the departments surrounding Paris more than twenty thousand sheep, and a large number of cattle and horses. If I were not pressed for time I would bring to your notice two other kinds of virus attenuated by similar means. These experiments will be communicated by-and-by to the public. I cannot conclude, gentlemen, without expressing the great pleasure I feel at the thought that it is as a member of an international medical congress assembled in England that I make known the most recent results of vaccination upon a disease more terrible, perhaps, for domestic animals than small-pox is for man. I have given to vaccination an extension which science, I hope, will accept as a homage paid to the merit and to the immense services rendered by one of the greatest men of England, Jenner. What a pleasure for me to do honor to this immortal name in this noble and hospitable city of London!"

FROM a privately issued report on silk cultivation in the Chinese province of Kwangtung, we learn that in the Pakhoi district, on the southern seaboard, wild silkworms are found which feed on the camphor tree, and their silk is utilized in a singular manner. When the caterpillar has attained its full size, and is about to enter the *pupa* state, it is cut open and the silk extracted in a form much resembling catgut. This substance, having undergone a process of hardening, makes excellent fish line, and is generally used for that purpose in the Pakhoi district.

CORRESPONDENCE.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. No notice is taken of anonymous communications.*]

To the Editor of "SCIENCE."

Mr. Samuel J. Wallace, commenting on my paper on "The Use of Water as a Fuel" ("SCIENCE," Vol. II., p. 321), in an interesting communication to you ("SCIENCE," Vol. II., p. 373), suggests an inadvertancy on my part in "not more clearly distinguishing between the degrees of temperature at which the transfer of oxygen takes place from the hydrogen of the water to the carbon set free by the dissociation of the naphtha and the number of heat units set free or absorbed by such transfer, which is a very different thing."

To this I would state in reply that I have purposely refrained from an elaborate calculation of the thermal effects in heat units for several reasons. Of these I shall detail but a few of the more important at present.

In the first place, my intention was to give the scientific rationale of the chemical processes involved in the generation of the tremendous heat produced by the Holland retort with so insignificant an amount of naphtha; and, furthermore, I wanted to show that the application of the principle of the correlation of forces and conservation of energy to this new and original process of combustion has been undertaken heretofore on an erroneous assumption; lastly, I intended to prove, in the shortest and clearest possible manner, what a proportion of heat was gained, and in what manner—viz., by the dissociation of steam in the presence and by the agency of the carbon contained in the naphtha.

For these and other reasons, I avoided long explanations and calculations of other points, such as, for instance, the "dissociation of the naphtha," as Mr. Wallace puts it, and the figuring up of the heat units generated by the several elements on combustion. In order to re-affirm my position, which is, on most points, not that assumed by Mr. Wallace, I may be allowed to offer the following remarks:

It is self-evident that the carbon of the naphtha, in order to act independently, must first be set free; this is accomplished by the heating of the naphtha, in its chamber of the retort, up to the point of gasification. On meeting the steam in the manifold, the carbon of the naphtha leaves its hydrogen and forthwith unites with the oxygen of the watery vapor, forming *either* carbonic oxide *or* carbonic acid, according to the amount of steam introduced.

Thus there is certainly a decomposition of the naphtha into its elements, as Mr. Wallace intimates; but by far the most important process is the *dissociation of the watery vapor* which Mr. Wallace refuses to recognize, insisting, as he does, that there is only a *transfer* of the oxygen from the hydrogen of the steam to the carbon of the naphtha. How this is possible, without the previous dissociation of the steam, I am unable to understand. Mr. Wallace furnishes, indeed, the best argument against his own statement, by mentioning the well-known fact that the carbon in the naphtha is very loosely held by its hydrogen. But it is also a well-known fact that the oxygen of the steam is very tenaciously held by its hydrogen, so much so that it was considered impossible to separate, *to dissociate*, them by heat for a long time. Not until the late Henri St. Clair Deville * devised an appa-

* It is with profound grief that the announcement of the great chemist's death has been received everywhere. At his funeral (July 5th) M. Pasteur made an eloquent speech. The London *Chemical News* has an obituary in which occurs the following passage: "His highest achievement, from a strictly scientific point of view, was the establishment of the laws of dissociation. Previously, decomposition was regarded as a simple phenomenon, effected and completed, in the case of every substance, at a fixed temperature. Deville showed that in some cases it is effected within certain limits of temperature, being arrested at a given heat by the equilibrium established between the decomposing body and the product of decomposition."

ratus *for this purpose* was this dissociation accomplished by heat alone.

The reason for this state of things is apparent. Hydrogen in uniting with oxygen to form water develops the greatest amount of heat, a greater amount, in fact, than an equal weight of any other known element. And just here I would ask Mr. Wallace which authority has stated that the "absolute heat of carbon and hydrogen are almost exactly equal in complete burning." On the contrary, all authorities agree, and all investigators have established beyond doubt the fact, that hydrogen develops *more than four times as much heat* on combustion than does an equal weight of carbon. The figures at present universally accepted as a standard are those determined by Favre and Silberman, during their carefully conducted and numerous experiments. According to them—

1 grain of hydrogen develops 34,462 units of heat.
1 grain of carbon " 8,080 units of heat.

on complete combustion.

This great advantage in the heat-producing power of hydrogen is the principal reason why scientists have constantly striven to substitute this element for carbon, which is now universally used as fuel. But until lately only this was thought impracticable, because it was believed that the same amount of heat was necessary to obtain the hydrogen by the dissociation of water, which would ultimately be obtained by the combustion of said hydrogen. And even the processes of Strong and others for the generation of so-called 'water-gas' have not changed this erroneous view. For, the advantages arrived at by them were ascribed rather to various extraneous causes* than to the one principal cause, *i. e.*, the dissociation of steam by the chemical affinity of carbon, and the consequent generation of a not inconsiderable amount of hydrogen.

This very same line of argument has been followed in the discussions about the Holland process, and the principal aim of my paper was to controvert it, and to show that it is *not heat, but chemical affinity*, which does by far the greatest part of the work of dissociation. I was enabled to do so on the basis of Dahlerus' experiments, which have proved conclusively that carbon will dissociate water at 400° C, instead of 8000° C, which is Deville's figure for the dissociation-temperature of water in the absence of any other element.†

From the foregoing the readers of "SCIENCE" will perceive that the enormous gain obtained by actual experiment with the Holland locomotive is satisfactorily explained on scientific grounds.

All the further argumentation of Mr. Wallace covers the earlier water-gas processes of Lowe, Strong and others; they generate their gaseous fuel in a separate contrivance (the generator) and afterward burn it. For this reason they want to accomplish only the first stage of carbon, combustion water-gas, consisting of hydrogen and carbonic oxide. In the process under consideration, however, the retort which prepares the fuel, *i. e.*, gasifies the naphtha and the water, is placed just where the heating is to take place. All the heat, therefore, that is developed by the carbon combustion is utilized, as is also all the heat which is developed by the dissociated hydrogen burning up with atmospheric oxygen.

Indeed, this process is the only one which comes pretty near to fulfill all the requirements of an ideal method. These are;

1. Gaseous condition of the fuel.
2. Complete combustion (no smoke, no ashes).
3. Full effects of the caloric energy developed.
4. Regulation of the draught-air, so as to admit the least amount of atmospheric air practicable.
5. Greatest possible percentage of oxygen in atmosphere of combustion. (The oxygen derived from the dissociation of the steam being employed for the combustion of carbon, the necessary draught-air is thereby materially reduced and thus the percentage of oxygen increased).
6. Universal adaptibility (kitchen and parlor stoves, fire places, stationary and other boilers, locomotives and ocean steamers can be accommodated with it, and illuminating gas is prepared automatically by an additional chamber in the retort).
7. Simplicity of apparatus. (May be managed by the turning of a few faucets.)
8. Cheapness of the fuel employed. (Water is certainly to be obtained everywhere at small expense, while the price of naphtha is only three cents a gallon if bought by the single barrel.)
9. Fuel used of the greatest heating capacity, with each atom of Carbon burned, there are burned at the same time *four* atoms of Hydrogen, thus:

$$\underset{\text{(Naphtha.)}}{C_2H_4} + \underset{\text{(Water.)}}{4\,HO} = 2\,(CO_2) + 8\,H.$$

The eight Hydrogen are burned with atmospheric Oxygen.

Crude oil *i. e.* petroleum that has undergone one distillation, to free it from its mineral and waxy ingredients, may be used, but would be much dearer. Naphtha, it may be said in conclusion, is not one of the distillation products, as might be inferred from the name: It is the unused residue from all the various distillation-processes to which petroleum is subjected. *It is a waste product* and therefore cheaper than anything else.

It is obtained in this wise:

The crude oil as it is received from the stills of the petroleum regions is subjected to twelve successive distillations, and the following products result:

Cymogene.
Rhigolene.
Gasolene.
C. Naphtha.
B. Naphtha.
A. Naphtha.
Benzine.
Kerosene.
Mineral Sperm Oil.
Lubricating Oil.
Paraffin.

Of these only the last four are completely used in the arts and for illuminating purposes. The unused residue of all the others is thrown back into the residue remaining from the last distillation. The quality of the mixture called Naphtha, and used in the Holland process is therefore not always the same, but this does not at all alter its value as a fuel, as it does not alter the main features of this process, as they have been explained in our remarks.

GEO. W. RACHEL, M. D.

* Some of these are: gasification of the fuel, substitution of the second for the first stage of carbon—combustion, reduction of the amount of draft-air, etc.

† The combustion- (and dissociation-) temperature may be found by calculation from the thermal effect and the specific heat of the product (*i. e.*, water) in the following manner, according to MOHR (Mech. Theorie d. chem. Affin., p. 102):

If one part of hydrogen burns up with eight parts of oxygen, forming nine parts of water, 34462 units of heat are generated which are contained in the watery vapor thus formed. If the specific heat of steam would be the same as that of water, the actual temperature of these nine parts of water would be:

$$\frac{34462}{9} = 38290^\circ \text{ C.}$$

Since the specific heat of steam is, however: .475, the actual temperature of the nine parts of watery vapor is:

$$\frac{3829}{.475} = 8061^\circ \text{ C.}$$

For this reason 8000° C has been assumed as the dissociation-temperature of watery vapor.

King's Cross Station, Great Northern Railway, is now lighted by means of electricity, a beginning having been made last week by means of the Crompton system. There are 12 Crompton lamps within the station, six being placed over the arrival, and a similar number over the departure platform. Two other lamps of larger size are placed outside the station building. The interior area lighted consists of two bays, each 880 feet long and 105 feet wide, and 72 feet high, as well as the cab-rank adjoining the arrival platform, which is 40 feet wide. The total area lighted is 220,000 square feet, giving an area of 18,133 square feet, or nearly half an acre, to each lamp. The lamps are suspended at a height of 30 feet from the platform level, and are arranged on four circuits, the light of each lamp being computed as equivalent to 4000 candles. Any unpleasantness from the intensity of the light is obviated by the use of semi-transparent glass in the lower portion of the lanterns. The two exterior lights are estimated at 6000 candles each, are placed at an altitude of 70 feet, the lanterns being of clear glass. The current is supplied by means of five Burgin dynamo-electric machines, which are driven by a semiportable engine by Messrs. Marshall, Sons & Co., of Gainsborough, working up to 35-horse power.

THE death of John Duncan, the Alford, England, botanist, is announced as having taken place last week in his 85th year. The deceased adopted the occupation of a weaver by trade, but devoted all his spare time to the study of botany. His splendid collection of plants he handed over to Aberdeen University a year ago, but he has lived barely six months to enjoy the fund which public recognition of his merits placed at his disposal in his declining years. The story of John Duncan's life is to be told by Mr. Jolly, himself an enthusiastic botanist.

Various attempts have been made to explain the tails of comets. A recent one by M. Picart is as follows: The Sun, the stars, nebulæ and comets, are composed not only of ponderable matter in the gaseous state, but of imponderable matter, the luminous ether, revealed, in the case of the sun by the zodiacal light, and in that of nebulæ, by their irregular forms contrary to gravitation. A comet far from the sun, appears in spheroidal form, due to gravitation of its ponderable matter (its luminous ether being then invisible because of distance and feeble light). But on nearing the sun, the luminous ether of this body repels that of the comet (this being a characteristic property of the ether) so forming the tail. The form and direction of the tail are thus quite independent of gravitation; and the enormous velocity ceases to be a difficulty, as it is if the matter of the tail be thought ponderable. M. Lamey has observed that the solar light, being unable completely to penetrate the comet's tail, illumines only the left part, producing a true cometary phase.

THE assimilation of nitrogen by plants has, of late, been carefully studied by Signor Lamattina, of Rome, who arrives at the following results: Plants absolutely require to assimilate nitrogen, and they obtain it in three forms: (1) In the nitrates of the ground; (2) In the ammonia of the air; (3) In the State of protoxide in the atmosphere. The nitrogen in the state of nitrates, absorbed by the roots, is for transport and diffusion of mineral substances, principally potash, in the leaves, helping to form chlorophyll and hydrocarbons. The nitrogen absorbed in the form of ammonia by respiration, serves for formation of albuminoids, fibrine, etc. The nitrogen absorbed in the state of protoxide, appears to serve as complement of the food of the plant, acting both as corrective, by neutralising the basis in excess, and helping in the formation of alkaloids.

METEOROLOGICAL REPORT FOR NEW YORK CITY FOR THE WEEK ENDING AUG. 27, 1881.

Latitude 40° 45′ 58″ N.; Longitude 73° 57′ 58″ W.; height of instruments above the ground, 53 feet; above the sea, 97 feet; by self-recording instruments.

TRIBUNE BUILDING, NEW YORK.

P. O. Box 3838.

SATURDAY, SEPTEMBER 10, 1881.

Residents of New York city who visited Cincinnati on the occasion of the meeting of the American Association for the Advancement of Science, doubtless returned with a better appreciation of the water supply of their own city.

Cincinnati draws its supply of water direct from the Ohio river, at a point within the city limits, and within a few yards of the outlet of a main sewer which discharges its abominations into the already discolored and muddy waters of the river.

Some idea may be formed of the condition of this water, when we state, that a small quantity poured into a washing basin, obscured the view of the bottom of the utensil, so opaque is the water by reason of its muddy impurity. And yet, the river at this time was at its best, for, undisturbed by rains or floods, it flowed past the city reduced to its lowest limits, and in its highest condition of purity.

Unanimity among the population of a large city on any one point, is not to be expected, but, it was with some surprise we heard expressions of admiration regarding this water, from some Cincinnatians. The majority of the people, however, were disgusted with the water supply of the city, and many were seeking their own remedy by the construction of artesian wells. The public press of Cincinnati, during our visit was loud in its denunciations of the evil, making excellent suggestions for obtaining the water supply from a purer source, and other needed improvements.

Recently the question has been much discussed, as to whether a city should draw its supply from a river, or from lakes and storage reservoirs. Which will give the best results?

This question is beset with many difficulties, and, in our opinion, cannot be determined in such a manner, that any particular decision for future guidance, *in all cases*, can be delivered. We apprehend that local causes and conditions which vary for every locality, having due weight and being well considered, should decide the question.

Of course absolute purity is not demanded, neither is it essential. The object to be aimed at, and that must be secured at any cost, is such a condition of purity which may be expressed by the term "fitness."

A water that is free from any impurities dangerous to health, of a good color and inodorous, may be considered "fit" for the supply of a city.

The question as to the best source for a supply of water, has of late received much attention from chemists and sanitary engineers. Reviewing the discussions, we express the opinion, that water drawn from a river which is free from sewage contaminations and not subject to discoloration, is preferable to water collected in lakes and storage reservoirs. The storage of water in reservoirs for long periods, without doubt, causes a deterioration in the quality of the water, generating a variety of animal and vegetable forms that are characteristic of stagnant waters, and which are dangerous to health. River water, on the contrary, if not contaminated directly near the source of supply, is usually free from those impurities which are most undesirable.

On this point we refer our readers to "Science," Vol. I. page 67, where will be found an analysis of the water supply of Newark, N. J., obtained from the river Passaic, contrasted with water used in that city, obtained from driven wells. The result showed that the water from the Passaic river, although contaminated with sewage to a certain extent, and below what may be considered a satisfactory condition, stood at the head of the list in regard to purity and general fitness for sanitary purposes. We believe that recently Professor Leeds, of Hoboken, has made analyses of the same waters, with very similar results.

But, from whatever source water may be obtained, a certain amount of manipulation appears to be essential before it is fit for distribution in a city. In the first place it should be held in a reservoir for 24 hours, to permit the suspended matter to subside; it should go through some simple process of filtration; and, lastly, be pumped to a sufficient elevation to secure a supply of water to the upper part of every house in the city.

The question of the public filtration of water for city use no doubt presents many difficulties, but until such filtration is accomplished by the authorities, every householder should make use of a filter, to cleanse from impurities, the water used for drinking and cooking purposes; for apart from the question of health, the interest of the public in securing pure water is

not confined to its use as an article of diet, because for all purposes for which water is employed, the purer it is, the better it is adapted for use.

THE CONNECTION OF THE BIOLOGICAL SCIENCES WITH MEDICINE.*

By T. H. Huxley, LL.D.

"The great man whose name is inseparably connected with the foundation of medicine, Hippocrates certainly knew very little—indeed, practically nothing—of anatomy or physiology; and he would probably have been perplexed even to imagine the possibility of a connection between the zoölogical studies of his contemporary, Democritus, and medicine. Nevertheless, in so far as he and those who worked before and after him in the same spirit ascertained, as matters of experience, that a wound or a luxation, or a fever, presented such and such symptoms, and that the return of the patient to health was facilitated by such and such measures, they established laws of Nature and began the construction of the science of pathology. All true science begins with empiricism, though all true science is such exactly in so far as it strives to pass out of the empirical stage into that of the deduction of empirical from more general truths. Thus, it is not wonderful that the early physicians had little or nothing to do with the development of biological science; and, on the other hand. that the early biologists did not much concern themselves with medicine. There is nothing to show that the Asclepiads took any prominent share in the work of founding anatomy, physiology, zoölogy and botany. Rather do these seem to have sprung from the early philosophers, who were essentially natural philosophers, animated by the characteristically Greek thirst for knowledge as such. Pythagoras, Alcmæon, Democritus, Diogenes of Apollonia, are all credited with anatomical and physiological investigation; and though Aristotle is said to have belonged to an Asclepiad family, and not improbably owed his taste for anatomical and zoölogical inquiries to the teachings of his father, the physician Nicomachus, the 'Historia Animalium,' and the treatise 'De Partibus Animalium,' are as free from any allusion to medicine as if they had issued from a modern biological laboratory.

"It may be added, that it is not easy to see in what way it could have benefited a physician of Alexander's time to know all that Aristotle knew on these subjects. His human anatomy was too rough to avail much in diagnosis, his physiology was too erroneous to supply data for pathological reasoning. But when the Alexandrian school, with Erasistratus and Herophilus at their head, turned to account the opportunities of studying human structure afforded to them by the Ptolemies, the value of the large amount of accurate knowledge thus obtained to the surgeon for his operations, and to the physician for his diagnosis of internal disorders, became obvious, and a connection was established between anatomy and medicine, which has ever become closer and closer. Since the revival of learning, surgery, medical diagnosis, and anatomy have gone hand in hand. Morgagni called his great work 'De Sedibus et Causis Morborum per Anatomen Indagatis,' and not only showed the way to search out the localities and the causes of disease by anatomy, but himself travelled wonderfully far upon the road. Bichat, discriminating the grosser constituents of the organs and parts of the body one from another, pointed out the direction which modern research must take; until at length histology, a science of yesterday, as it seems to many of us, has carried the work of Morgagni as far as the microscope can take us, and has extended the realm of pathological anatomy to the limits of the invisible world.

"Thanks to the intimate alliance of morphology with medicine, the natural history of disease has, at the present day, attained a high degree of perfection. Accurate regional anatomy has rendered practicable the exploration of the most hidden parts of the organism, and the determination during life of morbid changes in them; anatomical and histological post-mortem investigations have supplied physicians with a clear basis upon which to rest the classification of diseases, and with unerring tests of the accuracy or inaccuracy of their diagnosis. If men could be satisfied with pure knowledge, the extreme precision with which, in these days, a sufferer may be told what is happening, and what is likely to happen, even in the most recondite parts of his bodily frame, should be as satisfactory to the patient as it is to the scientific pathologists who gives him the information. But I am afraid it is not; and even the practising physician, while nowise underestimating the regulative value of accurate diagnosis, must often lament that so much of his knowledge rather prevents him from doing wrong than helps him to do right. A scorner of physic once said that Nature and disease may be compared to two men fighting, the doctor to a blind man with a club, who strikes into the *mêlée* sometimes hitting the disease and sometimes hitting all Nature. The matter is not mended if you suppose the blind man's hearing to be so acute that he can register every stage of the struggle and pretty clearly predict how it will end. He had better not meddle at all until his eyes are opened—until he can see the exact position of the antagonists, and make sure of the effects of his blows. But that which it behooves the physician to see, not indeed with his bodily eye, but with clear intellectual vision, is a process, and the chain of causation involved in that process. Disease, as we have seen, is a perturbation of the normal activities of a living body; and it is and must remain unintelligible so long as we are ignorant of the nature of these normal activities. In other words, there could be no real science of pathology until the science of physiology had reached a degree of perfection unattained, and indeed unattainable, until quite recent times.

"So far as medicine is concerned, I am not sure that physiology, such as it was down to the time of Harvey, might as well not have existed. Nay, it is, perhaps, no exaggeration to say that, within the memory of living men, justly renowned practitioners of medicine and surgery knew less physiology than is now to be learned from the most elementary text book, and, beyond a few broad facts, regarded what they did know as of extremely little practical importance. Nor am I disposed to blame them for this conclusion; physiology must be useless, or worse than useless, to pathology, so long as its fundamental conceptions are erroneous. Harvey is often said to be the founder of modern physiology, and there can be no question that the elucidations of the function of the heart, of the nature of the pulse, and of the course of the blood, put forth in the ever-memorable little essay, 'De motu cordis,' directly worked a revolution in men's views of the nature and of the concatenation of some of the most important physiological processes among the higher animals, while indirectly their influence was perhaps even more remarkable. But, though Harvey made this signal and perennially important contribution to the physiology of the moderns, his general conception of vital processes was essentially identical with that of the ancients; and in the 'Exercitationes de generatione,' and notably in the singular chapter, 'De calido innato,' he shows himself a true son of Galon and of Aristotle. For Harvey, the blood possesses powers superior to those of the elements; it is the seat of a soul which is not only vegetative, but also sensitive and motor. The blood maintains and fashions all parts of the body, *idque summâ cum providentia et intellectu, in finem certum agens, quasi ratiocinio quodam uteretur*. Here is the doctrine of the *pneuma*, the product of the philosophical mould into which the animism of primitive men ran in Greece, in

* International Medical Congress London, 1881.

full force. Nor did its strength abate for long after Harvey's time. The same ingrained tendency of the human mind to suppose that a process is explained when it is ascribed to a power of which nothing is known except that it is the hypothetical agent of the process, gave rise, in the next century, to the animism of Stahl; and later to the doctrine of a vital principle, that *asylum ignorantiæ* of physiologists, which has so easily accounted for everything and explained nothing, down to our own times.

"Now, the essence of modern, as contrasted with ancient physiological science, appears to me to lie in its antagonism to animistic hypotheses and animistic phraseology. It offers physical explanations of vital phenomena, or frankly confesses that it has none to offer. And, so far as I know, the first person who gave expression to this modern view of physiology, who was bold enough to enunciate the proposition that vital phenomena, like all the other phenomena of the physical world, are in ultimate analysis, resolvable into matter and motion, was René Descartes. The fifty-four years of life of this most original and powerful thinker are widely over-lapped on both sides by the eighty of Harvey, who survived his younger contemporary by seven years, and takes pleasure in acknowledging the French philosopher's appreciation of his great discovery. In fact, Descartes accepted the doctrine of the circulation as propounded by 'Hervæus, médecin d'Angleterre,' and gave a full account of it in his first work, the famous 'Discours de la Méthode,' which was published in 1637, only nine years after the exercitation 'De motu cordis;' and, though differing from Harvey in some important points (in which it may be noted, in passing, Descartes was wrong and Harvey right), he always speaks of him with great respect. And so important does the subject seem to Descartes, that he returns to it in the 'Traitè des Passions,' and in the 'Traitè de l'Homme.'

"It is easy to see that Harvey's work must have had a peculiar significance for the subtle thinker, to whom we owe both the spiritualistic and the materialistic philosophies of modern times. It was in the very year of its publication, 1628, that Descartes withdrew into that life of solitary investigation and meditation of which his philosophy was the fruit; and, as the course of his speculations led him to establish an absolute distinction of Nature between the material and the mental worlds, he was logically compelled to seek for the explanation of the phenomena of the material world within itself, and having allotted the realm of thought to the soul, to see nothing but extension and motion in the rest of Nature. Descartes uses 'thought' as the equivalent of our modern term 'consciousness.' Thought is the function of the soul, and its only function. Our natural heat and all the movements of the body, says he, do not depend on the soul. Death does not take place from any fault of the soul, but only because some of the principal parts of the body become corrupted. The body of a living man differs from that of a dead man in the same way as a watch or other automaton (that is to say, a machine which moves of itself) when it is wound up, and has in itself the physical principal of the movements which the mechanism is adapted to perform, differs from the same watch or other machine when it is broken, and the physical principle of its movements no longer exists. All the actions which are common to us and the lower animals depend only on the conformation of our organs and the course which the animal spirits take in the brain, the nerves, and the muscles, in the same way as the movement of a watch is produced by nothing but the force of its spring and the figure of its wheels and other parts.

"Descartes' treatise on 'Man' is a sketch of human physiology in which a bold attempt is made to explain all the phenomena of life, except those of consciousness, by physical reasonings. To a mind turned in this direction Harvey's exposition of the heart and vessels as a hydraulic mechanism must have been supremely welcome. Descartes was not a mere philosophical theorist, but a hard-working dissector and experimenter, and he held the strongest opinion respecting the practical value of the new conception which he was introducing. He speaks of the importance of preserving health, and of the dependence of the mind on the body being so close that perhaps the only way of making men wiser and better than they are is to be sought in medical science. 'It is true,' says he, 'that as medicine is now practised it contains little that is very useful; but without any desire to depreciate, I am sure that there is no one, even among professional men, who will not declare that all we know is very little as compared with that which remains to be known; and that we might escape an infinity of diseases of the mind, no less than of the body, and even perhaps the weakness of old age, if we had a sufficient knowledge of their causes and of all the remedies with which nature has provided us.' * So strongly impressed was Descartes with this that he resolved to spend the rest of his life in trying to acquire such a knowledge of nature as would lead to the construction of a better medical doctrine.* The anti-Cartesians found material for cheap ridicule in these aspirations of the philosopher; and it is almost needless to say that, in the thirteen years which elapsed between the publication of the 'Discours' and the death of Descartes, he did not contribute much to their realization. But for the next century all progress in physiology took place along the lines which Descartes laid down.

"The greatest physiological and pathological work of the seventeenth century, Borelle's treatise 'De motu animalium,' is, to all intents and purposes, a development of Descartes' fundamental conception; and the same may be said of the physiology and pathology of Boerhaave, whose authority dominated in the medical world in the first half of the eighteenth century. With the origin of modern chemistry and electrical science, in the latter half of the eighteenth century, aids in the analysis of the phenomena of life, of which Descartes could not have dreamed, were offered the physiologist. And the greater part of the gigantic progress which has been made in the present century is a justification of the provisions of Descartes. For it consists essentially in a more and more complete resolution of the grosser organs of the living body into physico-chemical mechanisms. 'I shall try to explain our whole bodily machinery in such a way that it will be no more necessary for us to suppose that the soul produces such movements as are not voluntary than it is to think that there is in a clock a soul which causes it to show the hours.'† These words of Descartes might be appropriately taken as a motto by the author of any modern treatise on physiology.

"But though, as I think, there is no doubt that Descartes was the first to propound the fundamental conception of the living body as a physical mechanism, which is the distinctive feature of modern as contrasted with ancient physiology, he was misled by the natural temptation to carry out, in all its details, a parallel between the machines with which he was familiar, such as clocks and pieces of hydraulic apparatus and the living machine. In all such machines there is a central source of power, and the parts of the machine are merely passive distributors of that power. The Cartesian school conceived of the living body as a machine of this kind; and herein they might have learned from Galen, who, whatever ill use he may have made of the doctrine of "natural faculties," nevertheless had the great merit of perceiving that local forces play a great part in physiology. The same truth was recognized by Glisson, but it was first prominently brought forward in the Hallerian doctrine of the 'vis insita' of muscles. If muscle can contract without nerve, there is an end of the Cartesian me-

* Discours de la Méthode. 6mo. partie. Ed. Cousin. P. 193.

† De la Formation du Fœtus.

chanical explanation of its contraction by the influx of animal spirits.

"The discoveries of Trembley tended in the same direction. In the fresh water *Hydra* no trace was to be found of that complicated machinery upon which the performance of the functions in the higher animals was supposed to depend. And yet the hydra moved, fed, grew, multiplied, and its fragments exhibited all the powers of the whole. And, finally, the work of Caspar F. Wolff,‡ by demonstrating the fact that the growth and development of both plants and animals take place antecedently to the existence of their grosser organs, and are, in fact, the causes and not the consequences of organization (as then understood), sapped the foundations of the Cartesian physiology as a complete expression of vital phenomena. For Wolff, the physical basis of life is a fluid, possessed of a "vis essentialis' and a 'solidescibilitas;' in virtue of which it gives rise to organization; and, as he points out, this conclusionstrikes at the root of the whole iatro-mechanical system.

"In this country the great authority of John Hunter exerted a similar influence, though it must be admitted that the too sibylline utterances which are the outcome of Hunter's struggles to define his conceptions are often susceptible of more than one interpretation. Nevertheless, on some points Hunter is clear enough. For example, he is of opinion that 'spirit is only a property of matter' ('Introduction to Natural History,' page 6), he is prepared to renounce animism (l. c., p. 8), and his conception of life is so completely physical that he thinks of it as something which can exist in a state of combination in the food. 'The aliment we take in has in it, in a fixed state, the real life, and this does not become active until it has got into the lungs, for there it is freed from its prison' (Observations on Physiology,' p. 113). He also thinks that: 'It is more in accord with the general principles of the animal machine to suppose that none of its effects are produced from any mechanical principle whatever, and that every effect is produced from an action in the part, which action is produced by a stimulus upon the part which acts, or upon some other part with which this part sympathizes, so as to take up the whole action' (l. c., p. 152). And Hunter is as clear as Wolff, with whose work he probably was unacquainted, that 'whatever life is, it most certainly does not depend upon structure or organization' (l. c. p. 114).

"Of course, it is impossible that Hunter could have intended to deny the existence of purely mechanical operations in the animal body. But while with Borelli and Boerhaave, he looked upon absorption, nutrition, and secretion as operations effected by means of the small vessels, he differed from the mechanical physiologists, who regarded these operations as the result of the mechanical properties of the small vessels, such as the size, form, and disposition of their canals and apertures. Hunter, on the contrary, considers them to be the effect of properties of these vessels which are not mechanical, but vital. 'The vessels,' says he, 'have more of the polypus in them than any other part of the body,' and he talks of the 'living and sensitive principles of the arteries,' and even of the 'dispositions or feelings of the arteries.' 'When the blood is good and genuine, the sensations of the arteries, or the dispositions for sensation, are agreeable. . . . It is then they dispose of the blood to the best advantage, increasing the growth of the whole, supplying any losses, keeping up a due succession, etc.' (l. c., p. 133).

"If we follow Hunter's conceptions to their logical issue, the life of one of the higher animals is essentially the sum of the lives of all the vessels, each of which is a sort of physiological unit, answering to a polyp; and, as health is the result of the normal "action of the vessels," so is disease an effect of their abnormal action. Hunter thus stands in thought, as in time, midway between Borelli, on the one hand, and Bichat, on the other. The acute founder of general anatomy, in fact, outdoes Hunter in his desire to exclude physical reasonings from the realm of life. Except in the interpretation of the action of the sense organs, he will not allow physics to have anything to do with physiology. 'To apply the physical sciences to physiology is to explain the phenomena of living bodies by the laws of inert bodies. Now, this is a false principle, hence all its consequences are marked with the same stamp. Let us leave to chemistry its affinity, to physics its elasticity and its gravity. Let us invoke for physiology only sensibility and contractility'* Of all the unfortunate dicta of men of eminent ability this seems one of the most unhappy, when we think of what the application of the methods and the data of physics and chemistry has done towards bringing physiology into its present state. It is not too much to say that one half of a modern text-book of physiology consists of applied physics and chemistry, and that it is exactly in the exploration of the phenomena of sensibility and contractility that physics and chemistry have exerted the most potent influence.

"Nevertheless, Bichat rendered a solid service to physiological progress by insisting upon the fact that what we call life in one of the higher animals is not an invisible unitary archæus dominating from its central seat the parts of the organism, but a compound result of the synthesis of the separate lives of those parts. 'All animals,' says he, 'are assemblages of different organs, each of which performs its function and concurs, after its fashion, in the preservation of the whole. They are so many special machines in the general machine which constitutes the individual. But each of these special machines is itself compounded of many tissues of very different natures, which, in truth, constitute the elements of these organs (l. c., lxxix.) The conception of a proper vitality is applicable only to these simple tissues, and not to the organs themselves (l. c., lxxxiv.).' And Bichat proceeds to make the obvious application of this doctrine of synthetic life, if I may so call it, to pathology. Since diseases are only alterations of vital properties, and the properties of each tissue are distinct from those of the rest, it is evident that the diseases of each tissue must be different from those of the rest. Therefore, in any organ composed of different tissues, one may be diseased and the other remain healthy, and this is what happens in most cases (l. c., lxxxv.). In a spirit of true prophecy, Bichat says: 'We have arrived at an epoch in which pathological anatomy should start afresh.' For, as the analysis of the organ had led him to the tissues as the physiological units of the organism, so, in a succeeding generation, the analysis of the tissues led to the cell as the physiological element of the tissues. The contemporaneous study of development brought out the same result, and the zoölogists and botanists, exploring the simplest and the lowest forms of animated beings, confirmed the great induction of the cell theory. Thus the apparently opposed views which have been battling with one another ever since the middle of the last century have proved to be each half a truth.

"The proposition of Descartes, that the body of a living man is a machine, the actions of which are explicable by the known laws of matter and motion, is unquestionably largely true. But it is also true that the living body is a synthesis of innumerable physiological elements, each of which may nearly be described in Wolff's words, as a fluid possessed of a *vis essentialis*, and a *solidescibilitas;* or, in modern phrase, as protoplasm susceptible of structural metamorphosis and functional metabolism; and that the only machinery, in the precise sense in which the Cartesian school understood mechanism, is that which co-ordinates and regulates

‡ Theoris Generationis, 1759.

* Anatomie générale, i., p. liv.

these physiological units into an organic whole. In fact, the body is a machine of the nature of an army, not of that of a watch, or of a hydraulic apparatus. Of this army, each cell is a soldier, an organ a brigade, the central nervous system headquarters and field telegraph, the alimentary and circulatory system the commissariat. Losses are made good by recruits born in camp, and the life of the individual is a campaign, conducted successfully for a number of years, but with certain defeat in the long run.

"The efficacy of an army at any given moment depends on the health of the individual soldier, and on the perfection of the machinery by which he is led and brought into action at the proper time; and, therefore, if the analogy holds good, there can be only two kinds of diseases, the one dependent on abnormal states of the physiological units, the other on perturbation of their co-ordinating and alimentative machinery. Hence, the establishment of the cell theory in normal biology was swiftly followed by a 'cellular pathology' as its logical counterpart. I need not remind you how great an instrument of investigation this doctrine has proved in the hands of the man of genius, to whom its development is due, and who would probably be the last to forget that abnormal conditions of the co-ordinative and distributive machinery of the body are no less important factors of disease. Henceforward, as it appears to me, the connection of medicine with the biological sciences is clearly defined. Pure pathology is that branch of biology which defines the particular perturbation of cell-life, or of the co-ordinating machinery, or of both, on which the phenomena of disease depend.

"Those who are conversant with the present state of biology will hardly hesitate to admit that the conception of the life of one of the higher animals as the summation of the lives of a cell-aggregate, brought into harmonious action by a co-ordinative machinery formed by some of these cells, constitutes a permanent acquisition of physiological science. But the last form of the battle between the animistic and the physical views of life is seen in the contention whether the physical analysis of vital phenomena can be carried beyond this point or not.

"There are some to whom living protoplasm is a substance even such as Harvey conceived the blood to be, *summâ cum providentia et intellectu in finem certum agens, quasi ratiocinio quodam;* and who look, with as little favor as Bichat did, upon any attempt to apply the principles and the methods of physics and chemistry to the investigation of the vital processes of growth, metabolism, and contractility. They stand upon the ancient ways; only, in accordance with that progress toward democracy which a great political writer has declared to be the fatal characteristic of modern times, they substitute a republic formed by a few billion of 'animulæ' for the monarchy of the all-pervading 'anima.' Others, on the contrary, supported by a robust faith in the universal applicability of the principles laid down by Descartes, and seeing that the actions called 'vital' are, so far as we have any means of knowing, nothing but changes of place of particles of matter, look to molecular physics to achieve the analysis of the living protoplasm itself into a molecular mechanism. If there is any truth in the received doctrine of physics, that contrast between living and inert matter, on which Bichat lays so much stress, does not exist. In nature nothing is at rest, nothing is amorphous; the simplest particle of that which men in their blindness are pleased to call 'brute matter' is a vast aggregate of molecular mechanisms, performing complicated movements of immense rapidity, and sensitively adjusting themselves to every change in the surrounding world. Living matter differs from other matter in degree and not in kind; the microcosm repeats the macrocosm; and one chain of causation connects the nebulous original of suns and planetary systems with the protoplasmic foundation of life and organization. From this point of view pathology is the analogue of the theory of perturbations in astronomy; and therapeutics resolves itself into the discovery of the means by which a system of forces competent to eliminate any given perturbation may be introduced into the economy. And as pathology bases itself upon normal physiology, so therapeutics rests upon pharmacology, which is, strictly speaking, a part of the great biological topic of the influence of conditions on the living organism, and has no scientific foundation apart from physiology.

"It appears to me that there is no more hopeful indication of the progress of medicine toward the ideal of Descartes than is to be derived from a comparison of the state of pharmacology at the present day with that which existed forty years ago. If we consider the knowledge positively acquired in this short time of the *modus operandi* of urari, of atropia, of physostigmin, of veratria, of casca, of strychnia, of bromide of potassium, of phosphorus, there can surely be no ground for doubting that, sooner or later, the pharmacologist will supply the physician with the means of affecting, in any desired sense, the functions of any physiological element of the body. It will, in short, become possible to introduce into the economy a molecular mechanism which, like a very cunningly contrived torpedo, shall find its way to some particular group of living elements, and cause an explosion among them, leaving the rest untouched. The search for the explanation of diseased states in modified cell-life; the discovery of the important part played by parasitic organisms in the etiology of disease; the elucidation of the action of medicaments by the methods and the data of experimental physiology—appear to me to be the greatest steps which have ever been made toward the establishment of medicine on a scientific basis. I need hardly say they could not have been made except for the advance of normal biology.

"There can be no question, then, as to the nature or the value of the connection between medicine and the biological sciences. There can be no doubt that the future of pathology and of therapeutics, and therefore that of practical medicine, depend upon the extent to which those who occupy themselves with these subjects are trained in the methods, and impregnated with the fundamental truths, of biology.

"And, in conclusion, I venture to suggest that the collective sagacity of this Congress could occupy itself with no more important question than with this. How is medical education to be arranged, so that, without entangling the student in those details of the systematist which are valueless to him, he may be enabled to obtain a firm grasp of the great truths respecting animal and vegetable life, without which, notwithstanding all the progress of scientific medicine, he will still find himself an empiric?"

NOTES ON EXPERIMENTAL CHEMISTRY.*

By Professor Albert B. Prescott.

I. Determinations of the limits of (1), temperature in solution; (2), temperature in dry state; (3), alcoholic fermentation; and (4), acidity, compatible with the starch converting power of diastase of barley malt.

II. Determinations of the solubility of precipitated aluminium hydrate in excess of ammonium hydrate, with and without ammonium chloride.

In a paper by M. L. Boudenoot in the *Nouvelles Annales de la Construction*, describing the various forms of explosives of the nitro-cellulose class, a new compound is mentioned, called by its inventor, M. Anders, gelatino-diaspon. It is composed of wood-cellulose and nitro-glycerine, is unaffected by cold, is not sensible to blows or shocks, and explodes only by a sudden increase of temperature to about 160° C. (320° Fahr.) It burns quietly when ignited in the open air, and is not injured by water.

THE PARIS ELECTRICAL EXHIBITION.

[FROM OUR PARIS CORRESPONDENT.]

To the Editor of "SCIENCE."

This letter leaves Paris somewhat late, considering the official opening of the Electrical Exhibition took place eight days ago, and that the opening to the public followed the next day, viz., the 11th of August, but in fact the exhibition is not opened even yet, although the public is admitted during some hours of the day to look at the half-finished structures and to inspect the dust-covered instruments.

The daily newspapers and some so-called scientific papers, which give to their readers sensational articles rather than correct information, have been for about ten days crowded with descriptions of the opening and the progress of the electrical exhibition, but the real good scientific papers have hitherto only given short notes, because it has, as yet, been impossible to study the value of the different instruments in the exhibition building, where everything is still in a half-finished state and where the noise of hammers and carpenters' instruments are still heard in every corner.

Notwithstanding this, I will endeavor to give you in this letter a description of the actual state of the exhibition, which will serve your readers as an introduction to the more special articles with which I will furnish your paper weekly.

When we first enter the Palais de l'Industrie through the principal pavilion, which is situated on the side of the Champs Elysées, we observe a series of beautiful statues which serve as "candelabres" for lamps of the Werdermann system, and when we approach the entrance to the great nave our eyes are attracted with two enormous images representing a male and female lion, while we observe above our head a beautiful chandelier of iron wrought in tasteful style, furnished with Siemens lamps. This lustre will undoubtedly be very attractive if the arrangements for the light are made as carefully by the French firm of the well-known house of Siemens, as those in the German department, where some evenings ago the preliminary experiments made with the Siemens lamps attracted the general admiration of all those who had the privilege to witness them.

In the centre of the nave a light-house is erected, which is a copy of the light-houses that guard the coasts of France. It is surrounded by a small water-basin, which, although it may be called ornamental, is perfectly useless for the purpose for which it is destined, on account of its limited dimensions and the outlines of its borders, which form a star. This basin is intended as a field of exercise for the boat of M. Trouvé, called the *Telephon*, which is driven by an electric motor, in connection with a Bunsen battery, and the length of which nearly equals the radius of the circumference of the basin.

I may here say a few words about M. Trouvé's boat, on account of which a good deal of nonsense has been published in European and American papers, one of the latter mentioning not long ago that M. Trouvé's boat, with which he experimented upon the Seine, contained a battery of M. Faure, but M. Trouvé is too well acquainted with the value of scientific instruments to depreciate the merits of the Planté battery and to substitute for it Faure's modification, as long as the former is better.

Count Du Moncel, whose name is well known among all electricians, on account of his excellent work on the "Application of Electricity," which is the most complete work of its kind in existence, and also on account of his other numerous publications and inventions relating to this part of Science, presented on the 7th of July last a note to the Academy of Sciences, in which M. Trouvé describes in a very precise manner the motor used by him in propelling a little boat. This note will give to your readers exact and correct information regarding the merits and properties of the motor used in the little canoe which is now seen in the Electrical Exhibition, and I therefore quote this note verbatim:

"A motor having a weight of 5 kilogrammes and in connection with six elements of a secondary battery of Planté, which produces a labor of 7 kilogrammeters per second, was placed on the 8th of last April upon a tricycle, which latter, rider and battery included, had a weight of 160 kilogrammes, and gave to the vehicle a celerity of 12 kilometers per hour."

"The same motor, used on the 26th of May, in a boat having a length of 5.50 meters and a breadth of 1.20 meters, holding three persons, gave to this boat a celerity of 2.50 meters in descending the Seine at Pont-Royale and of 1.50 meter in moving against the current. The motor obtained its electro-motive power by means of two batteries, consisting each of 6 elements of bichromate of potash, and the propeller was furnished with a coil having 3 branches.

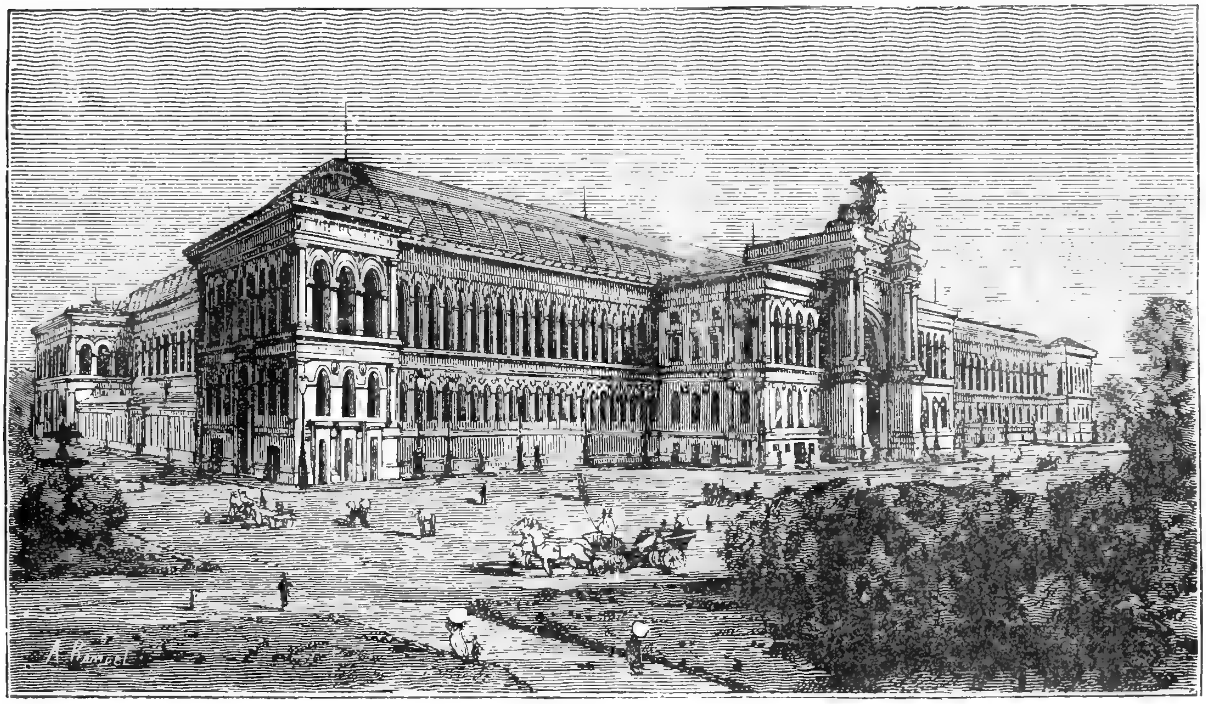
"On the 26th of June I renewed the experiment upon the quiet waters of the upper lake of the Bois de Bologne, using a coil with 4 branches having diameters of 0.28 meter and being in connection with 12 elements of Bunsen with flat plates such as are used in the Ruhmkorff battery. The liquid of these elements consisted of one part of hydrochloric-acid, one part of nitric acid, and two parts of water in the porous vessel, in order to diminish the disengagement of hypoazotic vapors.

"The celerity of the little boat, which was measured with an ordinary log, rose in the commencement to 150 meters within 48 seconds, or a little more than 3 meters per second; but after three hours of working it had diminished to 150 meters during 55 seconds. After five hours of working the electricity was still 2.30 meters per second."

So much about M. Trouvé's boat, of which a number of miniature specimens, in good working order, may be seen in the upper story of the Exposition building.

At the left-hand side of the nave, nearest to the light-house, are the exhibitions of Great Britain, Germany and the United States. The exhibition of Germany is that which has the most imposing appearance and is also that which was first completed. Two enormous "candelabres" in forged iron ornament the entrance of the department, and contain lamps of "Gebrueder Siemens" of Berlin. Near them stand two trophies crowned with the Prussian eagle, and behind them, upon a large number of tables, may be seen a collection of electrical instruments of all kinds, which we will describe in our reports hereafter. At the right-hand side of the department we see the busts of five German pioneers in the field of Electrical Science, viz.: Otto von Guericke, Ohm, Sömmering, Steinheil, and Gauss.

The historical collection of instruments in the German department is of the highest interest in a retrospective way. I will only mention an exact copy of the first machine for static electricity, constructed in the year 1670 by Otto von Guericke, consisting of a sulphur globe, which was electrified by turning it by means of an axis and using the hand as a rubber; an electrical egg, so-called, property of Prince Pless, of Germany, and constructed at the commencement of the 18th century; an electro-chemical apparatus for telegraphing, constructed by Thomas Sömmering in Munich in the year 1809—the telegraphing with this instrument is done by the decomposition of water. A magneto-electric telegraph of Gauss and Weber, constructed in 1833—this telegraph was used in 1837 in order to keep up a telegraphic communication between the physical laboratory aud the magnetical observatory in the University of Göttingen; the copy of the first telephone ever constructed, and invented in the year 1861 by Reis, and a great many other apparatus of equal interest.



EXTERIOR.

INTERIOR.

ELECTRICAL EXHIBITION.—PARIS, 1881.

Amongst the other electrical instruments in the front part of the department, especially worthy of attention, are some of the most important instruments used in thé physiological institution of Berlin and mostly due to the genius of the celebrated German professor "Dubois-Reymond" of Berlin. These instruments will be used in experiments before the French Academy of Sciences and the Electric Congress, by Professor Arthur Christianï, of the Medical Faculty of the Berlin University, who has been sent for this purpose to Paris and arrived here a few days ago.

A large space in the German department is occupied by the extensive exhibitions of the firm of Siemens & Halske of Berlin, and there may be also seen the first electro-locomotive constructed by this firm in the year 1867 and the first machine of that renowned type, which was invented at nearlv the same time by Mr. Wheatstone in England and Mr. Siemens in Berlin.

The exhibit of Mr. Siemens is, in my opinion, one of the most important of all the exhibits in the whole building of the Palais de l' Industrie, and the excellent instruments and apparatus manufactured by this firm, which occupy a large place in the German, French and English departments of the exhibition create general admiration. I shall endeavor, during the following week, to furnish you with an explicit description of some of the more important instruments of the Siemens exhibition and your readers will then be able to judge for themselves of their value.

The exhibition of *Great Britain* is still far from being complete, and this is very easily explained, by the fact that the English government, although after a very long hesitation, finally having taking part in the exhibition has not consented to contribute anything for the expenses, and it is marvellous that under such circumstances the English exhibitors have been able to contribute so much as they have. The only portion of the English exposition which is nearly complete is that of Siemens Brothers, who, among other things, exhibit a great number of apparatus for submarine telegraphy which are displaved on several large tables, and of which the most conspicuous is a full sized buoy ornamented with a flag. One fact which I must not forget to mention, is, that the pavilion of the British post-office is undoubtedly erected in excellent taste and is not only the most conspicuous but also the most beautiful in the exhibition (with the exception of the pavilions of the Italians). This pavilion is divided into two parts, the one containing a historical collection which is very remarkable and consists of the first instruments of telegraphy, among others that ingenious telegraph apparatus of Cook and Wheatstone, which was used with several wires and which now, after the invention of duplex, quadruplex and multiplex systems seems rather primitive, while the other part consists of a collection of all the modern instruments of telegraphy which can only be appreciated by a more minute description, and a great help to the study of these instruments is their excellent arrangement, which is due to the labors of Mr. Preece.

The exhibition of the United States is not at all what it should be, and it is greatly to be regretted that Europeans will receive a very wrong impression of the productiveness of your country if they judge by the scanty exhibits which America has sent to the Paris exhibition.

Most of the Americans to whom I have spoken seem to recognize this fact very fully, and it is generally regretted that many of the beautiful electrical inventions of the United States cannot be displayed here, where they would certainly create a sensation. But it seems that the United States Government was too interested in politics to care for a worthy representation at the electrical exhibition, and the more intelligent class of the French public know how to appreciate the difficulties with which the American exhibitors had to contend on this account, as well as on account of the great distance which separates their country from Europe.

Among the apparatus, which are already installed, may be mentioned the Bell telephone, the automatic time-register and alarm, the Dolbear telephone, of which you have already given a long description in your paper, and which is now exhibited in a neat little pavilion erected by Mr. Buck and Mr. Stetson, who, by their industry, set an example to the tardy French workmen; and the exhibition of the United States Signal Service, which contains an ingeniously constructed distance-barometer, anemoscope and anemometer, invented by Mr. Eccard. The display of the other exhibitors are not yet finished, and I reserve that of Mr. Edison's until it is more complete, as it promises to be the most interesting and valuable one in the building, and will demand a special report to do it justice.

If we continue our walk through the Exhibition towards the East Entrance, we come to the department of Belgium and Austria. That of Belgium offers a very beautiful aspect, and is displayed in two fine pavilions, which are furnished with several crystal cases ornamented by copper posts. The galvano-plastic exhibits in this department are worthy of the greatest attention, but scientifically, the most interesting exhibit is that of the meteorological station of Brussels. Austria has contributed a great many apparatus which serve for the security of railways.

The pavilion of Italy, which we next enter, is a beautiful oblong building, and attracts much attention. Until yesterday it was nearly empty, but the instruments begin now to be installed, and within a few days the visitors of the Exhibition will have the privilege of seeing the ingenious instruments that Volta, Gulvani and Nobili constructed with their own hands, and to read the original letters in which these great scientists published their first ideas regarding their new and wonderful discoveries. This Italian pavilion, in connection with the post office pavilion of England and the retrospective collection of the Germans, form together the material for the three most important chapters in the history of electricity.

The exhibition of Holland offers, so to say, an appendix to them, and the instruments for static electricity there shown, excel, perhaps not in quality, but at least in grandeur all other instruments of this kind. The enormous machine and battery of Leyden-bottles of Van Marum, of which we have all heard when we were school boys, form the most interesting part of this exhibition, and the whole, including the enormous natural magnets, makes upon the visitor an impression that he is visiting an exhibition of the Scientists of the land of the pyramids.

Passing the departments of Spain and Switzerland, and leaving at the left the exhibition of Russia and Norway, which have all contributed in an appreciable manner to the interesting show of apparatus, we arrive at the entrance station of the Siemens' electrical railway which is not yet completed on account of several modifications which his construction had to undergo. It will be running, however, within a few days.

Returning now again to the centre of the nave, and entering the western half of the building, we see before us the French portion of the exhibition.

At the left hand side viewed from the light-house, is a pavilion in very good taste filled with the shining silver and gold exhibits, and with the highly artistic galvano-plastic reproductions of the renowned firm of Christofle & Co., and on the right hand side from the light-house in a pavilion corresponding exactly in style with the former, we see the exhibits of the Jablochkoff Electric Light Company. This department contains a complete collection of all the different kinds of apparatus used by this company, and amongst others a new dynamo-electric machine of Jablochkoff, which is of excellent consttron.

The pavilion of the *City of Paris* contains instruments for the distribution of time and electrical instruments for the service of the fire companies. This pavilion is surrounded by the exhibitions of different French railroad lines, which contain an enormous amount of apparatus too complicated and too numerous to mention in this short review.

One of the most interesting parts of the French exhibition is the pavilion of the Ministry of Posts and Telegraphs, which contains a complete collection of all the modern apparatus employed in the telegraph service of France. This pavilion is bounded on its North, South and East sides by highly interesting collections of different French firms, while on its West side the great staircase leads to the upper stories. Of the exhibits in the upper story I will give only a general catalogue because the installments are as yet too unfinished to render it possible to give any detailed description of them, and the experiments with the electric lights and telephones, to which this portion of the palace is mostly dedicated, will not commence before eight days.

Hall A, immediately opposite to the grand staircase, is a beautifully furnished drawing room called the "Salon du President" and will be lighted by the Werdermann light.

Hall 1 contains a gallery of paintings but it is to be hoped that the light of the "Lampe-Soleil" which is here exhibited will be better than the pictures, which are wretchedly bad.

Hall 2 contains a stage which once figured in the, so-called, "Athenæum," in the "Rue des Martyrs." This stage will be used for showing stage effects produced by electric lights, and the light will be furnished by the Werdermann Company.

Hall 3 is a tastefully furnished dining-room, with table temptingly set, in which the Werdermann light will also be displayed.

Hall 4 is an apartment consisting of vestibule, kitchen and bathing-room, which will be lighted by incandescent lamps fed from reservoirs consisting of Faure's secondary battery and furnished by "La Société de la Force, et la Lumière."

I have made it a special object to study the value of the Faure-battery in regard to which so much has been said pro and contra, and propose to furnish your excellent paper with impartial reports on this subject as soon as any definite knowledge of it can be obtained.

Halls 5 and 6, which are united in one, will display lights of the "Systeme-Jamin" and contain a collection of Gramme-machines modified by M. Jamin.

Hall B contains a collection of smaller electrical apparatus, of electrical toys and also an exhibition of Jablochkoff candles.

Halls 7 and 8 are dedicated to telephone experiments, hall 7, being lighted by "La Société de la Force et la Lumière" while the light of hall 8, is furnished by Mr. Brush. The preliminary experiments with the telephones in these halls have been exceedingly satisfactory, the music of the Grand Opera and the words spoken in the "Théatre-Francais" (both of these buildings being connected by telephone-wires with halls) can be so plainly heard that one may really imagine himself to be one of the audience present, instead of being several kilometers distant from the places of performance. A person, who has never witnessed these telephone experiments can have no idea of the value of the microphone and telephone, and the public, before which these experiments will be made in about eight days, will be greatly astonished to see those reports verified which it has hitherto taken for exaggerated descriptions of sanguine writers.

Hall 9 contains chiefly electrical apparatus devoted to medical purposes, and will be lighted by Méritens, who also has there exhibited the most of his special apparatus.

Hall 10 is dedicated to the exhibition and the light of the firm of "Sautter et Lemonnier."

Hall 11 has Jablochkoff light and will also exhibit the apparatus used for photographing by electric light.

Hall 12 will be lighted by the Spanish society of electricity which employs Gramme's lamps.

Hall 13 serves for the display of Siemens' differential lamps and contains an excellent collection of instruments of precision and of Geissler tubes.

Hall 14 contains machines of the system Wilde and Alliance, it will be lighted by means of Wilde's candles, furnished by the Parisian Company of Wilde's light.

Hall C contains cables, telephones, and telegraph instruments and will be lighted by incandescent lamps of Maxim furnished by the United States Electric Lighting Company.

Hall 15 has, among other things, a nice collection of lightning-rods and contains Jaspar's light.

Hall 16 has lamps of M. Anatole Gérard.

Hall 17 contains electro-chemical instruments, apparatus for galvano-plastics, etc., and lamps of the Gramme system.

Hall 18 contains a highly interesting museum of historical instruments of electricity. The light is furnished by Messrs. Mignon and Rouart.

Hall 19 will be lighted by a company from Lyons, displaying the processes of Lontin, Bertin and Mersanne, and also contains the electro-pneumatic clocks of Mr. Mayrhofer, which form one of the most interesting parts of the electrical exhibition.

Hall 20 contains a retrospective museum and a library of works on electricity; the light in the former will be furnished by Mr. James Fyfe, that in the latter by Mr. Daft.

Hall 21 serves as a restaurant and is ornamented by a large chandelier containing Swan's incandescent lamps.

Hall 22 serves as a reading-room and will be lighted by the Brush system.

Hall D is the place where the Congress will meet, and halls 23 and 24 contain the exhibition of Edison, of which I shall not now speak in detail, reserving a description for a special letter, when I will attempt to do justice to this interesting exhibit. GUSTAVE GLASER, *Ph. D.*

PARIS, *August* 17, 1881.

THE AMERICAN CHEMICAL SOCIETY.

The first meeting of the American Chemical Society, after the summer vacation, was held on Friday evening, September 2, with Vice-President Leeds in the chair. The minutes of the previous meeting were duly passed on and Dr. H. Endemann elected to the position of Editor of the Journal. The first paper presented to the Society was "On the Detection of Oleomargarine," by Mr. P. Casamajor. This method is based on the differences between the density of butter and oleomargarine. A drop of the suspected fat is melted and poured into alcohol at 15°C; if it is butter, on account of its greater specific gravity, it immediately sinks to the bottom of the vessel, while if it is oleomargarine it remains on the surface.

Mr. Casamajor followed by a second paper on the "Detection of Sugar House Syrups from Starch Sugar Syrups." The author found that by dissolving the given sample (10c.c. are taken) in three times its volume of methylic alcohol, the ordinary sugar syrup will become entirely dissolved, while the starch sugar syrup becomes precipitated under the same conditions. Partially dissolving indicates, of course, a mixture of both.

"A Short Table for Testing Sugar by Inversion" was the title of the third paper. It was also by Mr. Casamajor. Assuming that $D =$ the first deviation in a reading of a polariscope and $- D'$ the second, substracting them we have $D + D'$.

$t =$ the temperature.

When a solution of pure sugar is 100, the sum of the two readings will equal 144. Making Δ equal to the

true deviation, we have from the above constants $\Delta = D + D' \times \frac{100}{144 - t}$.

In the table given by Mr. Casamajor the quantities which t was equal to was given, so that by a simple calculation it became readily possible to determine the value of the true deviation. The table was based on the much larger one of Clergets.

The fourth paper of the evening was by Mr. A. H. Elliot and it consisted of a description of "A New Form of Apparatus for the Analyses of Gases." It was very severely criticised by Dr. Endeman as being decidedly inferior to the more complicated forms devised by Professor Hempel. M. B.

THE SUCCESSFUL ADMINISTRATION OF NITROUS OXIDE AS AN ANÆSTHETIC FOR DENTAL AND SURGICAL OPERATIONS.*

DR. E. P. HOWLAND, Washington, D. C.

The successful administration of nitrous oxide consists in administering it to patients in such a manner that during operations they will not suffer pain, and that they will be in such a condition that the dentist and surgeon can successfully perform the operation and afterwards that the patients are found not to be injured by its administration. The first requisite for success is that the nitrous oxide should not have more than one per cent of pure oxygen or three per cent of atmospheric air, and that it should be perfectly free from all other gases or vapors. Nitrous oxide with two per cent or more of pure oxygen or five per cent or more of atmospheric air, will not produce perfect anæsthesia and the patient will feel the pain of the operation and pronounce the gas a failure. The adding of one per cent of pure oxygen to nitrous oxide has the benefit of partially oxygenating the blood and in a measure preventing the spasmodic action of the muscles and at the same time produce satisfactory anæsthesia. According to experiments made in France by P. Bert, ten per cent of oxygen or fifty per cent of atmospheric air can be added to nitrous oxide to oxygenate the blood, and at the same time produce perfect anæsthesia if it is breathed in a chamber under a pressure of two atmospheres. A certain amount of nitrous oxide taken into the lungs is necessary to produce insensibility, and it can be diluted with any innocuous gas and still produce anæsthesia, provided this amount is inhaled in the given time. Under pressure in a chamber more gas is breathed in a given time, as the nitrous oxide is condensed the same as the air in the chamber and under a pressure of two atmospheres, two volumes of nitrous oxide would be condensed into one volume, so that the nitrous oxide could be diluted with equal measures of atmospheric air and still the quantity of nitrous oxide inhaled would be the same as if breathed ordinarily and the quantity of oxygen breathed sufficient to arterialize the blood. Rapid breathing of nitrous oxide produces quick anæsthesia, but nothing is gained by it in practice. It is very difficult to produce anæsthesia with nitrous oxide at high elevations above the ocean, because the low pressure of the atmosphere allows the gas to expand so that a less quantity is taken into the lungs in a given time than is required to produce insensibility. Valve inhalers have generally proved a failure, because they admit atmospheric air with the gas in sufficient quantity to to prevent perfect anæsthesia. As near as I can ascertain, more than one-half of all the dentists of the United States who have used nitrous oxide have abandoned its use on account of want of success in producing satisfactory insensibility and thereby injuring instead of benefiting their practice. One cause of failure is the unskillful administration of the gas in allowing air to be inhaled with it, by not having the lips closed tight around the inhaler, and other causes; not using the nose as a valve for expiration exactly at the right time; not stopping the administration at the point of greatest anæsthesia and not having sufficient self-possession under all circumstances and emergencies to know just what to do and when to do it. But the greatest cause is the failure of producing perfect anæsthesia from the mixture of atmospheric air in the nitrous oxide that has been kept in a gasometer over water for a few days. The gas becomes mixed with air through the medium of the water and defective gasometers and cocks. The trouble and cost of making fresh gas every few days has caused the great abandonment of its use. Skillful administrators, who have a large practice and make fresh gas before deteriorated by air, are making nitrous oxide a success. Other dentists can make gas a success by obtaining it condensed in cylinders, when the gas will keep unadulterated and unchanged for years. The only drawback to a paying success is the present great cost of the condensed gas, which in the small cylinders amounts to about thirty-five cents for each administration, when the gas can be made in the dentists' laboratory for about three and a half cents for each administration. An apparatus can now be obtained that enables each dentist to make and condense his own gas and keep it for any length of time. Physicians and surgeons do not use nitrous oxide on account of the trouble and cost of making and keeping it, and the greater amount of practice and skill required in its successful administration than with the more dangerous ether and chloroform. Nitrous oxide requires a costly apparatus to manufacture it, and bulky receptacles to hold and administer it from, and the gas is for sale in but two places in the United States, while ether and chloroform can be carried in a bottle in the pocket and purchased at every drug store in the land. Nitrous oxide can be administered with almost absolute safety, while ether and chloroform can point to their victims in every city and hospital. Money, labor and skill can make nitrous oxide successful with both dentist and surgeon, and taking into account the value of human life, nitrous oxide should stand at the head of all anæsthetics, and its practical use be encouraged instead of ether and chloroform.

I have administered nitrous oxide in over thirty thousand cases for dental and surgical operations, and have had uniform success. I have never had a case of injury from lung or heart disease, but in many cases of throat and lung diseases a marked and permanent improvement. I have kept a large number of patients perfectly anæsthetic for surgical operations from five to thirty-five minutes, and the pulse during these operations has been nearly uniform and full. The success of prolonged operations consists in first producing perfect anæsthesia and then breathing air to arterialize the blood and before consciousness returns again breathing nitrous oxide, the necessary intervals varying in different patients from one-fourth to one-half minute. The average length of time occupied in dental operations from the first commencement of breathing the gas till return of consciousness has been two minutes. To encourage and make nitrous oxide a greater success in the future, the dental and medical colleges should employ successful operators to lecture and instruct graduates so that the particular knowledge and skill acquired by them in practice can be learned by others.

* Read before the A. A. A. S., Cincinnati, 1881.

ON October 17 next, fifty years will have elapsed since Prof. Bunsen, the eminent chemist, received his doctor's diploma from Göttingen University. He, however, intends to absent himself from Heidelberg on the day in question, in order to avoid all congratulations and speech-making.

MR. W. H. M. CHRISTIE, F. R. S., First Assistant at Greenwich Observatory, has been appointed Astronomer Royal, in succession to Sir George Airy, who retires after holding the office for nearly half-a-century.

SOME NEEDED REFORMS IN THE USE OF BOTANICAL TERMS.*

By CHARLES E. RIDLER, M.A., Master of High School, Kingston, Mass.

I.

Seventy per cent of 700 examined species and varieties of "flowering plants," and 65 per cent of all the "flowerless plants," as given in Mann's Catalogue, have different names; 3646 "flowering plants" and 178 "flowerless" are given in the list. If to these per centages, the names of the genera and orders be added, there will be a total of more than 4000 different ones to be remembered, east of the Mississippi; and if collections are made elsewhere, the number becomes appalling. Only 14 names are used five times or more, and over 50 per cent are used but once; that is, among the flowering plants every other name is new, and among the flowerless two out of every three are new.

Many of the specific names describe the plants as being "like" some other plant or thing, and both Latin and Greek terms are employed to do this. Thus, over a hundred different specific names were found ending in *folium* or *phyllon* (leaf), and *oides* (like)[1] Among some other things noted are the following: Adjectives are frequently used in their different degrees of comparison without any meaning whatever; there is a great diversity in the use of proper names of persons, countries and States; specific words are frequently found differing only in their endings and not in their roots; one English word is often described by several Latin, with only a slight difference in meaning, and the question is whether one word might not be used in place of several given in a set[2]; Greek and Latin names exist with the same meaning; Greek and Latin terms are used to describe the same plant; double specific names, and similar specific and generic terms are common; occasionally a term is employed which denotes a specific difference far more common than it is used; and many compound and coined words of doubtful authority[3] are scattered throughout the list—in all of which there is a great need of reform. The plan is suggested, at least in this country, and especially for use in the school-room, of having in the study of botany nothing but English words for the English-speaking race. If Greek and Latin, however, are to be retained, they should be kept in their purity. These reforms in the use of botanical nomenclature are urged for the great mass of tired students of both sexes, and their teachers, in the United States, rather than for the eminent botanists and horticulturists, who may remonstrate against any change which will rob the science of its choicest literature.

THE *Révue Industrielle*, in a recent number, gives a curious instance of the spontaneous galvanization of an engine piston, which took place at Cette, Hérault. The boiler having become much encrusted, some scraps of zinc were introduced to loosen the coating. Several days afterwards, the piston began to work with difficulty; when it was taken out, it was found to be covered with a thick coating of copper. This is supposed to have occurred from the particles of zinc carried with the steam into the copper steam-pipes forming a number of minute galvanic elements in combination with the copper; the vibration of the piston then attracted the copper molecules to itself, whilst the heat and the electric properties of the steam are considered to have facilitated their attachment to it.

[1] With *folium: Alismae, apii, alni, bellidi, delphini-ilici. myrti, parnassi, primulæ, rosmarini*, etc., etc.; with *phyllon: tricho, argo, chryso, lepto, rhizo, lepido*, etc., etc.; with *oides: anemon-lunarin, scirp, hesperid, cheiranth, melilot*, etc., etc.

[2] Such as, *Vulgaris, officinalis, vulgata, media, communis* (common); *sylvestris, nemorosa, sylvatica* and the like.

[3] The paper gave a long list of words used by botanists which cannot be found in the lexicon, such as *grandiflora*, and other compounds of *flos; arabisans, advensis, cucullaria, variolaris, cataria, asprellum, lateri—folia* and other compounds of *folia; salina, atro-purpurea*, and others.

BOOKS RECEIVED.

THE ANCIENT BRONZE IMPLEMENTS, WEAPONS AND ORNAMENTS OF GREAT BRITAIN AND IRELAND, by JOHN EVANS, D. C. L., LL. D , F. R. S., &c. D. Appleton and Company, 1, 3, and 5 Bond street, New York, 1881.

As Dr. Evans admits, the period covered by the Bronze age cannot be fixed within a precise limit, especially for any particular country. Through the successive stages of civilization, when the Stone period gave way to that of the bronze period, and was succeeded by the Iron, a long course of years must have passed, and even in any particular district the change could not have been sudden.

There must, therefore, have been a time when in each district the new phase of civilization was introduced, and the old conditions had not been changed; the three stages of progress represented by the Stone, Bronze and Iron periods, like the three principal colors of the rainbow, overlapping and intermingling one with the other, through their succession.

In discussing the chronological position of the bronze-using period, the possible use of copper unalloyed with tin, cannot be overlooked; in fact the probability that native copper may have continued for a lengthened period before it was discovered that the addition of a small portion of tin rendered it not only more fusible but added to its elasticity and hardness, must be apparent to all. While dwelling on this point Dr. Evans points out that even after the advantages of the alloy over the purer metal were known, the local scarcity may at times have caused so small a quantity of that metal to be employed, that the resulting mixture could hardly be recognized as bronze; or at times the dearth may have necessitated the use of copper alone, either native or as smelted from the ore.

Of this Copper Age, however, but feeble traces are to be found in Europe, if, indeed, any can be said to exist, but in India important discoveries have been made of copper instruments; these, however, were accompanied with ornaments of silver, which appeared to mitigate against their extreme antiquity, as the production of silver involves a considerable amount of metallurgical skill, and probably an acquaintance with lead and other metals.

The most instructive instance of a Copper Age, as distinct from one of Bronze, is that which has been discovered in our own country, where we find good evidence of a period when, in addition to stone as a material from which tools and weapons were made, copper also, was employed, and used in its pure native condition without the addition of any alloy. The State of Wisconsin alone, has furnished upwards of a hundred axes, spear heads and knives formed of copper, and to judge from some extracts from the writings of the early travellers given by the Rev. E. F. Slafter, that part of America would seem to have entered on its Copper Age long before it was first brought into contact with European civilization, towards the middle of the sixteenth century. On some parts of the shores of Lake Superior native copper occurs in great abundance, and no doubt attracted the attention of the early occupants of the country, who undoubtedly availed themselves of its ductile property to produce spear-heads and other weapons.

To those who have supposed that iron, which is a simple substance and easily produced from its ores, may have been in use before copper; the author replies, that without denying the abstract possibility that in some parts of the globe such might have been the case, he considers that among the nations occupying the shores of the Mediterranean—a part of the world which may be regarded as the cradle of European civilization—not only are all archælogical discoveries in favor of the suc-

cession of iron to bronze, but even historical evidence supports their testimony.

The study of this subject necessarily involves an investigation relating to the date when man first became acquainted with the methods of working the various metals, and the reader will find in this work a carefully prepared synopsis of all the evidences bearing on their disputed points. The introductory chapter describing this controversy will be found one of the most interesting and instructive in the book.

The great body of the work is devoted to an examination and description of the various forms of Bronze weapons and instruments which have been found in the British Isles, treating separately the different classes of instruments, intended each for special purpose, and at the same time pointing out their analogies with instruments of the same character found in other parts of Europe. To bring this department within the comprehension of all readers, Dr. Evans has presented five hundred and fifty superb wood engravings of specimens; thus the archæologist who possesses this work, finds himself, as it were, passing through a museum of Bronze antiquities, aided by the friendly guidance of one who is a master of the subject, and capable of pointing out important details and characteristics, even in the most ordinary implements, which, to the cursory observation of a student, would appear devoid of meaning.

Dr. Evans concludes this interesting work with a chapter on the chronological arrangements of the various types of bronze, and an examination of the various means at our command for fixing the *approximate* date and duration of the period. On the latter point, after what we have stated on the subject, no surprise need be expressed when we state, that Dr. Evans offers an opinion only with great reserve. Subject to this reservation, we find that he attributes eight or ten centuries as the total duration of the Bronze Period, placing the beginning some 1200 or 1400 years before the Christian era. It is questionable whether such an antiquity will meet all the necessities of the case, for as Professor Evans himself points out, it is difficult to believe that the Phœnicians, or those who traded with them, landed in Britain and spontaneously discovered tin.

This work will prove to be of the highest value to archæologists and to all who would trace the course of human progress to its earliest phases. Its general arrangement is most excellent, and adapted for practical work. In addition to a general index, a geographical and topographical index is presented, which greatly adds to the value of the work. The publishers have performed their part of the work most efficiently, and have produced a handsome volume, illustrated in the highest style of the engravers' art, which will in future be held as an authoritative work of reference, and a store-house of facts from which the student and specialist may draw material of the highest value.

IT has been resolved to invite the British Association to meet in Aberdeen in 1883. The invitation will be presented at the forthcoming meeting of the Association at York. The Association will meet in Southampton in 1882, and an influential local committee has already been appointed.

THE Government of India has declined for the present to award the prize of £100 offered for the best "manual of hygiene" for the use of the British soldier.

P. O. Box 3838

SATURDAY, SEPTEMBER 17, 1881.

In a recent Government publication, prepared by Professor F. W. Clarke, S. B., of Cincinnati, we find the following paragraph relating to the purchase of scientific apparatus, which may be studied with profit by the manufacturers:

"Some years ago Congress passed an act authorizing schools and colleges to import apparatus free of duty. This act is not so widely known among teachers as it ought to be, nor do those who know it fully realize the saving in expense which it implies. Goods bought of a local middleman cost their European price, plus a heavy duty and the expense of transportation, with a large profit to the dealer over and above the sum of the foregoing items. A school, by importing its apparatus directly, can save the duties and the local dealer's profit—a retrenchment of from forty to fifty per cent. A hundred dollars thus expended on a direct foreign order will buy as much material as a hundred and fifty laid out at home. A knowledge and an application of these facts will enable many a school to do far more in the way of laboratory work than is considered possible now. To be sure, it is desirable that home trade should be patronized, but not in such a way as to cripple science. The present duties bring in but a trifling revenue to the government and might be abolished without injury to any one. If this were done, our schools and colleges could afford to buy more goods of American dealers; the latter, with larger sales, could ask more reasonable profits; and so both buyer and seller would be benefited.

This paragraph once more revives a question which we trust will not be dismissed until some practical decision has been arrived at. Congress has abolished the duty on scientific apparatus and instruments, in the interest of colleges and other rich corporations, but, demands of the poor student, a tax of fifty per cent. upon every instrument purchased by him.

Such a discrimination in the collection of duties is neither just nor reasonable, and appears to have failed even in achieving any good results in the direction anticipated. On the contrary, it has crippled the business of the American manufacturers, and forced them to charge exorbitant prices on the limited sales they could make under such a system.

We fully concur in the suggestion made by Professor Clarke, that, as these duties bring in but a trifling revenue to the government, they might be abolished, and that without injury to anyone.

We are also glad to find Professor Clarke, while speaking as the representative of the class most benefited by this discriminative legislation, taking such a liberal view, and advocating its entire abolition.

We are unable to offer the view that "the trade" may take on a measure which will bring them in open competition with European manufacturers, possibly they may require to be educated to an apppreciation of a course, that will ultimately result in a condition of business, which will be beneficial to their best interest.

With the abolition of the discrimination in favor of colleges, etc., and of all duties on scientific instruments, the first result would be to equalize the prices of such manufactures, irrespective of the place where they are made. Universities and colleges in such a case could afford to buy of the domestic manufacturer and would doubtless do so. The one point that would have to be considered in such an open market, would be that of *quality*, and the American manufacturer of scientific apparatus has nothing to fear on that head, while with larger sales more reasonable profits could be accepted; thus both buyer and seller would be benefited. We trust that the next Congress will take some action in this matter, and place scientific apparatus and instruments on the free list of the tariff, and thus remove an obnoxious tax on knowledge, and increase the facilities for the acquisition of scientific and technical education among the masses of the people.

We are informed that Dr. T. Sterry Hunt, of Montreal, and Professor James Wall, sailed for Europe on the 10th instant, for the purpose of attending the International Geological Congress, to be held at Bologna, Italy, on the 26th of September. We have written to Dr. T. Sterry Hunt, who is both a subscriber and contributor to this journal, to send us a report of this meeting, and have no doubt that we shall be thus enabled to place before our readers a reliable account of the doings of this Congress.

We understand the Edison Light Company has been notified that the French Government, after inspecting all the electric lights in the Paris Electrical Exposition, has selected the Edison Company to light the Grand Opera-house of Paris with the Edison electric light. The Edison Company will ship the necessary electrical machinery to France by the next French steamer, and will light up 800 Edison electric lamps in the opera-house on Oct. 7.

HISTORIC NOTES OF COSMIC PHYSIOLOGY.*

By Dr. T. Sterry Hunt.

[Abstract.]

The author began by insisting that general physiology, as the philosophy of material nature, is co-extensive with general physiography, in which sense it was employed by the best writers up to the first year of this century. In the abridgements of the Philosophical Transactions of the Royal Society up to 1700, and to 1720, the chief division is into Mathematical and Physiological subjects, the latter including the phenomena of the three kingdoms of nature. There is a physiology not only of animals and plants, but of the inorganic world, and from terrestrial physiology we rise to a conception of the physiology of the Cosmos or material universe; a subject which from the earliest times has attracted the attention of philosophers. One of the most evident of the problems thus presented is that of interstellar space, and its relations to our earth and its gaseous envelope. After noticing the views of the ancient Greeks, the author referred to the discovery by Alhazen of the refraction of light, from the phenomena of which the Arab philosopher attempted to fix the limit of the terrestial atmosphere. He then noticed the similar attempts of later observers, and adverted to the well-known hypothesis of Wollaston, who endeavored to assign thereto an absolute limit on grounds which are inadmissible. He adverted to various views as to the so-called ether of space, which Newton thought, must include exhalations from celestial bodies, and noticed the hypothesis of Grove that the medium for the transmission of radiant energy through space is but a more attenuated form of the matter which constitutes the gaseous envelopes of the earth and other celestial bodies, between which, through this medium, Grove supposed material interchanges might take place. The suggestion of Arago as to the possibility of determining the density of the rare matter of interstellar space was noticed, as well as that of Sir William Thomson, who has even attempted to fix the minimum density of the luminiferous medium, which he, like Grove, conceives may be a rarified extension of the terrestrial atmosphere. Mattieu Williams, adopting the hypothesis of the atmospheric nature of the interstellary matter, has attempted to show how the sun in its course through space may condense this matter with the evolution of heat and thus replenish the solar fires. From this ether also by a stoichiogenic process the various chemical species are perhaps generated.

The author had endeavored to approach the study of interstellary matter from a wholly different side. From a consideration of the chemical and geological changes of which we have evidence in the earth's crust since the beginning of life on the planet, it is clear that enormous volumes of carbonic dioxide have become fixed partly in the form of carbon, with evolution of oxygen, and partly as carbonates—equal in the aggregate to 200 atmospheres or more. This enormous volume, it is held, must have come from outer space to supply the gradual absorption of the gas from the atmosphere, while by a reverse process of diffusion the great amount of liberated oxygen may have been got rid of, and the equilibrium of the atmosphere in this way maintained. The consequences, both meteorological and geological of this process were discussed by the author in 1878, and more fully in 1880 in an essay on The Chemical and Geological Relations of the Atmosphere in the *American Journal of Science.* As a farther contribution to the history of these views, the author proceeded to show that Sir Isaac Newton not only held to the presence in interstellar space of exhalations from the sun, the fixed stars, and the tails of comets, which he supposed to become diffused in and to form part of the ether, but even suggested that this etherial matter is the solar fuel and essential to planetary life. From a consideration of the processes of vegetable growth and decay, Newton arrived at the conclusion that elements from interstellar space, brought by gravity within the terrestrial atmosphere, serve to nourish vegetation, and by its decay are converted into solid substances. In this way are, according to him, generated not only combustible (sulphureous) bodies, but calcareous and other stones, whereby the mass of the planet is augmented. These views put forward in Newton's famous Hypothesis concerning Light and Color in 1675, and in the Queries to the *Optics*, are more definitely enunciated in Propositions 41 and 42 of Book III of the *Principia.*

* Read before the A. A. A. S., Cincinnati, 1881.

ON THE UNIFICATION OF GEOLOGICAL NOMENCLATURE.

By Richard Owen.

With a view to proposing such Geological Terminology as would probably be acceptable to a large majority of the scientific representatives of those nations sending delegates to the International Congress for the Unification of Geological Nomenclature, it seems necessary to offer for discussion some principles, and to lay down some

SUGGESTIVE RULES:

1. To agree that all questions shall be decided by a plurality vote; or, if thought best, by a two-third majority.

2. To assign distinctive names for the headings of geological divisions and subdivisions, instead of calling, for instance the "Silurian," sometimes an "Age," at others a "Period, System, Era, Formation," or as by the French "Etage," which is translated by Surenne as meaning (when applied to Geology) stratum or layer. Further suggestions on this point will be given in the "Conspectus of Headings."

3. To arrange under these heads, when thus decided upon, such formations as are generally considered of nearly coördinate value, in lieu of giving the same apparent importance to a minor subdivision, say of Upper Silurian (such as Salina), or one of the Devonian (e. g. Chemung) that we assign to the whole Tertiary. The subjoined Tabular View offers a modified coördination.

4. To select, as far as practicable, for the geological formations thus arranged, geographical terms, indicating the areas where these formations prevail extensively, or have been studied very thoroughly. This would obviate any controversy on mooted points regarding the lithological or paleontological character of the formation. In order to illustrate the practical application of this rule, let us take for examination the nomenclature proposed by the illustrious Sir R. Marchison, in his great work of 1854, "Siluria," descriptive of the geological formation in the country inhabited by the ancient "Silures." His work of 1839 was entitled "The Silurian System," but his later publication showed a preference for the shorter and more expressive form as a noun. The adjective has, with slight modifications, been adopted in most modern languages; but by selecting the noun "Siluria," we unify for universal recognition. The same may be said for "Devonia." If it is not considered too great an innovation to alter terms already so well received, we might say "Silur-Britannia," "Devon-Caledonia," and proceed then to distribute the honors among different nationalities, as more fully exhibited in the Conspectus. The term Carboniferous is not correct when applied to Mountain Limestone or Millstone Grit, besides Coal Measures cannot be so rendered into other modern languages as to make a suitable subdivision, it is therefore suggested to name the system after the region having the greatest Coal area (the United States), and the Coal Measures after a European country in which coal is well developed. This would give us Appalachia or Carbon-Appalachia for the system, and Belgia for

the productive Era, while the great development of Millstone Grit in Ireland furnishes the term "Hibernia," and the celebrated Adelsberg grotto or cave in Mountain Limestone suggests the term "Austria," as appropriate for that Era. So also Perm-Russia, because the Permian system prevails so extensively from Kasan to the Gulf of Tscheskaïa, near the White Sea; Trias-Germania, because the Germans have given to all geologists the subdivision of that system (Bunter, Muschelkalk and Keuper) also Jura-Gallia, because the system prevails largely, and has been studied minutely in France. This plan of nomenclature would also serve to recall to the geologist, and convey to the student, important facts regarding the distribution of the formation.

5. Somewhat in the same manner, uniformity might be given to the names of nonfossiliferous rocks, by adopting Dr. Dana's orthography, as given in his latest works, where he employs the letter "y" instead of "i" as in Granyte, to distinguish rocks from minerals with names ending in "ite." Even the final "e" may as well be omitted in order to unify for other languages; and we then have, for example, Granyt, Syenyt, etc., or we may even so apply the rule as to have international names for Limestone, Sandstone, Magnesian limestone and the like, calling them Calkyt, Silikyt, Dotomyt, etc. Some German scientists (see Cotta's "Gesteinslehre") use, for instance, the word Quartzit, writing it however with an "i."

6. It is thought further that, in many cases, geological terms might be abbreviated, so as to be readily intelligible in all languages, somewhat on the symbolic system adopted in chemistry. A conspectus of the proposed modifications in geological nomenclature, with a column

SUGGESTIVE CONSPECTUS, TOWARDS UNIFICATION OF GEOLOGICAL NOMENCLATURE.

DIFFERENT HEADINGS, WITH ONE OR TWO EXAMPLES.

MACROCHRONE.	EON.	PERIOD.	ERA.	EPOCH.	MICHROCHRONE.
(Greatly extended time.) *Examples.* Neptunia (all aqueous rocks.)	(" A space of time, a life-time.") Paleozoic Eon.	(" An inteıval of indefinite time.") Permia Carbonaria Devonia Siluria	(" A succession of years between two fixed points.") Austria (Mt. limest.) Cambria	(" A pause.") Iowaia Potsdamia Acadia	(Comparatively short time.) Karkaskia, St. Louis, etc., etc.

EXAMPLES SHOWING THE ADAPTABILITY OF CERTAIN HEADINGS TO MOST OF THE MODERN LANGUAGES.

		System. (" An assemblage of objects ranged in regular sub-ordination, or related by some common law.") Σύδεημχ (το) Le système. Das System, Il sistéma. El sistéma.	*Sub-system.*	*Group.* (" An assemblage of objects in a certain order.") Le Groupe. Die Grüggen. Il grúppo. El grúpo.	*Sub-group* or *Section.* Sectio. La section. Die section. La sezione. La seccion. or *grade* or *member*, with slight modifications can be used in the above languages.

ABBREVIATED FORMS WITH SOME EXAMPLES.

		For *Periods.* Roman numerals, I, II, III, etc., or Capital letters A B C, etc., applied thus: I = Silusia. or A = "	For *Eras.* Arabic numerals 1, 2, 3, etc., applied thus: 2. = Canadia 1. = Cambria	For *Epochs.* Small letters a, b, c, etc., [repeated for the epochs of each era.] 2^b = Vitrè-Murcia 2^a = Llandeils-Esthonia 1^b = Potsdamia 1^a = Acadia	For *Members,* marks used to the right and above the era letter, similar to the power-sign in mathematics. Thus to designate the Burlington member of the Iowa subcarniferous, we would write: III. $9^{a''}$ or C. $9^{\circ}a''$

of the leading present equivalents is submitted below, in which it will be observed that one great object, kept in view, was the recording particularly by the Epoch names, such localities as are noted for having given us remarkable fossils, characteristic of that peculiar formation, whether found in well-known regions of Europe and America, or in such distant countries as Patagonia, N. Zealand, the Cape of Good Hope, Greenland or Spitzburgen, etc.

NOTE TO TABLE I.

To further facilitate the understanding of some of the suggestions submitted, a tabular view is subjoined, giving different headings, with their definitions from standard dictionaries, as well as a conspectus of the symbols.

NOTE TO TABLE 2.

Probably some difficulties, and, despite of care exercised, some errors in the details may be pointed out; but if the general principles are found acceptable, or suggestive of such discussion as may ultimately lead to unification of our Geological Nomenclature, the object proposed, in the preparation of this paper, will be attained.

A NEW MATERIAL FOR STOP-COCKS AND STOPPERS FOR REAGENT BOTTLES.*

By H. W. WILEY.

For some time I have been working with a compound invented by Mr. T. J. Mayall, of Reading, Mass., and known as the Mayall metal. One form of this compound was intended as a material for journals, pneumatic tubes, etc. It is made of 5 to 6 parts graphite, 1 part rubber and ½ part sulphur. Instead of sulphur, sulphide of antimony can be used. The material is a perfect self-lubricant and to a high degree resists the action of acids and alkalis.

From its properties I was led to believe that it would be especially useful for chemical apparatus, in the manufacture of stop-cocks, connecting tubes, etc. My expectations were fully realized.

I have used it with success for burettes, cocks for hydro-sulphuric acid, stoppers for hydrote bottles, etc, These never stick, no difference how firmly they are pressed in nor how long they are left. The material is firm and elastic and will hold threads nearly as well as a metal.

I regard it as peculiarly useful for stop-cocks for acids, especially hydro-sulphuric. It is capable of a high polish, and will not tarnish. Slightly modified in composition it is used for covering houses and plating the bottoms of ships. Placed on ships it seems to prevent entirely the adhesion of barnacles, Strange as it may seem, it also makes an excellent insulating material for telegraph wires. I have not yet tried the effect of ozone upon it and only partially of permanganate of potassium.

PHONETICS OF THE KAYOWE LANGUAGE.*

By ALBERT S. GATSCHET.

Books printed in Indian languages often render those tongues in a most imperfect manner, on account of the deficient knowledge of Indian phonetics on the part of the authors. The Kayowe language is a fair average specimen of Indian pronunciation, and is very rich in sounds, having no less than forty-four sounds, if we count in the long and the nasalized vowels. In its phonetic series the most conspicuous fact is the prevalence of the nasals and the total absence of dsh, tch, which are so conspicuously frequent in the majority of American languages, of r and of v. The palatal series is represented by one consonant only; the guttural and dental series are well represented, while in the labial series p, b, and m are the only frequent sounds. F is found in some words only, where it alternates with p, pai, or fai, land, earth. Among the sounds not frequently met with are sh, w.

* Read before the A. A. A. S., Cincinnati, 1881.

Nasalizing is a prominent feature in Kayowe phonetics, more so in the vocalic than in the consonantic series No word begins in l or w. Final syllables of words terminate just as often on a consonant as in a vowel, but all other syllables usually end in a clear or nasalized vowel. Every diphthong is adulterine; that is, every combination of two colliding vowels differing from each other can be pronounced as a monosyllable and a dissyllable. Thus we can pronounce as well ze-iba as zeiba arrow. The fact that every vowel can become nasalized (and many of the consonants also) is one of the curious features of the language. This nasalization is either the one observed in the French an, in, on, un, or it consists in the addition of an n to the vowel. All these Kayowe peculiarities are very commonly observed in the majority of American languages, and also in most of the unwritten languages of other parts of the world. The standard orthography which is adopted for recording a written literary language exercises undoubtedly some influence upon the pronunciation of the natives, but where the language is not fixed by writing, we perceive constant alternation of the sounds pronounced with the same vocal organ, as of the gutturals, dentals, and labials among themselves.

"This is also the case in Kayowe, and a full list of the sounds in it is as follows:

CONSONANTS:

Gutturals: k, g, kh (aspirate), h, ng.
Palatals: y.
Linguals: *k̲*, g̲, sh, l.
Dentals: t, d̄, s̄, z, n, nd, 'dl.
Labials: p, b, f, w, m, mb.
VOWELS: a, ā, â, ä, e, ē, ĕ, (the primitive vowel), i, ī, î, o, ō, u, ū, û."

TYPICAL THIN SECTIONS OF THE ROCKS OF THE CUPRIFEROUS SERIES IN MINNESOTA*.

By PROFESSOR N. H. WINCHELL.

This paper was in pursuance of the same line of investigation as that by the same author read last year before the Association, but gave the detailed methods by which general results had been attained in the study of the stratigraphy of the cupriferous rocks. By means of the microscopic examination of the crystalline rocks of the series, two groups of rocks were discovered, one being those generally accepted as igneous by Pumpelly, Chamberlin and by Owen, and the other the result of change from the sedimentaries. The former one dark colored and heavy, consisting essentially of labradorite, augite and magnetite, but the latter are lighter colored, generally showing a reddish tint, and consist essentially of orthoclase, quartz and hornblende. It is the latter group that in this connection possesses the greatest interest, as the author regards them as the true equivalents of the shales and sandstones that in some places are seen interbedded, without metamorphism, with the igneous rocks of the other group. They play a very important part in the geology of northeastern Minnesota, where, in their varied lithology, exhibiting different stages of crystallization, they not only are spread over a large geographical area, but afford some of the most interesting geological studies.

The author suggested that probably the titaniferous iron ore which is so largely associated with the igneous rocks of the cupriferous series, had its origin in the ferruginous shales of the sedimentary series, by the reduction of the oxides with which they are colored, at the time of the igneous disturbances.

The paper was accompanied by a series of fifty thin sections made by the author, with brief descriptions, and by samples of the rocks from which they were taken, intended to illustrate the lithological distinctions pointed out.

* Read before the A. A. A. S., Cincinnati, 1881.

WORKED SHELLS IN NEW ENGLAND SHELL-HEAPS.*

BY PROF. EDWARD S. MORSE.

Mr. Morse called attention to the fact that heretofore no worked shells had been discovered in the New England shell heaps. A similar absence of worked shells had been noticed in the Japanese shell heaps. Worked shells were not uncommon in the shell heaps of Florida and California. Mr. Morse then exhibited specimens of the large beach cockle (Lunatia), which showed unmistakable signs of having been worked. The work consisted in cutting out a portion of the outer whorl near the suture. To show that this portion could not be artificially broken he exhibited naturally broken shells of the same species, both recent and ancient, in which the fractures were entirely unlike the worked shells.

A REMARKABLE INSTANCE OF RETENTION OF HEAT BY THE EARTH.†

BY H. C. HOVEY.

The fact is well known that heat may be retained for a long period by the rocks and soils of the earth; but it is seldom that dates can be fixed with approximation to accuracy as can be done in the instance the particulars of which are now given.

My attention was called, a year ago, by Mr. James Hudson, manager of the Albion mines, in Pictou county, Nova Scotia, to a peculiar area including about two acres of ground, where the snow never lay long without melting, and the frost, even in severe winters, never penetrated but for a short distance. All over this space are scattered fused masses of clay and ironstone, resting on the outcrops of what are locally known as the "Main" and the "Deep" seams of bituminous coal, which at this point are about 450 feet apart and partially affecting the outcrops of other seams. On inquiry as to the probable date of the fire that had left this area of scoriæ and ashes, I was told that this portion of Nova Scotia was visited early in the seventeenth century by French explorers, and that an account of the harbor called Pictou was given in 1672 by Monsieur D'Enny, who was appointed Governor of the Gulf of St. Lawrence in 1654. The name "Pictou" is said to be derived from a Micmac word signifying *fire;* and the traditions of the Indians still point to this locality as having been, a long time ago, the scene of a fierce and long-continued fire, which made them avoid the place as being visited with the anger of the gods.

The coal measures of Pictou were discovered in 1798, at the very point now described; and the discoverers represented the spot as covered with ashes, over which grew large hemlock trees. About twenty years ago, while a drain was being dug in this locality, a tree was cut down that showed 230 rings of annual growth; and three feet below the root of this tree a large piece of wood, fashioned by some sort of axe, was found in a good state of preservation. It is Mr. Hudson's opinion that at least 300 years must have passed since the extinction of the fire at this point, and it is known that none has been rekindled since; its ignition may have been effected by chemical action, or by a stroke of lightning, or by artificial means applied to one of the so-called springs or feeders of inflammable gas that issue along the outcrops of these unusually thick seams.

Last spring it was found necessary to sink a small pit at the crop of the Deep seam on this area, in doing which

* Read before the A. A. A. S., Cincinnati, 1881.

† Read before the A. A. A. S., Cincinnati, 1881.

the facts were obtained concerning the long retention of heat by the earth, to which I have already referred. Mr. Edwin Gilpin, Government Inspector of Mines, has kindly placed at my disposal what information he could gather on the subject, which I give, using, to some extent, the language of this careful and accurate observer. Mr. Gilpin has prepared a comparative view of sections of the same strata, made only a short distance apart, the design being to exhibit the changes made by igneous action.

The *present section* is taken at the new pit sunk by the Albion Mines Company on the burnt area; and what is termed the *original section* is one given in Sir William Logan's Report of the Geological Survey of Canada, 1869, p. 69. The distance between the localities where these two sections were made is so small that the comparison is at least instructive, and answers our purpose as well as anything that can be had.

Present Section.	ft. in.	Original Section.	ft. in.
Surface of burned clay	22. 0	Black, argillaceous shale, with many bands of iron-stone 1 to 2 inches thick. Total thickness 144 ft. 6 in.	2. 6
Band of hard scoriæ	4. 0	Brown carbonaceous shale	1.10
		Bad coal	0. 2
Reddish ashes	3. 0	Good coal	3. 7
Hardened shale	2. 0	Black shale with iron-stone bands	1. 2
Good coal (being upper part of the Deep Seam)		Good coal	3. 5
		Coarse coal	0. 8
		Good coal	3. 9
Depth of Pit	32. +	Coarse coal	0.11
		Good coal	3. 4
		Coarse coal	5.10
		Total thickness of the Deep Seam.	22.10

The surface cover consists of clay, with boulders of sandstone and layers of gravel. The small portion of the 144 feet of black argillaceous shale filled with iron-stone balls, passed through by the shaft, has been converted into an almost continuous mass of scoriæ, very hard and compact, and difficult to drill through.

The next layer represents the upper portion of the deep seam, which has been completely burned away, leaving a *compact, laminated reddish ash*. And it was in this ancient bank of ashes, known to be more than 300 years old, that the retention of heat was observed, which it is now my object to place on record. Immediately on opening the pit, the heat of the ashes, at a point 30 feet below the surface, was tested by a reliable thermometer, and was found to be 80° Fahr. at a time when the surface temperature varied from a minimum of 45° to a maximum of 65° Fahr.

Soon after an opening had been made through the pit to the workings in the mine, the air-currents caused the temperature rapidly to fall to the normal point.

The consideration of the gradual radiation of the heat of the earth suggests the idea that abnormal increases in the temperatures of deep mines may be due in some cases to the presence, at comparatively short distances, of masses of heated matter, which are, geologically speaking, modern, though they may be historically ancient.

Recovery of Old Vulcanized Caoutchouc.—The pieces are heated in contact with steam, when the sulphur is volatilized and the caoutchouc melts and is collected as a liquid, used in preparing water-proof covers, etc.

Radiophony.—Professor Mugna, repeating M. Mercadier's experiments, in which an intermittent beam meets a smoked surface within a glass tube, containing aqueous or ammoniacal vapor, and furnished with an ear tube, adds to the effects by attaching a small microphone to an elastic membrane closing the tube. By this means he finds it possible to operate at a sufficient distance from the interrupting disc to render its noise no longer disturbing.

PILOCARPIN:—ITS ACTION IN CHANGING THE COLOR OF THE HUMAN HAIR.*

By D. W. Prentiss, M. D. Washington, D. C.

Pilocarpin is an alkoloid of Jaborandi and the active principle.

Jaborandi is a Brazilian drug recently introduced into medicine.

The leaves are the official part of the plant. (Pilocarpus Pennatifolius.)

The effect upon the human system is powerful and peculiar.

(It produces profuse sweating and salivation, and stimulates the growth of the hair.)

Two cases were reported.

In the first case, the medicine was given to relieve uraemia consequent upon suppression of urine due to *Chronic Pyelitis.*

The patient was a lady twenty-five years of age, a blonde of petite figure.

The pilocarpin (hydrochlorate) was administered by hypodermic injection, commencing December 16, 1880. and being continued at intervals until February 22, 1881. The usual dose given was one centigram, but on several occasions this dose was doubled.

The object of its use was to eliminate urea from the system by sweating and salivation.

The immediate effect produced was profuse sweating and salivation, calculated to amount to not less than fourteen pints. (See Phila. *Med. Times*, July 2, 1881.)

The result to the patient on each occasion was great exhaustion, but the ureamic symptoms were relieved.

Twenty-two "sweats" were administered in all, and from thirty-five to forty centigrams of *pilocarpin were used.*

CHANGES IN THE COLOR OF THE HAIR.

Specimens of the hair were exhibited to the section, as also a colored plate showing the changes in the color.

Two specimens dated respectively November 1879, and November, 1880, were of a very light color, tinged with yellow, and showed that the color of the hair had not changed during that year.

The third specimen dated January 12, 1881, was a chestnut brown, and the fourth dated May, 1881, almost pure black.

The administration of the Pilocarpin began December 16, 1880, the change was first noticed December 28. 1880, and was thenceforth progressive.

In addition to the change of color the hair has become thicker and coarser than formerly, and while previously dry, is now quite oily.

The hair on other parts of the body is also changed in color.

The eyes have become a much darker blue.

In the second case, the Pilocarpin was administered to an infant fourteen months of age, afflicted with Membraneous Croup. (See Phila. *Medical Times*, August 13, 1881.)

The treatment was commenced June 19, 1881; two milligrams of hydro-chlorate of Pilocarpin being given every hour, afterwards increased to four milligrams every hour. It was administered for nine days, the amount being diminished towards the last.

The first specimen of hair was taken June 17, 1881, and the second June 27, 1881.

The color of the first is light yellow, and the second is a decided shade darker. This effect, of changing the color of the hair, if subsequent experience shall confirm it, adds another to the marvellous influences of Jaborandi on the human system.

The *modus operandi* of the change is still to be determined. It is probably connected with the fact that Jaborandi stimulates the nutrition of the hair.

* Read before the A. A. A. S., Cincinnati, 1881.

There appears to be reason to believe that the color of the hair is due to an oily pigment, and that this is increased under the influence of Jaborandi.

Shaving the scalp usually has the effect of making the hair thicker and darker, on the contrary, as age advances and the processes of nutrition are enfeebled, the hair becomes thin and dry and whitens.

THE CONSTITUTION OF THE "ATOM" OF SCIENCE.*

By MRS. A. B. BLACKWELL, SOMERVILLE, N. J.

[Abstract.]

This paper developed the hypothesis that in each atom of matter a given quantity of force and extension are conditioned by each other to act in special modes, rigidly adjusted in time and space. All atoms react against many opposed and unlike forces simultaneously, hence each atom must be a highly complex (not compound), elastic structure, which, by its changes in space, gives the direction, extent, rate of vibration, and all modes and transformations of the atomic force.

We can explain this variety and change of action, if we suppose every atom to alternately expand and contract unlike filaments or poles that act and react in vibrations towards and from a common axis, which is at rest. No point outside this axis can be at rest, except when held in equilibrium by other atoms. Reaction is equal and opposite between every part of the atom, and between it and all other atoms. Chemical combination is the interlocking, the literal intertwisting of certain poles of the combining atoms. Such combination brings to rest, makes latent, the opposed combining poles, wholly or in part; the more completely this is done the greater the transformed motion called heat, and the more stable the compound.

In combining, the uniting poles are massed or knotted, as any intertwisting cords would be, and many-atomed molecules require no extra room for their vibrations; but all gases contain equal numbers of molecules to the volume. But the atomic axes are shifted to a common centre; and thus the vibrations of all the free poles are more or less modified, according to the number and kind of the combining factors; they are always so far modified that the molecules of any compound vapor cannot repel those of either of its constituents, nor those of any unlike vapor—the explanation being that the periods of greatest expansion, the stretch outwards in their free poles are not synchronous. In like molecules they are synchronous, and the free poles, striking at any point short of greatest expansion, drive the atoms asunder. We call them mutually repellant. The action of all repulsive forces will admit of similar explanation. Push or strain in one direction compels counter-push or strain in another direction; hence opposed electricities, magnetisms, and polarization in general.

Gravitation may be considered the concurrent result of brief intertwisting of the physical poles; cohesion and crystalogenic energy represent more permanent interlocking. But chemical and physical combination are supposed to be alike in kind—the result of opposed, adapted mechanical energy. Chemical action in general produces more radical changes in the sensible properties of substances, because, taking the initiative, it sifts the atomic axes, and subsequent combinations are but in accommodation to these previous changes.

The hypothesis attempts to give a fairly adequate explanation of material changes; of the *how* and *why* of such changes.

The unlike elements of matter are supposed to be conditioned in special groups, but are essentially of the same type, and their changes are all in time and space only. There is held to be a higher type of atoms in the living sentient, or "mind matter" group, which we know only through their active organisms. In these atoms, force is conditioned both by extension and by intensiveness, and not in time and space alone—as with simple matter, but in time and space and sentience.

Possible changes in sentience, emotion, may be nascent in these atoms just as complex motion is nascent in all uncombined or but little combined atoms. Complexity of action in molecule and larger mass against which any atom must react in equal measure and opposite directions, compels complexity in the atomic reactions, and in the higher type of atoms one phase of all these reactions represents changes in sentience-sensations, thoughts, volitions.

Molecular complexity sufficient to excite a pleasurable degree of feeling would tend instinctively to repeat itself; hence the rise of organisms. The organism is the sentient atoms everchanging active molecule; and organic growth is adapted to the more and more complex sentient states. Decadence means failure in such adjustments. Sentient changes vary all the way between the low sentient state of profound sleep and the most alert phase of self-consciousness, but they are all individual or atomic changes. This hypothesis claims to offer an explanation of the joint facts both of matter and of mind.

BACTERIA AND THEIR RELATIONS TO PLANT CULTURE.

BY THOMAS TAYLOR, MICROSCOPIST, OF THE DEPARTMENT OF AGRICULTURE.

If we examine, under a high power of the microscope a small portion of the scum of a fermenting infusion of vegetable matter, numerous particles of a globular shape will be observed, measuring about one twenty-thousandth of an inch in diameter, uniform in size and shape, highly refractive and frequently found in gelatinous masses. These are known as micrococci, or spherical bacteria. Associated with them is generally found another description of germs of the same diameter, but of a rod-like shape, jointed and of various lengths. In common vegetable fermenting infusions they are seldom observed over .003 of an inch in length, and are frequently under .001 of an inch. They have generally an active motion, as seen under a high power (as have also the micrococci), and are known as rod-bacteria (from bacterion, a staff). Botanists of the present day assign both of these organisms to the division algæ.

Many investigators believe that certain species of these organisms produce contagious fevers, but there certainly are other species which perform a most useful part in the economy of nature, and in many of our valued industries their active co-operation is absolutely necessary. It is well-known that they are the chief agents of fermentation and putrefaction, and it is to the decomposing power they thus exert, in conjunction with the action of the elements, that all organic bodies decay and restore to the earth soluble fertilizing salts, instead of the insoluble and therefore unavailable material of which, in their unchanged state, they are made up. There is high authority for stating that organic substances are not inherently unstable. Under suitable conditions they may remain for an indefinite period wholly unaltered. It is well-known that in some portions of the earth the carcasses of dead animals tend to dry up and become mummified. In the arctic region the remains of animals imbedded in ice are kept in perfect preservation for centuries. It is only under conditions more or less favorable to the existence and multiplication of the small organisms which produce fermentation and putrefaction that rapid decay takes place.

Without bacterian fermentation the compost heap of

Read before the A. A. A. S., Cincinnati, 1881.

the farmer would remain valueless as plant food. The stubble and the dead grasses of our fields, and the fallen leaves, twigs, branches and trunks of trees would remain comparatively unchanged but for the chemical action excited by the same agency. Fish guano, and all unfermented organic fertilizers, must undergo bacterian fermentation or putrefaction after their application to the soil, or they will remain in a stable form, and their ammonia, locked up in the tissues of which it forms a component part, will fail to yield its return of profit to the farmer. It is asserted that the great nitre beds of India owe their origin to the action of microscopic germs, and the production of nitrate of lime by artificial means presents a similar instance of the results of bacterian action. In this last-named operation animal and vegetable matter combined with lime is laid out in great beds and left for a period of two years, or until fermentation and putrefaction, coupled with the action of the air, have produced nitric acid, when nitrate of lime is formed, to be subsequently converted into nitrate of potash.

Some of the most beautiful colors used in dyeing are produced by subjecting lichens to bacterian fermentation, and the fermentation of stable refuse yields an even heat, which is extensively utilized in the manufacture of white carbonate of lead, as well as in the cultivation of mushrooms and of various early vegetables. The value of the edible fungi thus produced, alone amounts in Europe, Asia and America to millions of dollars per annum. The utilization of bacteria and similar organisms in the operations of baking and brewing, and the production of wine and vinegar, is familiar to every household.

While bacterian fermentation or putrefaction is an essential part of the process which fits dead organic matter to become food for plants, the former appears to be an incidental source of one of the common practical difficulties encountered by the farmer and horticulturist, viz.: the tendency of soils to become sour. Some of the lower forms of fungi are denominated "acid formers," and the mode in which these act will, I think, illustrate the process by which sourness of soil is brought about. If we dissolve a little sugar in water, add a small quantity of yeast fungus, and subject the solution to a suitable temperature, fermentation ensues—the sugar is converted into alcohol and carbonic acid, and in process of time the alcohol is oxidized, becoming acetic acid. As the result of some late observations, I am convinced that a similar change often takes place during the progress of those fermentations of which bacteria are the agents, and that these organisms, though in a less distinctive sense, might also be called "acid formers." So far as my observation extends, solutions in which bacterian ferments are in active progress, invariably become acidulated, and I have also found that soils in which bacteria and micrococci are revealed by microscopic examination—and I find them in all soils of average fertility—give perceptible acid reactions when tested by litmus paper.

That acidity is so often produced in excessive quantities may be due in part to the character of the unmarketable substances left upon the land in the operations of agriculture, such as the stalks of corn, the stubble of the smaller cereals, decayed grasses, the fallen leaves and twigs of fruit trees, and the roots of field and garden plants in general. In all of these there is a preponderance of cellulose, which substance is resolvable successively into starch, dextrine and glucose, and from this last, as from the solution of sugar in the experiment above referred to, is ultimately produced acetic acid.

The neutralization of the excess of acid in the soil is not the least of the ends subserved by the use of lime and other alkalies in agriculture; but another means which contributes to keep its quantity within wholesome limits is thorough drainage. If the soil of potted plants be not watered with sufficient frequency and copiousness it soon becomes sour, and gardeners have learned by experience to leave at the top of each flower-pot a water space of two inches, more or less, depending on the size of the pot. By filling this space with water as often as necessary the soil is kept sufficiently free from organic acids, which are washed out through the aperture below; and this is precisely similar to what takes place in any well-drained field.

I have already referred to the opinion that certain species of bacteria produce contagious fevers; but from what has been said above, it will be sufficiently apparent that this is by no means the chief function of this class of organisms. However great their baneful activity at times may be, their services to man and to organized existence in general are infinitely greater. Moreover, the former is but occasional and sporadic, while the latter is practically constant and universal. If the materials once used by the life principle in building up organic bodies could not be used over and over again for the same purpose, life must soon cease through the exhaustion of all that is capable of sustaining it. It is in that which has lived, but lives no longer, that life finds the greater part of its sustenance; but, as we have already seen, that vegetable life upon which all animal life ultimately depends can not use this sustenance in the form in which life left it. Before organic matter is available as plant food, it must be reduced almost to its primitive elements; and, as has been pointed out, its reduction is mainly effected through those processes of fermentation and putrefaction, in which bacteria appear to be the most active and important agents. Thus we find among those simple forms of life, which are supposed to have been the first to make their appearance on our planet, and to which, if we accept the theory of evolution, even the most complex of existing organisms owe their origin—an agent which, from the very inception of life upon the earth, has continuously performed a function without which the successive generations of plants and animals could not have existed; and stupendous as is its work, it is an agent so minute that twenty million individuals of its class might be inclosed within a globe small enough to pass through the eye of a cambric needle.

ANCIENT JAPANESE BRONZE BELLS.*

By Prof. Edward S. Morse.

Mr. Morse described the so-called Japanese Bronze Bells which are dug up in Japan. These bells had been described and figured by Prof. Monroe in the Proceedings of the New York Academy of Sciences. Mr. Kanda, an eminent Japanese archæologist, had questioned their being bells from their peculiar structure.

Mr. Morse had seen a number of bells of different kinds, some of considerable antiquity, but none of them approached these so-called bronze bells. Mr. Kanda had suggested that they were the ornaments which were formerly hung from the corners of pagoda roofs, but the fact that none of them showed signs of wear at the point of support, rendered this supposition untenable. Mr. John Robinson, of Salem, the author of a work on Ferns, had given the first suggestion as to the possible use of these objects. He has asked why they may not have been covers to incense burners. Curiously enongh, old incense burners are dug up which have the same oval shape that a section of the bell shows. The bell has openings at the base and also at the sides and top, so that the smoke of burning incense might escape. It is quite evident that these objects are neither bells nor pagoda ornaments, and this suggestion of Mr. Robinson's may possibly lead to some clue regarding their origin.

Electric Motive Power for Omnibuses.—The Faure accumulators have been tried again by the Paris omnibus company on a tramway with a carriage arranged for the purpose. The experiment is said to have been highly successful.

TIME SERVICE OF CARLETON COLLEGE OBSERVATORY, AT NORTHFIELD, MINNESOTA.*

WILLIAM W. PAYNE.

The observatory of Carleton College is located at Northfield, Minn., forty miles south of St. Paul, on one of the main lines of the Chicago, Milwaukee and St. Paul Railway. It was built in 1878. Its latitude was determined by Professor B. F. Thomas in 1879, by a series of observations made with a Würdemann zenith telescope of two-inch aperture loaned to the Observatory for that purpose by Lieut. Edward Maguier, Chief Engineer of the Department of Dakota. He used the Talcott method and found the latitude to be 44° 27′ 41″±. In August, 1880, the work was done a second time by myself, using the same instrument and method, and observing forty pairs of stars from Sofford's catalogue on three different nights. After the proper reductions the latitude was found to be 44° 27′ 40.″8.

In October, 1880, by the aid and courtesy of the officer just named, and Lieut. O. B. Wheeler, of the Lake Survey Corps, the longitude of the observatory was determined. The Coast Survey meridian of St. Paul was used as the base of operation. Observations were taken at both points on two different nights and telegraphic signals were exchanged. Independent reduction of the observations showed the longitude of the Observatory to be $1^h\ 4^m\ 23^s.85$ west of Washington and 14.3 seconds west of the meridian of St. Paul.

INSTRUMENTS.

The Observatory is furnished with the following instruments:

A Clark Equatorial, 8¼-inch aperture, 10½ feet, with complete mounting.

A Byrne Equatorial, 4.3-inch aperture, with portable mounting.

A Transit made by Fauth & Co., Washington; telescope of 3-inch aperture and 42-inch focal length with reversing apparatus.

Two Howard clocks with electric and magnetic attachments for use in regulating and sending time.

A Bond Siderial Chronometer with break-circuit and an ordinary Clark Chronograph.

TIME SERVICE.

The time service of the Observatory began October 23, 1878, immediately after the clock was set and regulated, the N. W. Telegraph Company (now Western Union) having previously asked for time, and having built a line to the Observatory and furnished it with a telegraph office.

The electrical time-signals are given by the mean time clock which has a break-circuit attachment operated by a small wheel on the shaft carrying the seconds hand. This wheel, which contains thirty-one teeth, spaced to represent two seconds except three which give continuous seconds to mark the close of each minute. This clock is placed in a local circuit with appliances for cutting it into the main telegraph lines for daily, noon signals. By arrangement with the railroad companies the clock is put into line before twelve daily and thus give *three* full minute signals, the last stroke of the third minute being the time of twelve exactly.

Until recently the distribution of the time has been effected in the following manner:

The principal officers of five of the seven different railroads centering in St. Paul and Minneapolis were connected with the main office of the Chicago, Milwaukee, and St. Paul Railway either directly or at some intersecting point, and in this way our central mean time clock has daily operated all the main lines of these companies. The branch lines use the same time, having it repeated by hand. When the main lines are thus connected the clock has given its break-circuit signal distinctly over 1285 of wire in six different States and territories and ranging from Kansas City to St. Paul, Winona and McGregor in Iowa.

For a few weeks recently, the signal has been modified by reversing the points of the relay in the local circuit for the purpose of a make circuit signal on the main line. A five minute signal attachment has also been applied to the clock that time balls may be dropped at noon daily in connection with our railroad time service. Arrangements are already made to drop a time ball in each of the cities of St. Paul and Minneapolis, apparatus for the same being already in hand.

The five-minute attachment, as it is called, that aids in dropping these time-balls, is a plain disk attached to the train of the clock so as to revolve once in five minutes; a portion of the circumference representing fourteen seconds is cut away. This disk is placed in the local circuit and serves to keep it closed, and hence main lines open during fourteen seconds preceding the *sixtieth one* before noon. The interval gives opportunity to connect time-balls with electrical apparatus for dropping the same by the single twelve o'clock stroke from the clock. The dropping apparatus that I use for these balls is manufactured by Prof. H. S. Pritchett, of St. Louis. It is neat, simple and effective.

DISTRIBUTION OF THE TIME.

The following railroad companies take the Northfield meridian time directly or indirectly, and use it over their lines without change.

	Miles.
1. C. M.and St. P. R'y, on its five divisions West of the Mississippi now embracing an aggregate length of....................................	2271
2. W. & St. Peter R'y, (branch of N. W. R'y,) uses both Northfield and Barabvo signals but runs on Northfield time West of the Missisippi........	484
3. St. P. M. & O. from Sioux city to Elroy Wis., on all its branches...........................	963
4. M. & St. L. R'y, from Minneapolis South....	260
5. Northern Pacific Railway to the end of its track....................................	680
6. St. P. M. & M. certainly to St. Vincent and (I think to Winnepeg)...........................	630
7. St. P. & Duluth..........................	153
Making a total of..........................	5541

The last two companies named do not take time directly from the observatory but from jewelers in the city of St. Paul who receive our daily signals.

It will be seen readily by inspecting a map that the territory traversed by these great railroads embraces all of Minnesota and forts of Iowa, Nebraska, Dakota, Wisconsin, Montana, and probably the Province of Manitoba.

CHANGES IN MYA AND LUNATIA SINCE THE DEPOSITION OF THE NEW ENGLAND SHELL HEAPS.*

BY PROF. EDWARD S. MORSE.

This communication embraced a comparison between the shells peculiar to the ancient deposits made by the Indians along the coast of New England, and similar species living on the coast at the present time. Mr. Morse referred to similar comparisons which he had made in Japan, wherein he had found marked changes to have taken place; changes which showed that the proportions of the shells had greatly altered.

He had made a large number of measurements of shells from a few shell heaps of Maine and Massachusetts, and had obtained very interesting results. The common

*Read before the A. A. A. S., Cincinnati, 1881.

*Read before the A. A. A. S., Cincinnati, 1881.

clam (Mya) from the shell heaps of Goose Island, Maine; Ipswich, Mass., and Marblehead, Mass., in comparison with recent forms of the same species collected in the immediate vicinity of these ancient deposits, showed that the ancient specimens were higher in comparison with their length than the recent specimens.

A comparison of the common beach cockle (Lunatia) from the shell heaps of Marblehead, Mass., showed that the present form had a more depressed spire than the recent forms living on the shore to-day, and this variation was in accordance with observations he had made on similar species in Japan.

AMERICAN COAL FIELDS.

The areas of the anthracite coal fields, confined to a few counties of our State, are so well defined that we need be in no doubt as to their extent; and this limited area admonishes us that we should carefully husband our inheritance, and not waste it. The fact is well established, that for every ton shipped to market, two are wasted. The loss in the operations of mining, the pillars left to support the roofs of the mines, the loss in prepaiation, each contributes to this great aggregate. How to prevent these losses, by use of improved machinery, and by more thorough methods of working the mines, should be the study of our mining superintendents and engineers. Several suggestions with a view to a partial remedy, present themselves.

First.—The owning of the land by the operators would make them careful to mine all the coals. As tenants for a limited term of years, their object is merely to take out that coal, and in such a manner as will cost them little, and bring them much.

Second.—If the lands are to be leased, the term should be long enough to enable them to mine all the coal beds covered by the lease.

Third.—The lease should contain clauses subjecting the methods of mining, ventilation and drainage to the supervision of the owner's mining engineers; limiting the lengths of "breasts" to seventy yards or less; forbidding the use of monkey rolls, or the rebreaking of the coal; providing for the dumping in separate heaps of the coal dirt and the slate and rock.

Fourth.—We need larger collieries, and fewer of them, with perfected machinery, for hoisting, pumping and breaking.

Fifth.—More capital is required to open the mines for extensive and exhaustive working, by driving the gangways to the extreme ends of the territory, and then mining towards the outlet, so as to obviate the necessity of retracing our steps and robbing the pillars.

In Schuylkill county we are specialists. We are dependent upon one substance: coal is king. There is no gold, silver, lead, copper, or other valuable metals. Though we have good iron ores, they are so disseminated as not to furnish us one workable bed. Yet we largely help Pennsylvania to furnish nearly halt the iron manufactured in the United States. We have a large farming area well cultivated by our industrious and frugal German farmers. Our convenient location to the great markets of the Atlantic seaboard, our canals and abundant railroad facilities, our great commodity, always give a promise and an attitude among the great countries of our grand old commonwealth, which we are ever proud to realize.—*Geology of Schuylkill County, by P. W. Scheafer. Pottsville, Pa.*

The latest addition to microscope stands is the swinging sub-stage. This American invention has been adopted by most of the English manufacturers. In the last number of the *Journal of the R. M. S.* we find the value of the swinging sub-stages disputed by Mr. Crouch, and that Mr. Stevenson concurred in this view, and described them as useless incumbrances and unsuitable for use with certain apparatus, which is essential to the display of some objects.

ASTRONOMY.

COMET C (SCHÄBERLE), 1881.

This comet has been observed here since the 16th of July. When first seen it was large, round and bright, and slightly condensed at the centre, being very plainly visible in a 1¼-inch telescope. On the morning of the 19th it had increased sensibly in brightness; a faint tail could be traced for a distance of fully 15′, pointing in a northwesterly direction; on the above date its position was obtainee from θ (*Theta*) *Aurigas* in the following manner: Thd comet and star were separated too far to be both seen in the field of the telescope together, the comet was also too far north of the star for both objects to be seen at once in the finder. One of the wires in the finder eye-piece was made parallel with the meridian, and then the star, which preceded the comet, was brought into the field and its passage of the wire obtained; the telescope was then carefully moved northward in declination until the comet, entered the field when its passage of the wire was observed; in this manner the difference of R. A. was obtained; the difference of declination was then estimated. From a mean of several passages of the star and comet its position on July 18th at 15h. 40m., Nashville mean time, was found to be R. A. 5h. 52m. 52sec., and Decl. 40° 15′. The R. A. will be very little out, but the declination may be over a minute in error.

Its position was obtained in the same manner on the 20th (A. M.), using the same star at 3h. 35m., R. A. 5h. 53m. 54sec., Decl. + 40° 42′, with probably several minutes of error in the declination. On July 24, at 15 hours, the comet was visible to the naked eye, appearing about as bright as a sixth magnitude star (Prof. Swift, of the Warner Observatory, saw it with the unaided eye as early as the morning of the 23d).

On the 28th a small star-like nucleus was visible with the telescope.

Aug. 3 (A. M.), it was very easily visible with the naked eye, traces of the tail being seen without a telescope. A naked eye comparison with comet B showed C to be the brighter. Comparing it with a six magnitude star it was of the same brightness, but, covering a larger area, it was more noticeable than the star. The tail, in the telescope, was long and slender and straight as a shaft.

Aug. 4 (A. M.), the comet was quite conspicuous with the unaided eye, the tail stretching out for some distance. In the telescope the nucleus was small, round and pale, and star-like in form, Turning the telescope from comet C to comet B, the two were identical in brightness, but B was slightly broader about the head and tail, and the nucleus was not so distinct; but considering the low altitude of C it must have been really much brighter than B.

On August 14 it was visible in the evening after sunset, being quite plainly visible to the naked eye, with its tail streaming upwards for several degrees. In the telescope it was many times brighter than comet B.

21 inst., in the evening, the comet was as bright to the eye as a 3½ mag. star. It appeared very graceful, straight and slender in the telescope. On this occasion I obtained its position with the aid of a ring micrometer, referring the comet to *Psi ursæ minoris.*

1881, August 21 ds., 14.1m. Washington, m. t. $\left\{ \begin{array}{l} \alpha = 11h.\ 08m.\ 08.5s. \\ \delta = +45^\circ\ 13'\ 42'' \end{array} \right.$
This was the *apparent position.*

22 inst., evening, its tail could be traced with the telescope for a distance of about 6°, and was visible to the naked eye for about the same distance. A faint lightish stripe was visible on this date, extending from near the head to a degree or so along the middle of the tail. The following side of the comet's head and tail were distinctly defined, the sky appearing quite dark up to the very body of the comet, but the preceding side was ill-defined and blended, the sky being whitish for some distance from the comet; there also appeared to be a diffused sort of short tail running out some 10′ or so from the n. p. side

of the head ; the nucleus was small and not very well defined.

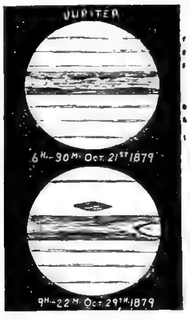
This comet differs considerably in general appearance from the comet now in *ursæ minor*. The head of B was large and broad, and its tail spread out greatly. Comet C has a small, narrow head with a very long slender shaft-like tail running from it in a straight line.

E. E. BARNARD.

NASHVILLE, TENN., *August* 26.

JUPITER.

The following cut represents the planet Jupiter on October 21st and October 29th, 1879, as seen with the 18½ inch Chicago refractor, with power 638.



The numbers on the right indicate the faint belts, which were systematically arranged on either side of the planet's equator.

The great Equatorial Belt, crossing the center of the disc, was composed of two separate belts, being divided by an irregular rift extending through the central portion. The color of this belt was reddish-brown-brick color, and the total width was 15,780 miles.

The great red spot shown in the center of the disc, on October 29th, was essentially of the same color as the equatorial belt, only more brilliant; it was about 30,000 miles in length and 8000 in breadth. Under fair atmospheric conditions, the equatorial belt was always visible up to the edge of the disc, with very slight diminution of color.

CORRESPONDENCE.

COMET *b*., 1881.

HARVARD COLLEGE OBSERVATORY,
CAMBRIDGE, U. S. *September* 13, 1881.

To the Editor of "SCIENCE."

SIR:—The spectrum of comet *b*, 1881, according to Dr. Konkoly (*Observatory*, 53, p. 257) contains five bright bands. From the mean of measures made with different spectroscopes on different nights, their wave-lengths in millionths of a millimetre were found to be 560, 545, 515, 472 and 468. The first, third and fourth of these bands are evidently due to carbon and, as Dr. Vogel has shown, are coincident with those of the banded stars of Secchi's fourth type. The other two bands appear to coincide with those of Ll. 13412. Last winter the spectrum of this star was found to consist mainly of bands having wave-lengths 545, 486 and 466 (*Nature*, xxiii, 604). The line 486 is probably due to hydrogen. The singular kinship of comets and banded stars is thus confirmed by a star whose spectrum seems to be quite unique.

EDWARD C. PICKERING.

To the Editor of "SCIENCE."

About two weeks ago, I found that one of the turtles which I keep for experimental purposes, a *Chrysemys picta* had laid eggs; all but one of these had been devoured whether by the turtle itself (as I have known to be the case with the same species, when kept in captivity) or by some alligators living in the same tank I could not discover. The perfect egg, I imbedded in moist sand, after carefully washing it, and finding yesterday, that it had not undergone development, I opened it and to my surprise found a living maggot, the larva probably of the *Musca vomitoria*, creeping around actively in the space between the half dessicated yolk and the shell membrane. It measured about four millimeters in length. As it crawled out of the aperture in the shell which I had made I threw the specimen away as it did not show the original anomoly.

Analogous observations have been made in the chick's egg. Cases are not infrequent where one egg has enclosed another or even several eggs, legs of beetles, wisps of straw and other foreign bodies. But this is I believe the first case where a living animal has been found in an egg. Of course the explanation of its presence is the same as in the case of the other substances referred to.

E. C. SPITZKA.

BOOKS RECEIVED.

ELEMENTS OF ALGEBRA, by G. A. WENTWORTH, A. M., PROFESSOR OF MATHEMATICS IN PHILLIPS EXETER ACADEMY, 8° BOSTON. Ginn & Heath, 1881; viii, 380 pp.

This addition to American algebraic literature is the sort of book that is to be expected from a live teacher. It bears the stamp of experience upon it and gives evidence throughout of the one end and aim of teaching beginners in algebra the art of algebraic manipulation. We say the art rather than the science, because the aim is clearly to familiarize the pupil with the *art*, to teach him *how* to manipulate rather than to lay stress upon the reasons for the processes, the author being evidently a disciple of Thomas Hill in his belief "*Facts before reasoning*." This is shown by such statements as "From these it may be assumed, etc."; "It may be verified that, etc."

The author has paid "particular attention to brevity and perspicuity in definitions," a thing which cannot be too highly commended, and without which any algebra, however good in other respects, will not succeed.

This matter of definitions is, as every teacher understands, a very important matter, if not for the algebra itself, then at least as a matter of right training and clear thinking. Definitions should be memorized, but memorization is not enough; they must be thoroughly understood. With those teachers who do not agree with this view we will have no disagreement, for the student trained to thoroughly comprehend is generally found by that very process to have secured that definition in his memory. In a text book, therefore, which aims at clearness and brevity in definition, a valuable training is afforded the student by leading him to carefully weigh the definitions; to consider whether the definition can be curtailed without loss of clearness, or whether it be not already too brief to be intelligible; to consider whether it is too restricted or too extended in its application, etc.

With the view of emphasizing this important matter we shall call attention to some of the definitions in this book, and at the outset let us premise that the definitions of mathematical terms must conform to the usage of mathematicians. It is a well-known fact that certain features of text books, faults as well as excellencies, are faithfully reproduced. Witness the statement concerning the rotation period of one of the major planets, erroneously given in one of the earlier editions of "*Herschell's Outlines*," and this error faithfully copied into astrono-

mical text books for nearly half a century. Witness also those mathematical tables "independently computed for this work" containing errors identical with older tables. The definitions given by a professional teacher, whose knowledge is gained from and chiefly confined to text books, will therefore be found to differ from those of a mathematician, astronomer or physicist, whose conceptions are drawn from memoirs and documents differing radically from text books. If a mathematician, not a teacher, should write an algebra he would probably reflect usage of mathematical terms by mathematicians better than the teacher; at the same time the teacher might express himself with more clear conciseness and in a manner better adapted to the class room.

The differences pointed out above are illustrated in the work before us. A co-efficient is defined as a *known* factor, in accordance with the usual custom of defining it; it is certain that this restriction is not kept up even in algebraic text-books, as they speak of indeterminate (meaning undetermined) co-efficients. That the leading letters of the alphabet usually stand for known quantities is something which the student has to *un*learn as soon as he gets out of the elements, and often before, as is the case in this work when Interest, Annuities, etc., is reached. The statement (p. 27) that "it is usual to prefix to the parenthesis the sign of the first term that is to be enclosed within it," may be questioned.

"An equation" according to this book "is a statement that two expressions are equal." Suppose we make this statement: "One pound is equal to sixteen ounces," will not this conform to the definition and at the same time will it not fail to represent the algebraist's conception of an equation? According to the definition of "Equation of Condition" $x^2 = my$ is not an equation of condition. "To solve an equation is, to find *the* value of the unknown quantity," thus implying that there is but one value that will satisfy the equation, an impression that will subsequently require correction. The terms *cancel* and *reduce* so much used are not defined. The usage of the first is in accordance with general use but not in accordance with the usual definition. In fact no definition of it in any algebra (I am ready to be corrected) conforms to mathematical usage.

The definition of fraction is purely the arithmetical one in which the numerator and denominator are supposed to be integers and hence fails as a general definition, just as the definition of *index* or *exponent* fails through too great limitation or from tacitly assuming that a general symbol will only have special values.

In spite, however, of the points to which we have called attention above we consider this algebra a useful one. The numerous examples afford the student ample resources for getting practically familiar with algebraic manipulation, and the conspicuous absence of set rules compels the work to be done thoughtfully rather than by rule of thumb. Factoring, that important branch of algebra is fully treated, though the same can hardly be said of radicals. The chapter on logarithms is well done, much better than is common, and to our mind is decidedly the best chapter in the book. The book is well printed and attractive in appearance in spite of the lines at the top of the page and is very free from typographical errors. We have only noticed one, p. 349, Ex. 20, where $10 should read $5.

ENCKE'S COMET.

This comet is now visible in telescopes of moderate power, and will increase in brightness until November, when it may be visible to the naked eye. Tbe corrections to the ephemeris, computed by Dr. Backlund, of the Pulkowa Observatory, are as follows:

$$\Delta\alpha = -39^s.0 \quad : \quad \Delta\delta = -1'.4$$

These corrections may vary a little as the comet approaches the earth, but it can be found without trouble. If we consider the great care and labor that have been given to the calculation of the ephemeris; and the fact that the perturbations by nearly all the principal planets have been computed, as well as the effect of the resisting medium in space, the corrections to the ephemeris seem to be very large. This comet affords another example of what is now most needed in Astronomy, viz., complete and careful theoretical investigations. It will be comparatively easy to obtain a great number of observations of this comet during its present return, while a much smaller number of good observations is sufficient. The attention of astronomers should be given rather to a satisfactory determination of the motion of the comet, since the recent computers of its orbit do not have the success of Encke in predicting its returns.

THE WARNER-ASTRONOMICAL PRIZES.

We recently explained, in an editorial, the conditions on which Mr. H. H. Warner consents to present to each of the discoverers of comets during the year 1881, the sum of two hundred dollars. We also stated that applicants for the prize for Comet *b*, 1881, were presenting their claims at the rate of sixty *per diem*.

We now learn by a communication from Mr. C. S. Whittemore, secretary to the Rochester Astronomical Society, that nearly 3000 letters were received claiming priority in the discovery of this comet, all of which have been examined. As a result of such examination, Professor Lewis Swift reports that "no conclusion can be reached that would be scientific and satisfactory." In other words, the claims of the 3000 applicants are ignored, and the prize of $200 for this, the most important of the three comets, so far discovered in 1881, is withdrawn.

We cannot refrain from expressing our dissatisfaction with this decision, and the methods employed in arriving at it, which we believe to be neither "scientific nor satisfactory."

Mr. Warner, in a letter to the public dated September 5th, states, that two of the conditions on which he consented to give a prize of $200 to the discoverer of every comet appearing in 1881, were as follows: That it should be "telescopic" and "unexpected." He now claims that "Comet *b* was neither telescopic nor unexpected." Under these circumstances if Mr. Warner had simply announced that Comet *b* did not come within the meaning of his advertised prize, his course would have been intelligible and satisfactory. But he himself has stated, that in spite of these disqualifying circumstances, he "was anxious, could the first discoverer be found, to make a special reward of $200." In other words, a decision was arrived at to waive the disqualifications, and to proceed as if they did not exist, and the same letter admits that Professor Lewis Swift "examined" the 3000 applications on their merits. Such being the case, when Professor Swift found that he was unable to arrive at a "scientific and satisfactory conclusion," he should (under the terms of the contract between Mr. Warner and the public), have instantly referred the matter to Professor Asaph Hall, of Washington, and the other gentleman named as referee.

Under these circumstances we consider that Mr. Warner is under the moral obligation of carrying out his contract in regard to this matter, and insisting on Professor Swift taking the proper steps to arrive at some decision. Probably the mere perusal of the 3000 letters would instantly reduce the number to some half dozen applicants, whose cases could be submitted to Professor Hall, who would probably decide upon their merits within a week.

The second point in Mr. Warner's letter to which we would draw attention, is that in which he states, that to mitigate his disappointment in not being able to trace the "first discoverer" of Comet *b*, he proposes as a balm to the claimants, and to encourage astronomical study, to offer a prize of $200 to the person who shall prepare the best essay on "COMETS: *Their Composition, Purpose and Effect upon the Earth.*"

The conditions are as follows:

"1st. The essay must be written in plain language, each term to be defined in brackets immediately following, and must not exceed 3000 words.

"2nd. Each essay must be signed with a *nom de plume*, and a sealed envelope must accompany the essay superscribed with the *nom de plume*, and containing the real name of the author.

"3rd. All the essays must be filed with Dr. Lewis Swift, Director of the Warner Observatory, Rochester, N. Y., by November 1, 1881, and he will submit them to the judges.

"I hope that this prize will produce valuable additions to popular astronomical literature."

We regret that Mr. Warner was not better advised when he arranged the title of the essay and named the conditions. By "*plain*" language we presume he calls for "simple" language, but we are unable to explain his desire that "each technical term shall be defined in brackets immediately following." For whose benefit is all this defining to be offered? Is it to aid Professor Swift and the judges? If to aid readers, when the essay is subsequently published, would not a simple glossary of the scientific terms used, added at the end, be more appropriate? If "*each* technical term is to be defined," we fear that a large percentage of the 3000 words permitted will be used for this purpose.

Again, would it not be a more creditable arrangement, that the essays be filed with some independent person, instead of Professor Swift, who is at least a beneficiary of Mr. Warner, and is both a competitor and the judge in these prize gifts? (We think Professor Swift awarded the first Warner prize for comets to himself.)

Lastly, we find that no names are given of those who are to be judges of the value of the prize essays. This omission is very important, and seems to raise a doubt whether any judges whose opinion is worthy of respect can be secured to connect themselves with a scheme proposed under such conditions. Again, what disposition is to be made of the essays received by Mr. Warner? nothing is guaranteed in this respect; and will Professor Swift once more announce to the essayists that "no conclusion can be reached which is scientific and satisfactory?"

We do not wish our remarks to be interpreted in a sense which implies that either Mr. Warner or Professor Swift are desirous of acting improperly in this matter, although their behaviour may, in some quarters, be severely criticised; we rather lean to the view that their judgment and discretion is at fault, and that they require the counsel of some friend who can so advise them, that they arrive at "conclusions which *are* scientific and satisfactory." Mr. Warner hopes that his prize "will produce valuable additions to popular astronomical literature;" we fear that under the conditions he offers, he will be inundated with vulgar scientific trash.

In conclusion, we offer Mr. Warner one word of advice. If he honestly desires to encourage real scientific work and literature, let him permit such men as Hall, Newcomb, Pickering, Young, Stone, Holder or Draper to arrange the title of his prize astronomical essay, and request them to name the conditions, and be the judges, of the merits of the papers submitted. The decision of any two of the gentlemen we have named would be satisfactory to those who are likely to be competitors, provided they acted independently, and untramelled by Mr. Warner or any of his Rochester friends.

HYPERMNESIA OR EXALTATIONS OF MEMORY.*

[Translated from the French by the Marchioness CLARA LANZA.]

Until now our pathological study has been confined to destructive forms of memory. We have seen the latter diminished, sometimes completely destroyed. There are however, precisely contrary cases, in which the apparently abolished memory comes to life again as it were, and faint recollections become intensely vivid. Is this exaltation of the memory (called technically hypermnesia) a morbid phenomena? It is at least certainly an anomaly. When we remark further that it is always connected with some organic disorder or bizarre condition, we cannot deny that it comes within our province to discuss it. There are other subjects, amnesia for instance, which are more instructive, but we should not neglect it for that reason. We will see therefore what there is to learn about *persistence of recollections*.

Hypermnesia is divided into two classes—general and partial.

General exaltation of memory is difficult to determine, because the degree of excitation is quite relative. The force of this faculty varying to a great extent in different individuals we cannot measure it by any common standard. The amnesia of one person may possibly be the hypermnesia of another. It is, if we may employ the word, a change of *tone* in the memory, such as occurs in every other form of psychological activity, thought, imagination or sensibility. Moreover, when we say that the excitation is general, it is nothing more than a probable induction. Inasmuch as the memory is subject to the condition of our consciousness, and as consciousness is only produced in the form of succession, all that we can affirm is, that in the course of a period more or less extended a mass of recollections spring up in every direction.

General exaltation seems to depend exclusively upon physiological causes, particularly the rapidity of cerebral circulation. It is therefore apparent very often, in cases of acute fever. It is also produced in insanity, ecstasy, and hypnotism, sometimes in hysteria and in the beginning of certain mental diseases.

Besides these purely mental pathological instances there are others of a more wonderful nature which depend probably upon the same cause. Numbers of persons who narrowly escaped drowning have stated, that in the moment when asphyxia began, they seemed to see all at once their entire life in all its details, even the most

* See *Les Maladies de la Mémoire* by Th. Ribot, Paris 1881.

trifling incidents appear distinctly before them. One person in particular, declared that he saw his whole existence rolled out in retrograde succession, not like a mere indistinct sketch, but in precise details, making a panorama of his life, in which every act was accompanied by a feeling of pleasure or pain.

An analogous circumstance relates to a man of remarkable intelligence who happened to cross a railroad track just as an express train approached. He had just time to throw himself lengthwise between the rails. As the train passed over him, the sense of his danger caused every incident in his life to suddenly rise before him in memory.

Even allowing for possible exaggerations, these facts reveal a hyper-activity of the memory, of which in a normal state we can form no idea.

I will quote one more instance, due to stupefaction from opium, and at the same time I will beg the reader to observe how well it confirmed the explanation of the mechanism of recollection given in another chapter.

"It seems to me," says DeQuincy in his celebrated *Confessions*, "that I have lived seventy years or a whole century in one night. The most trivial events of my youth, forgotten scenes belonging to my early years, were constantly brought before me. It cannot be said that I remembered them, for had they been mentioned to me while awake, I should not have been capable of recalling a single one of them as forming a part of my previous existence. But placed before me as they were in a dream, like so many intuitions, made up of the most vague circumstances and their accompanying sentiments, I recognized them instantly."

All these general excitations are transitory. They endure no longer than the causes which produce them. Does permanent hypermnesia exist? If the word can be accepted in this rather forced sense, it must be applied to those singular developments of the memory which are the continuation of some chance accident. In ancient authors we find many cases of this kind related. We have no reason to doubt them, for modern investigators, Romberg among others, have noted a wonderful and permanent development of the memory, following small-pox, etc. The mechanism of this transformation being impenetrable, we have, however, no reason to insist upon it.

Partial exaltations are by their very nature limited. The ordinary tone of the memory being maintained in its generality, everything beyond this can be easily ascertained. These forms of hypermnesia are the necessary co-relatives of partial amnesia.

In the production of partial hypermnesia there is nothing resembling a fixed law. It presents itself under the form of isolated facts, that is to say, it is the result of a series of conditions which escape us. Why is a certain group of cells forming a particular dynamic association put in motion sooner than another? We can give no reason, neither a physiological nor a psychological one. The only cases wherein we can affirm the appearance of a fixed law, are those of which we shall speak later, where several languages return successively to the memory.

Partial exaltations generally spring from morbid causes. But sometimes they occur in a healthy state. Here are two examples:

"A lady in the last stages of a chronic malady was taken from London into the country. Her little daughter, who was a baby, not yet able to speak, was brought with her, and after a short interview, was taken back to the city. A few days later the lady died. The child grew up without having any recollection of her mother. When she had attained maturity, however, she had occasion to see the room in which her mother died. Although she was ignorant of this fact, she trembled as she crossed the threshold. On being asked the cause of her emotion, she replied: 'I have a distinct impression of having been in this room before. There was a lady in bed here in this corner. She seemed to be very ill, and she bent over me, weeping.' "[1]

"A man endowed with a highly artistic temperament (observe this point) accompanied some friends to a castle somewhere in Sussex. He had no recollection of ever having been there before. On approaching the entrance he had a sudden vivid impression of having already seen it, and, with the remembrance of the door came also a recollection of people above and beneath the portico, together with some donkeys standing by. As this conviction grew upon him more and more, he questioned his mother, thinking she, perhaps, might be able to enlighten him. She told him that when he was about sixteen months old he had been in the neighborhood with a large party of people, that he had been carried in a basket upon a donkey to the castle and left down stairs with the servants and their donkeys while the other members of the party had installed themselves above the portico to eat their dinner."[2]

The mechanism of recollection in these two cases does not admit of any ambiguity. It is a revival, by contiguity, after a long interval. They present that which happens throughout every instant of life in a striking and uncommon form. In order to recover a lost recollection have not many of us returned to the spot where the idea arose, endeavored to place ourselves as nearly as possible in the same material situation and thus see the remembrance spring to life?

As to hypermnesia arising from a morbid cause I will give one example.

"At the age of four years, a child submitted to trefining in consequence of fracturing its cranium. When his health was quite restored he had no recollection of the accident or the operation. But at the age of fifteen, while suffering from delirious fever, he described the operation to his mother, mentioning the physicians and those present, the details of their dress, and other minute particulars, with the utmost exactitude. Up to this time he had never spoken of the matter nor had he heard any one mention it."[3]

The revival of languages completely forgotten deserves to be spoken of more at length. The instance reported by Coleridge is so hackneyed that I shall not repeat it. There are many others of the same kind which are to be found in the writings of Abercrombie, Hamilton and Carpenter. Anæsthetic sleep produced by chloroform or ether can produce the same effects as febrile excitation. "An old forester lived during his youth on the frontier of Poland, and spoke scarcely anything but Polish. Later he removed to German territories. His children testified that for thirty to forty years he had neither heard nor pronounced a single Polish word. During an anæsthetic sleep of about two hours this man spoke, prayed and sang fluently in Polish.[4]

A still more curious thing is the *regressive* recollection of several languages. Unfortunately, the authors who have mentioned this use the term and note the fact without properly interpreting either.

The most interesting case was observed by Dr. Rush, of Philadelphia. An Italian named Dr. Scandella, a man of remarkable learning, resided in America. He was a complete master of the Italian, English and French languages. He took the yellow fever, and died of it in New York. In the beginning of his illness he spoke nothing but English. After that only French, and on the day of his death, Italian—his native language.

The same writer speaks in rather confused terms of a woman who was subject to transitory attacks of acute mania. When first seized she always spoke very poor

[4] M. Duval. HYPNOTISME *dans le Nouveau dict de Médicine*, p. 144.

Italian. When at the height of her insanity—French. During the first period of recovery, German; and while convalescent, her mother tongue, English.

If we throw aside this regression as far as it deals with several languages and content ourselves with more simple cases, we find abundant and very precise instances. A Frenchman living in England, and speaking English perfectly, received a violent blow upon the head. During his entire illness, he was unable to say a word in any language except his native French.

There is nothing, however, more instructive than the following fact, related also by Dr. Rush: "A Lutheran clergyman, of German origin, living in America, had in his congregation a great number of Germans and Swedes, who, before dying, repeated prayers in their mother tongue. Most of these, he said, he was sure had not spoken a word of German or Swedish for fifty or sixty years."

Winslow has stated that numbers of Catholics, converted to Protestantism, have prayed strictly in accordance with the Roman ritual, during attacks of delirium preceding death

This revival of languages, lost forms and ceremonies, seems to me only to be interpreted by a particular case of the law of regression. In consequence of a morbid action, which generally precedes death, the most recent impressions of the memory are destroyed, and this annihilation descends gradually until it reaches the oldest acquisitions and impressions. They acquire a temporary activity, and are produced in consciousness for a certain period before being wiped out forever. Hypermnesia, then, is merely the result of negative conditions. Regression does not follow from a normal return to consciousness, but from the suppression of more intense and vivid conditions. It resembles a weak, faltering voice, which cannot make itself heard until the loud speech of others has ceased. Impressions, certain habits belonging to childhood or youth, suddenly return, not because they are pushed forward by some cause, but because there is no longer anything to cover them. Recollections of this kind, are, strictly speaking, only a march backwards towards certain conditions of existence which seemed to have disappeared forever, but which a final working of the memory, before entire dissolution, brings once more to the surface. I will abstain, however, from further reflections which these facts naturally suggest, reserving them more properly to moralists. It could be shown, for example, that certain religious frenzies, which have overtaken people upon their death-bed, are, to psychology, merely the necessary effect of a general breaking up, for which there is no remedy.

Independent of this confirmation of our regressive law, is the surprising persistence of these latent conditions of memory which we have called residuum. Were it not for these disorders of the memory we could form no idea of it, for consciousness reduced to itself can only affirm the conservation of those conditions which constitute life and a few others dependent upon the will, inasmuch as they have become fixed by habit.

Must we draw, then, the conclusion that nothing is ever lost in the memory? Must we infer that an impression once formed there is indestructible, and that at any moment it is likely to be revived? Several writers, Maury particularly, have given striking examples to uphold this theory. However, there is no peremptory reason to deny that even without the existence of morbid causes, there are residuums which disappear. It is quite possible that certain cellular modifications and other dynamic associations are too unstable to last. In short we may say that the persistence agrees with a fixed rule, at least, in the majority of cases.

As to the manner in which these distant impressions are preserved and reproduced in memory, we do not know. I will tell you, however, how it can be conceived in the hypothesis which I have adopted throughout this work.

If we admit cellular modifications and dynamic associations to be the material substratum of recollection, there is no memory, however crowded with facts and impressions, which is unable to retain everything. For, if the cellular modifications are limited, the possible dynamic associations are innumerable. We may suppose that the old associations reappear when the new ones, being temporarily or effectually unorganized, leave the road free. The number of possible revivals being diminished the chances augment in proportion for the return of the most stable associations, that is to say, the oldest. I have no desire to insist upon a non-verifiable hypothesis. My aim is to keep closely within the bounds of certainty, and not wander off into doubtful paths.

It has been found impossible to place under the category of any of the preceding morbid types, a certain illusion of a peculiar nature, which occurs rarely, or rather, is seldom observed. There have only been three or four cases mentioned, and up to the present time no special term has been used to designate it. Wigan has called it very improperly, double consciousness. Sander, an illusion of the memory (*Errinnerungs-tauchung*). Other writers have termed it false memory. This latter name seems to me the most preferable. The condition consists in the belief that an entirely new state has been experienced before, so that, when it is produced in reality, for the first time, it seems to be a repetition.

Wigan, in his well known work upon the duality of the mind, says that while present at the funeral service of the Princess Charlotte in Windsor Chapel, he suddenly experienced the impression of having witnessed precisely the same spectacle sometime previous. The illusion was, however, but transitory. Many others of a more lasting nature have been recorded. Lewes associates the phenomenon with some which are more common. When we are in a strange country, for instance, it frequently happens that a sudden turn in a path or river brings us face to face with a view which we are certain we have contemplated before. Sometimes, on being introduced to a stranger, we feel sure that we have already seen him. While reading, new thoughts will often present themselves to the mind as being familiar[6].

This illusion, I think, can be easily explained. The impression received, evokes in our past, similar or analogous impressions, vague, confused and hardly perceptible, but nevertheless sufficiently defined to make us think the new condition is only a repetition of a former one. There is a basis of resemblance rapidly felt between two conditions of consciousness, which causes one to be identified with the other. It is, of course, an error, but it is only a partial one, because there really exists in the past, something which resembles an identical former state.

If, however, this explanation suffices for simple instances, here are others which do not admit of it.

A sick man, says Sander, on being told of the death of an acquaintance, was seized with an access of ungovernable terror because he thought he had already experienced the impression at some former time. "It seemed to me," he said afterwards, "that I was in the same bed on another occasion and X came to me, saying 'Müller is dead.' I answered, "he died long ago. How can he die twice?" "[7]

Dr. Arnold Pick reports the most complete case of false memory that I know of. It assumed the form of a chronic disorder. An educated man, of good reasoning powers, was suddenly attacked—about the age of thirty-two—with a most peculiar mental affection. If he was at an entertainment of any sort, or paying a visit, the

6 Lewes, See *Problems of Life and Mind*, 3d series.

7 Sander, *Archiv für Psychiatrie*, 1873, IV.

event, with all its attendant circumstances, appeared so familiar to him that he was absolutely sure he had previously experienced the same impressions, surrounded by the same people or objects, with the same sky, weather, etc. If he ventured to undertake a new occupation of any kind whatever, he was certain he had done it before and under identical conditions. Sometimes the sensation would occur the same day, in the course of a few minutes or hours, sometimes it did not strike him until the day following, but it was always a distinct impression.

In this phenomenon of false memory, there is an anomaly of mental mechanism which escapes us, and which is difficult to comprehend in a healthy state. The person affected, no matter how acute an observer he might be, could only analyze the condition when he ceased to be deceived by it. From the examples given it would seem to me that the impression received is reproduced in the form of some image. To employ a physiological term, there is a repetition of the primative cerebral process. This is a very ordinary phenomenon. It occurs in every recollection which is not caused by the actual presence of the object. The only difficulty is to discover why this image which arises a minute, an hour or a day after the real condition, should appear to be a repetition of the latter. We may possibly admit that the mechanism of recollection acts in a distorted manner, for my part, however, the following explanation seems more explicit:

The image formed in this manner is very intense and partakes of the nature of an hallucination. It is, apparently, a reality, for nothing rectifies the illusion. Consequently, the real impression is forced back, as it were, and assumes the character of a recollection. It becomes realized in the past, erroneously if we consider the facts, objectively, properly, if we consider them subjectively. The hallucination, although very vivid, does not efface the actual impression, but as the latter is quite separate, and as the former is produced at a comparatively late period, the real occurrence appears to be a second experience. The hallucination assumes the place of the actual impression, it seems to be more recent, and this is really the case. Of course, to us who judge according to what we see externally, it is false to say that the impression was received twice. To the person afflicted, however, who determines solely as his consciousness may dictate, it is true that the impression was actually received twice.

To the support of this explanation, I would call attention to the fact that false memory is nearly always allied to some mental affection. The person mentioned by Pick suffered from a form of insanity. He was continually endeavoring to escape from people he supposed were his persecutors. Hallucinations in this instance would be perfectly natural. I do not, however, wish to assert that my theory is the only possible one. In regard to this isolated condition of false memory, much more numerous and concise observations than mine are probably required.

THE EXCAVATION OF THE GRAND CAÑON OF THE COLORADO RIVER.*

By Capt. C. E. Dutton, U. S. A. U. S. Geological Survey.

The Grand Cañon of the Colorado River is the longest, widest and deepest of the almost continuous chain of cañon valleys through which the upper half of that river flows. Its length is 218 miles, its width from 5 to 11 miles, and its depth from 4500 to 6000 feet. For convenience of discussion it may be arbitrarily divided into four divisions: 1st. The Kaibab division; 2d. The Kanab; 3d. The Uinkaret; 4th. The Sheavwits division. The upper or Kaibab division is the grandest, widest and most diversified, and a little deeper than the others

* Read before the A. A. A. S. Cincinnati, 1881.

The three others are simpler in form and much alike in their topographical features. Capt. Dutton first exhibited a view of the cañon in the Uinkaret division, showing its simplest and most typical form. It consists of an inner and an outer chasm, or a cañon within a cañon. The outer chasm is five to six miles wide, and is walled on either side with palisades 2000 feet high, of singularly noble and graceful profiles, which confront each other across a comparatively smooth plain. Within this plain is sunken the inner gorge, descending 3000 feet lower, and having a width a little greater than its depth. At the bottom of the inner gorge flows the Colorado River, a stream about as large as the Ohio between Pittsburg and Wheeling. The strata in which the chasm is cut are chiefly of carboniferous age. The summit of the outer cañon wall is very near the summit of that series. The chasm throughout the greater part of its extent cuts below the carboniferous and penetrates the Lower Silurian, and even the Archæan schists, revealing the fact that before the carboniferous was deposited the country had been extensively ravaged by an erosion which swept away heavy bodies of Silurian, and probably also of Devonian strata. The carboniferous now rests upon the beveled edges of the flexed older strata, and in many places rests upon the completely denuded Archæan.

The region adjoining the chasm and for 40 to 60 miles on either side is a nearly level platform presenting the summit beds of the carboniferous system patched over here and there with fading remnants of the Permian. The strata is very nearly, but not quite horizontal. There is a slight dip to the northward rarely exceeding one degree, but as the general course of the river is along the strike, the edges of the strata disclosed in the Cañon walls are to all appearances rigorously horizontal.

From 40 to 60 miles north of the river are found the principal masses of the later formations, including the Permian, Trias, Jurassic, Cretaceous and Lower Eocene. These form a series of terraces rising successively like the steps of a gigantic stairway as we move northward. Each formation is terminated southwardly by a great cliff and the strata are nearly horizontal, collectively they have been named the Southern Terraces of the High Plateaus. The latest formation which was deposited in this region was the Lower Eocene.

To the geologist it is obvious that the formations of the Terraces now terminated by gigantic cliffs once extended further out towards the southward and formerly covered regions from which they have been denuded. Captain Dutton is confident that all these terrace formations once reached entirely across the Grand Cañon platform in full volume, and that their ancient shore line is found in Central Arizona. The thickness of the strata thus denuded was a little more than 10,000 feet on an average, and the area from which they have been swept away is more than 13,000 square miles. It is through the heart of this denuded region that the course of the Grand Cañon is laid. The denudation began probably at an epoch not far from Middle Eocene time, since at that epoch took place the final emergence of the region from a marine condition (through the brackish water and lacustrine stages) to the condition of *terra firma*.

It is apparent that the cutting and development of the present Grand Cañon is only a closing episode of a long history of erosion, extending from Middle Eocene time down to the present. Before the river could begin its attack upon the summit beds of the carboniferous which now form the crests of its upper walls, it had to cut through more than 10,000 feet of superior strata. This would alone indicate that the beginning of the present cañon cannot date far back in Tertiary time, and Capt. Dutton thinks that the evidence points strongly to the conclusion that its excavation in the carboniferous began in Pliocene time. This evidence is cumulative and not direct, but is derived from a comparison of many groups

of facts which are too numerous and complex to be summarized very briefly. One group of facts bearing upon the question of age is found in the comparative study of the lateral drainage channels and their gradual extinction by the progressive development of the arid climate of the region which took place in Pliocene time. Nearly all the ancient tributaries of the Grand Cañon appear to have dried up at the beginning of its excavation or very soon after, and the whole work shows the influences upon arid climate.

The Grand Cañon district has also been subject to a great amount of uplifting, amounting in the aggregate according to locality, to 16,000 to 19,000 feet. The present elevation of its surface above the sea is the difference between the amount of uplift and the thickness of strata removed, and is from 7,000 to 9,000 feet. This great elevation is considerably surpassed in some other portions of the West. Obviously, it has been an important factor or essential condition in the process of cañon cutting.

The peculiar forms of the drainage channels of the Plateau country, and of which the chasms of the Colorado are extreme developments, are ascribed to the operation of two groups of processes acting under abnormal conditions. It is customary to say that the rivers have cut their cañons. This is but a partial truth, for the rivers cut passages no wider than their water surfaces. The first group of processes is termed corrasion, the result of which is the continuous sinking of the bed of the stream by the grinding action of flowing water charged with sand. Many factors enter into this result, and their mutual relations are highly complex. But in a general way it may be said that a river with a rapid descent, carrying a notable quantity of sediment, but not enough to overload it or overtax its transporting power, will continuously corrade or grind down and deepen its channel. If it is overloaded, a portion of its sediment will be deposited and form a protective covering to the bed-rock. Under special conditions it will actually build up its bed. Most rivers, along their middle and lower courses have their general conditions so adjusted that there is little or no tendency either to build up or corrade. To this equilibrium of adjustment all rivers are tending, and most rivers have nearly or quite reached it. The Colorado is exceptional in this respect, and its tendency is to corrade. Its waters, though carrying great quantities of sediment, are still under-loaded, and could carry more if they could get it. This tendency to corrade may be ascribed to the fact that the country through which it flows has been gradually rising in altitude through Tertiary and probably also Quaternary time, and this elevation produces and maintains a rapid declivity in the stream-bed, which in turn imparts a high velocity, and consequently great transporting power to its waters.

The widening of the cuts made by corrasion is the work of the second group of processes, viz., weathering. This is also a very complex action, and cannot be briefly summarized. To this action is due the remarkable sculpture of the cañon and cliff walls and all those surprising resemblances to architectural forms which are so abundantly displayed in the Plateau country, and most especially in the Grand Cañon.

The concluding portion of Captain Dutton's lecture was devoted to a description of the scenery in the Kaibab division of the cañon, which is declared by all who have seen it to be the most sublime and impressive spectacle in the world.

New Observatory.—A meteorological station is to be erected at Pavia, under the direction of Professor Cantoni. Investigations will be made at this station on the influence of heat, light, electricity, etc., on vegetation in general, and some cultivations in particular, and also the diurnal and annual variations of terrestrial magnetism.

MIXED SUGARS.*

By Professor H. W. Wiley.

Mixed sugars are made of cane sugar and *amylose* (starch sugar.) Within a few years the mixed sugar industry has advanced from a small beginning to a business of considerable importance. It is difficult to get accurate data of the amounts of this sugar made. Manufacturers and dealers are extremely reticent on the whole subject, and often refuse to talk about it at all. I have, however, after considerable trouble, been able to get at the figures which will give at least an approximate estimate.

The principle centers of the grape sugar industry are Brooklyn and New York, Buffalo and Peoria. From a careful comparison of the data which I have been able to collect, I place the daily product of mixed sugars at the several factories at 1,500 barrels. This will be found not far from the truth. It is rather under than over the true number. It is thus seen that the mixing of sugars is a fact which is altogether too large to be laughed at. It must be remembered, too, that the manufacture is rapidly increasing, and is only limited now by the quantity of dry white amylose that can be made.

Amylose costs 3½ to 4 cents a pound by wholesale. Uuntil the price of corn became so high it was half a cent less than this. It is, therefore, a very profitable business to mix it with cane sugar and sell the whole for the same price which the cane sugar would fetch alone. I have here on the table specimens of these mixed sugars. Here are eleven samples made by the Manhattan Refinery, of New York, also six samples from the Atlantic Refinery, of Buffalo, and six samples from Henry Hobart, of New York. These sugars are sold retail under various names. Of these I may mention "New Process Sugar," "Niagara A B C," "Harlem B," "Excelsior C." and various others. To the eye these sugars look very much like straight cane sugars, and are generally pure and wholesome. They differ from the pure cane sugars in being less soluble in water and in being less sweet to the taste.

It has been estimated that amylose is two and a half times less sweet than sucrose ; but this depends largely on the method of manufacture. Some samples of amylose will be found quite sweet, while others impart even a bitter taste.

In the manufacture of mixed sugars it is highly important that the amylose be dry. If hydrated amylose be used it is found almost impossible to pulverize it, and when ground it is pasty and sticky. Machines have been patented for obtaining finely granulated amylose from the well dried specimens. It is quite impracticable, however, to obtain amylose entirely dry, and it is capable of being worked very well when it still contains 8 to 10 per cent of water. This water is put in when sold at the same price as pure sucrose. In a commercial sense it is, therefore, not a disadvantage. The amylose which is used in mixing is generally made by high conversion under pressure. It, therefore, contains a high percentage of glucose, (dextrose) as compared with the maltose and dextrine present. It is, therefore, less sweet to the taste than the liquid amylose, where the percentage of maltose is larger.

Many schemes for the estimation of the different constituents of a mixed sugar have been proposed. For a discussion of the methods of analysis by reduction and fermentation, I refer to my paper read before this section last Saturday. I will content myself here with a brief outline of the method which I have employed. The water is estimated by heating two or three grammes in a flat platinum dish to 150° C. for two hours. The percentage of cane sugar I determine by Clerget's method. First get the total rotation in the polariscope then invert

* Read before the A. A. A. S., Cincinnati, 1881.

by heating to 68°, then polarizing again, carefully noting the temperature. From these readings the percentage of cane sugar present is calculated from the following formula:

$$x = \frac{a - a'}{144 - \frac{t}{2}}$$

Here a=first reading of polariscope.
a'=second reading of polariscope.
t=temperature of observation.
x=percentage cane sugar required.

In connection with the polariscope readings I also made reductions both before and after inversion, and thus obtained valuable data in regard to the nature of the amylose present, as well as securing a check on the optical results.

Following is a scheme of an analysis which will illustrate the method of procedure:

Reduction. Took 10 g. in 1000 c.c. Of this, to reduce 10 c.c. Fehling's Solution, took 27.8 c.c.

Then 1000 : 27.8 = x : .05 (.05 g = sugar corresponding to 10 c.c. copper solution.)

Whence x = 1.8 g. = 18 per cent reducing matter.

Polarization. 26.048 g. in 100 c.c. gave........ 97°.8+
After inversion at 21° " .... 2°.6—

Difference, = ... 100°.4

$$100^\circ.4 \div 144 - \frac{21}{2} = 75.2 = \text{per cent sucrose.}$$

Reduction after inversion.
For 10 c.c. copper solution took 5.35 c.c.
Then 1000 : 5.35 = x : .05.

x = 9.35 g. = ...	93.50	per cent.
Deduct 18 per cent due to amylose = ..	75.50	"
Due to invert sugar....................		"
Sucrose by polariscope................	75.2	"
Amylose, water and ash by difference...	24.8	"

Following are the results of twelve examinations of mixed sugar:

No.	Per cent Reducing Matter.	Per cent Sucrose by Polariscope.	Amylose, Water, Ash, etc., by difference.
1	*29.70	*71.4	28.6
2	24.6	64.35	35.65
3	25.64	68.2	31.80
4	25.00	64.72	35.28
5	22.52	66.80	33.20
6	24.4	60.34	39.66
7	26.88	60.7	39.30
8	25.00	68.6	31.40
9	30.5	59.9	40.10
10	25.8	71.6	28.40
11	26.6	61.0	39.00
12	18.0	75.4	24.60

The analysis of mixed sugars is at this time a matter of great public interest. It is important that the public be not defrauded by purchasing sugars under false names. It is true that the manufacturers, as far as I know, do not sell the mixed sugars as *straight*, but when they pass into the hands of the retail dealers they are usually disposed of as if they were genuine. I do not anticipate that mixed sugars will jeopardize the public health. When well made they are certainly palatable and harmless. For boiling with fruits, etc., as in making preserves, they are quite as efficient as cane sugars. Nevertheless a "mixed sugar" should be bought, sold, and consumed as a mixed sugar, and thus all "winking" at fraud be prevented.

* One of these numbers is evidently incorrect. On looking over my notes I cannot find the mistake, and I have no more of the sugar with which to repeat the analysis. I think the error is in the per cent of reducing matter.—H. W. W.

COAL DUST AS AN ELEMENT OF DANGER IN MINING; SHOWN BY THE LATE EXPLOSION IN THE ALBION MINES IN NOVA SCOTIA.*

By H. C. Hovey.

My object, in this communication, is to lay before the public by permission of Mr. Edward Gilpin, Inspector of Mines for Nova Scotia, the results of his investigations into the part played by coal dust in spreading and augmenting the terrible explosion that took place in the Albion mines, near Stellarton, on the East river, N. S., on the 12th of November, 1880.

Explosions are frequent in the coal mines of England and Belgium, causing loss of many lives and the destruction of much property. But in our own country, as a rule, we are fortunately exempt from such calamities. On the other side of the Atlantic there are special causes leading to these explosions; the thinness of the seams, the depth of the workings, the gaseous nature of the coals most prized for their coke and illuminating power, all combining to render difficult the great problem of producing ventilating currents sufficiently powerful and searching to insure the safety of the workmen.

Within the last few years men of scientific and practical knowledge have studied into these disasters and their causes, hoping that some remedy might be found that could remove the dreadful uncertainty hanging over the lives of those who help to sustain the fabric of modern civilisation. It was discovered by a rigid inspection of all available accounts of explosions, that many of them had occurred in pits known to be, as a rule, not dangerous from explosive gas, or declared to be free from it shortly before the moment of the accident. Then the fact gradually became apparent that a seemingly innocuous constituent of the mines, namely, *coal dust*, played an important part in spreading and augmenting the blasts. It was as if the wadding of a gun was composed of an inflammable material which, on ignition of the charge, doubled its effect.

It is well-known that chemical action is often induced in heaps of slack, such as exist in thick coal workings, and that the heat evolved may be enough to cause ignition. The danger is increased when the broken coal is comminuted, and floats in the air, as in this form, under various conditions, it may undergo rapid oxidation. Galloway's experiments show that when the particles of dust are so fine as to pass through the gauze shield of a safety lamp, an explosion may be caused by their ignition. Bauerman states that, in the Franco-Belgian collieries, "several fatal explosions have been traced to the firing of coal dust from the flame of a shot, even in cases where no fire-damp was present in the workings."

A brief glance at the history of the Albion Mines will not be misplaced. The main seam, which has been continuously worked since 1807, attains the remarkable thickness of 37 feet 6 inches, and is a highly bituminous coal, well adapted for gas and coke-making. It contains several layers of iron stone up to one foot in thickness, but may be considered as an unbroken mass of coal.

The earliest workings, now known as "the Burnt Mines," furnished large quantities of coal, until they were abandoned in 1839 on account of fire, which blazed so fiercely from the shafts that the chains used in raising the coal tubs, were melted. A new opening, the Bye Pit, was worked till 1863, when a fire occurred from a shot lighting gas. This was extinguished; but a short time after the gas ignited at the boilers, which were within a few yards of the top of the pit, and the works had to be closed up. The Foster Pit was next opened, but in 1869 spontaneous combustion caused a fire, which necessitated its abandonment before it was fairly under way.

* Read before the A. A. A. S., Cincinnati, 1881.

At length the Foord Pit was won out, and, with its great pumps and engines, formed one of the finest coal-mining establishments in America. The ventilation was effected by a large Guibal fan, similar to those used in the Pennsylvania Mines, and capable of circulating 120,000 cubic feet of air per minute through the ramifications of the mine. The workings of the Foord Pit, which is nearly 1,000 feet deep, extend about 1,800 yards to the north, and 1,700 yards to the south, having an average breadth of 350 yards. The galleries varied in height from 9 to 15 feet, being driven in the upper part of the seam, the lower part being left for later operations. The ventilation through the south side was maintained at the average rate of 25,000 cubic feet per minute. Shortly before the accident referred to, I went entirely through the colliery, in company with Mr. Gilpin and the overman, and we remarked the perfection of the ventilation, and the consequent absence of deleterious gases, even in the remotest bords.

On the morning of the disaster the night watchmen reported the mine to be free from gas, except in small and harmless quantities. From what source, then, originated the series of explosions that began within an hour from the time this report of entire safety was made, and continued at intervals until the mine became a furnace, whose flames could be subdued only by emptying into its burning chambers the waters of the adjacent river? Was there some sudden exudation of gas from the solid coal, or was this explosion due to the firing of coal dust from a safety-lamp or the flame of a blast?

None of the forty-four men who witnessed the beginning of the catastrophe escaped to tell the story or explain the mystery, and those rescued from more distant galleries had but conjectures to offer. The workmen on receiving the assurance that the mine was free from gas, received their orders, descended the drawing shaft, received their safety-lamps at the lamp cabin and a part of them went into the north side workings and the rest went into the south side dips and waited for their tools to be sent in for distribution. At this moment the explosion took place that was first noticed at the fan-shaft, where it blew the cover of the fan-drift off, and about one minute later it was apparent at the drawing shaft, having traveled in the one case *with* and in the other *against* the ventilating current.

The only additional facts definitely ascertained were gathered by an exploring part led by Mr. Gilpin, who, shortly after the original explosion and at the risk of life, descended into the pit and penetrated as far as the after-damp would allow them to go. The locality where the unfortunate workmen whom they tried to save were known to be was 1,200 yards south of the shaft; and the point reached by the party was only about 600 yards in that direction.

It was evident that the flame of the explosion had not reached as far as this, for there were no marks of fire on the dead bodies of men and horses found, nor was the splintered wood-work charred. They carried two corpses to the surface for examination, and it was found that one of these died of the after-damp, and the other from being dashed against some timber.

The walls of the galleries had been swept clear of timber, and presented the appearance of having been brushed with a broom. This was due to the passage of great volumes of dust which lay on the floor of the level in waves and drifts, into which the party often sank up to their knees. A similar effect was visible in the mine level, but not to so great a degree; as it was damper about the floor, and from the effects observed it would appear that, while the explosion passed along each level simultaneously, it had greater power in the lower one, as the doors were blown toward the upper, or main level. Clouds of the finer particles were carried up the shaft, and were swept on into the North-side levels.

At the lamp-cabin, where the safety lamps were cleaned and given to the men after being examined by the shot-firers, an open light had been kept burning for years, as it was considered a safe place, being within a few feet of the bottom of the shaft. But here a *secondary* explosion took place, demolishing the cabin, burning the horses between the shaft and the cabin, and fatally injuring the lamp-man by igniting his oil-soaked clothing, so that he died in a few days. The effect of the explosion did not extend far into the north side, and some of the men there were ignorant of the disaster until warned by the over-man to leave the pit.

Secondary explosions caused by extracted, or generated gas, are nearly always in the vicinity of the primary one; but here is a case where the second was half a mile from the first, with an intervening space of at least a quarter of a mile known to be free from gas, because men were in it with lamps which showed no indications of its presence.

The ignition of these volumes of dust would, no doubt, have done serious injury to the shafting, had not the latter been wet and indeed saturated with water oozing under pressure through the upper strata into the shaft, and then falling to the bottom; so that, although elsewhere the mine was a very dry one, it was here in such a condition that the flame would be extinguished as soon as it touched the damp walls. The necessity of watering dusty mines has been pointed out by Inspector Gilpin, and this is said to be practised in some of the Belgian collieries. The present instance shows that such a precaution would tend to reduce the range of the explosion of the dust.

Attempts were made to restore the ventilation of the workings in the Albion Mines, when the presence of a large fire was discovered, and this made it necessary to flood the galleries. In about 48 hours after the explosion, a trench had been cut through to East River, and the water was let in at the rate of 15,000 gallons per minute, until, within a week, all the workings were filled. This, of course, made further investigations impossible, and nothing will be known beyond what has here been told.

The subject is one of acknowledged importance. There have been frequent explosions in flouring mills, said to be attributable to the ignition of flour dust. At a late meeting of the Manchester Geological Society, (in England), experiments were made to show that even finely powdered slate will spread the flame of gas explosions. Since the preparation of the present paper, a report has been made before the royal commission on accidents in mines, by Mr. F. A. Abel, Chemist to the British War Department, in which it is claimed, as demonstrated, that coal-dust is not only a fiercely burning agent, but when suspended in air currents may operate as an exploding agent. It operates, aside from its inflammability, as a finely divided solid, in "determining the ignition of only small proportions of fire-damp and air, and consequently in developing explosive effects," *i. e.*, under circumstances which, in the absence of the dust, would be attended by no danger.

HISTORY OF ALHAZEN'S PROBLEM.

Abstract of a paper read before the American Association for the Advancement of Science, Cincinnati, August, 1881, by MARCUS BAKER, U. S. COAST AND GEODETIC SURVEY, Washington, D. C.

Alhazen's problem is an optical one and was thus stated by the Arabian Alhazen for whom the problem is named. "*Given a luminous point and a point of vision unequally distant from the center of a convex spherical mirror, determine the point of reflexion.*" The solution of this problem involves the solution of the following geometrical problem now generally known among mathematicians as Alhazen's problem. *From two given points in the plane of a given circle draw lines meeting in the circumference and making equal angles with the tangent drawn at that point.*

This problem was first solved by Alhazen, a learned Arabian of the 11th century, and published at Basle, in Latin, in 1572. Since that time it has been studied by several distinguished mathematicians and a variety of solutions given. The paper presented contained a collection of these solutions aiming to be complete. Eleven solutions were contained in this collection, beginning with Alhazen and ending with a solution by E. B. Seitz, in 1881.

The first five solutions are by geometrical constructions, in which the points sought are determined by the intersections of a circle and hyperbola. The sixth solution, also a geometrical construction, is by means of the intersection of a circle and parabola. The seventh, eighth, ninth and eleventh solutions are by analytical or algebraical methods, while the tenth is a trigonometrical solution.

Among the people who have studied and solved the problem are Alhazen, Barrow, Hutton, Huyghens, Kaestner, Leybourn, L'Hospital, Robins, Seitz, Sluse and Wales. A complete list of bibliographical references was appended to the paper.

The paper contained further, an extension of the problem, *first*, to the surface of a sphere, and *second*, to an ellipse. The first case was illustrated by the following practical example:

The great circle track between San Francisco, Cal., and Yokohama, Japan, reaches nearly to latitude 52° N. The Pacific mail steamers plying between these ports usually avoid going north of latitude 45° N. Now, if the 45th parallel of latitude be designated as one north of which the steamer is not to go, in what longitude must this parallel be reached in order that the steamers' path between the ports shall be the shortest possible? The extension of Alhazen's problem to the surface of the sphere solves this problem and the longitude required is 168° W. from Greenwich.

The extension of the problem to the case in which an ellipse replaces the circle gives rise to a very complex equation of no special value.

WASHINGTON, D. C., Sept. 13, 1881.

ROTATION OF REDUCING POWER, AS MEASURED BY FEHLING'S SOLUTION TO THE ROTATORY POWER OF COMMERCIAL AMYLOSE (GLUCOSE AND GRAPE SUGAR).

SECOND PAPER.*

BY PROF. H. W. WILEY, Lafayette, Ind.

In a paper read at the Boston meeting of this Association[1] I called attention to the fact that the reducing power of Amylose, measured by Fehling's Sol., could be readily determined by the polariscope. Since that time I have extended the series of observation then reported, and with such results as justify the conclusions at which I arrived.

In commercial Amyloses, whose specific gravities do not vary much from 1.410, the reducing power is reliably calculated from the reading of the polariscope. The average percentage of water in these Amyloses is nearly thirteen. If we allow one per cent for optically inactive substances present, we may safely place the optically active matter at 86 per cent. By prolonged boiling with acids, even if they be quite concentrated, only about 82 per cent of reducing matter is obtained.[2] Further boiling causes the mass to turn brown, and may even cause a decrease in the amount of reducing matter found. Since there is so much difference of opinion respecting the reliability of Fehling's solution, and since there is no other reducing mixture that works as well, it would, perhaps, be better to use the polariscope for the determination of the amount of substances present in an Amylose capable of reducing the various solutions used for grape sugar measurements.

In the following table the calculation of the reducing power was made by the formulæ,[3] which I have already explained. Although, in a few cases, the specific gravity varied by a few thousandths from 1.410, the difference has not been of sufficient importance to make any correction[4].

Since the ordinary Amyloses, called grape sugars, of commerce differ from those called glucoses only in having the processes of conversion carried further, it is found that the same rule applies to them also. In fact, I believe it will be found true with all varieties of Amylose made by use of sulphuric acid, provided 8.6 grammes of the anhydrous substance be used in each 100 c.c. of the mixture to be examined.

Following are the results of my observations:

TABLE I.

The above analyses were of samples sent by the manufacturers, the Peoria Grape Sugar Company. They represent the whole number of samples examined and in the order in which the analyses were made. Seventeen of them were of syrups, and the eighteenth of a solid sugar. Only four out of the eighteen show discordant results. In one of these the specific gravity was not determined. It was my intention to make these four analyses in duplicate, but a press of other business prevented. In general, it appears that the results given by the polariscope, by the above method of calculation, are a little too high. If they were diminished by 5 the agreement would be better. That the reducing power of Amylose can be correctly calculated from its rotatory power is certainly established from the thirty-eight unselected instances which have been presented.

ELECTRIC LIGHT FOR LIGHTHOUSES.—The first of the series of lighthouses round the French coast which are to be henceforth illuminated by electricity, has, with all its necessary machinery, been completed. It is called the "Phare de Planier," and is situated at the mouth of the Rhone, near Marseilles.

ON THE INTERIOR CONDITION OF THE TERRESTRIAL GLOBE.

By M. E. Roche.

Generally we admit that the earth is entirely fluid in its interior, with the exception of a thin crust, and most of the mathematical studies on the figure and the constitution of the earth assume this fluidity. Thus by attributing to this fluid a certain law of compression, Laplace has deduced a corresponding law of densities, which Legendre had already examined before him, and which permits the calculation of the flattening of the different surfaces *de niveau* of the terrestrial mass. I have myself proposed another law of compressibility, which conducts to a very simple formula for the increment of the density. The conditions which every hypothesis must satisfy, on the distribution of the mass in the interior of the earth, are that it must accord with the value of the superficial flattening, and also with a certain constant depending on the phenomenon of precession. These conditions are very approximately satisfied in the hypothesis of fluidity, if we admit that the terrestrial flattening is nearly $\frac{1}{300}$; but if this flattening is greater than $\frac{1}{295}$, as it seems to result from the most recent determinations, the agreement no longer exists.

There is need, therefore, of a new examination of these researches under a different hypothesis, for example, in considering the globe as formed of a nucleus or solid mass very nearly homogeneous, covered with a lighter shell whose density, from geological considerations, can be estimated as 3 with respect to water. This constitution of the globe being supposed, I find that it is possible to conciliate the actual values of the precession and of the flattening, if we take account of this, that the interior nucleus of the globe solidified and has taken its definitive form under the influence of a rotation less rapid than that with which the earth is now animated.

In every case the contraction due to this cooling of the globe must lead to a progressive acceleration of its angular velocity. But if this globe is fluid the figure of the different strata adapts itself continually to the rotation which has place at each instant, in such a way that finally there remains no trace of the successive variations which their flattening have undergone since the origin. If, on the contrary, at a certain epoch of the cooling the interior strata have passed to a solid state, these strata have taken and preserved a flattening very different from that which would be attributed to them by the general equation of hydrostatics applied to a mass entirely fluid and possessing a rotation common to all its parts. The formulæ calculated in the hypothesis of a solid nucleus contains at the same time the constant q, the actual ratio of the centrifugal force to the equatorial gravity, and value q_0, of the same ratio at the epoch of the solidification of the central mass. This last element, not being determined, we can give to it a value such that the superficial flattening accords with the coefficient of precession. It is necessary for this to suppose q_0 less than q, whence it results that the terrestrial rotation has undergone an acceleration since the consolidation of the interior nucleus.

The physical and astronomical conditions of the problem permit also the determination, with some precision, of the dimensions and specific weight of this central mass. If we leave out of consideration the crust purely superficial, as also a slight condensation towards the centre where the heavier materials would be collected, the constitution of the globe will be as follows: a nucleus, of which the density is nearly 7, covered with a shell of density 3, whose thickness does not attain one-sixth of the entire radius.

The central terrestrial mass is therefore in specific weight analogous to meteoric iron, while the stratum that envelops it is comparable to aerolites of a stony nature, where iron enters only in a small proportion.

BOOKS RECEIVED.

The Microscope and its relation to Medicine and Pharmacy. Edited by Chas. H. Stowell, M. D., and Louisa Reed Stowell. Published monthly. Ann Arbor, Michigan, 1881.

There are already two journals published monthly which are devoted to microscopy, it is therefore with some surprise that we find a third journal of the same description appealing to the patronage of Microscopists.

"*The Microscope*" claims to supply a want in offering physicians a journal which treats exclusively of Medical and Pharmaceutical Microscopy, thus differing from the two former microscopical journals which cover the whole field of Microscopy.

We believe that the success of "*The Microscope*" will depend upon that journal being conducted strictly within the limits of its own programme. Undoubtedly the majority of American microscopists are members of the medical profession and, therefore, "*The Microscope*" may look for a numerous constituency.

"*The Microscope*" has been produced in an excellent form, is well printed, and illustrated with good illustrations, and if the editors will confine the columns to *Microscopy*, to the exclusion of facetious "items" clipped from their exchanges, they may hope to place their journal on a firm basis.

CORRESPONDENCE.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. No notice is taken of anonymous communications.*]

To the Editor of "Science."

Permit me to suggest a few questions that should be answered by the author of "The Great Primordial Force." (See "Science," p. 405.)

Let me introduce my questions by announcing my *belief* in the conservation of energy and in the unity of force and by expressing a *hope* that the time will come when the phenomena peculiar to the different *manifestations* of force may be comprehended and their identity demonstrated.

The following questions are respectfully suggested:

1. When, and by whom, has it been demonstrated that gravitation is resolvable into light or heat?

2. If all force "is substance," or matter, (see "Science," p. 405, last paragraph), then, at least some matter is force. What then is the distinction between matter and force?

3. On p. 406, it is asserted that the two elements, "*Motion* and *Magnetism*," "develop all known forces of the universe." How can motion exist without a *prior* force, and what *is* magnetism?

4. What produces the revolution of the revolving celestial armatures?

The foregoing questions may be sufficient for the present, but it is due to science that statements claiming to be scientific should be *truths*. Let us examine some of the author's statements.

It is asserted that "if gravity acts inversely as the square of the distance, then the earth at aphelion could not, without the aid of some other force, return to perihelion." It is to be feared that the author of the above question is not aware that the inertia of matter is an experimental fact, and is entirely sufficient to bring back the planet from aphelion to perihelion.

As to the law of inertia, all matter, if not acted upon by some external force, will continue in its present state, whether of motion or rest, and because while a planet is passing from perihelion to aphelion the tangent to its orbit makes an obtuse angle with its radius vector; therefore its inertia counteracts, and to a certain extent,

opposes its centripetal force, from perihelion to aphelion, and because at aphelion, the tangent of its orbit, is at right angles with its radius vector, and from aphelion to perihelion the angle between the tangent and radius vector is acute, therefore, the inertia of the planet co-operates with the centrifugal force from aphelion to perihelion.

Hence, *inertia*, in conjunction with the centripetal force, is sufficient in all cases of elliptic motion, to bring back the planet from aphelion to perihelion.

Again, the writer says, (p. 407) "the degree of ellipticity of each planetary orbit is due to the inclination of its axis." That the reader may judge how much weight should be allowed the author's statement, let this statement be compared with known facts.

The eccentricity of the earth's orbit is .0167922; that of Venus is .0068618. The inclination of the earth's axis is about 23½°; that of Venus 75°. That is, the inclination of the earth's axis to its orbit is less than one-third that of Venus; whereas, the eccentricity of the earth's orbit is more than twice that of Venus.

The author's statement, therefore, is not only not supported by the facts, but is in conflict with the facts.

J. E. HENDRICKS.

DES MOINES, Sept. 3, 1881.

To the Editor of "SCIENCE":—

The prevailing scientific ideas of any period are regarded by the common people, and even by the scientists of that period as indubitable facts, without due examination of their origin or their foundation. But further thought and observation often compel a reluctant retreat therefrom. Thus present conceptions have all the weight of perfect truth. We call them "*facts.*"

The rapid discoveries of the present age, and the unprecedented freedom of thought are disturbing all theories that are not well founded. The new law of Conservation of Force will cause the final destruction of every theory that is not in harmony with it. The paper upon the "Great Primordial Force" was but an effort to bring the explanation of the physical forces into consistency with that all-governing law.

That the paper should give rise to such questions as those proposed by our critic was most natural, and we shall endeavor to answer them in the same candid spirit in which they were asked.

1. Bodies fall by force of gravitation. Resistance to such fall of course produces light and heat, precisely as resistance to the motion of the electrical current produces the same. If we admit that the electrical current is convertible into these forms, by parity of reasoning, so is gravity.

2. The relations of matter and force seem adequately set forth in the paragraph referred to. (See "SCIENCE," p. 405.) Electricity, which in its tenuity pervades all matter, is abundantly demonstrated to be itself matter in varied form, as in the thunderbolt, the fire ball, and in the St. Elnios fire.

3 and 4. The only rational explanation, whether to us satisfactory or unsatisfactory, of the origin of force, is found in the hypothesis and admission of already existing force, the *primum mobile*. HELMHOLTZ says, that a body set in motion around the sun in vacuous space, and with a certain velocity will continue to move with the same velocity to all eternity. It is sufficient for us to know that the motion *is*, and the magnetism *is*, and thus we have the "celestial armatures" already in revolution, —the effects of which it is for us to observe. To us the effects are, and are called, the "physical forces."

Our critic is disturbed by our questioning of the dogma that "gravity acts inversely as the square of the distance," —on the ground that if that force is weakened by the earth's being removed to aphelion, it could not again bring back the body to perihelion. We re-affirm FARADAY'S position; "The received idea of gravity appears to me to ignore entirely the principle of the conservation of force, and by the terms of its definition, if taken in an absolute sense, 'varying inversely as the square of the distance' to be in direct opposition to it." But we would not rest the assertion upon any great name. It is evident that inertia can "bring back" nothing, that inertia, or momentum, or centrifugal force, or whatever other expression is used, may effect only motion in a straight line. Momentum, (which evidently is what the critic means by "inertia,") has no tendency towards circular motion. It is attraction, gravity, centripetal force alone that draws, or "brings back," and if that force is *weakened*, how can it make itself stronger? If once diminished (as the principle, "gravity acts inversely as the square of the distance" necessitates,) then the opposite force has the balance of power, has destroyed the equilibrium, and except some favoring force steps in to restore the lost ground, momentum, ("inertia") must forever send it farther and farther into space.

Finally, our critic in order to show that the electrical theory, which makes the inclination of a planet's axis to govern the ellipticity of its orbit, is not true to fact, adduces the instance of Venus. This asserted "*fact*" (?) that Venus' axis has an inclination of 75°, is wholly unfounded, Astronomers to-day are not so ready to assert it. The dazzling brilliancy of this planet prevents any positive disclosures as to the period of its daily revolution, to say nothing of the more delicate and difficult determination of the inclination of its axis.

Our distinguished astronomer NEWCOMB says:—The latest physical observations on Venus, with which I am acquainted are those of Dr. VOGEL, "Bothkamp Observations, 1873." The result to which these observations point is that the atmosphere of Venus is filled with clouds so dense that the solid portion of the planet cannot be seen, and no time of rotation can be determined." HERSCHEL said that he was never able to see any permanent markings on Venus,—but it is only by such markings that these determinations are made.

H. RAYMOND ROGERS, M. D.

DUNKIRK, N. Y.

MEDICAL CONGRESS NOTES.

(London, 1881.)

At the close of Professor Huxley's address, Mr. MacCormac followed with a statement, the most important items of which were that the number of members amounted to 3,210; that the sections had held 11 meetings, extending over 293 hours; that there had been delivered 464 written papers and 360 oral addresses. The attendance at the sections had been large, and had not shown signs of falling off even quite to the close. The museum was referred to as a great success, and the demonstrations of living patients had been attended by crowds each morning.

ENDORSING VIVISECTION.

Sir James Paget then presented the following resolution forwarded by Professor M. Foster, from the Physiological Section: "That this Congress records its conviction that experiments on living animals have proved of the utmost service to medicine in the past, and are indispensable for its future progress; that, accordingly, while strongly deprecating the infliction of unnecessary pain, it is of opinion that, in the interest of men and animals, it is not desirable to restrict competent persons in the performance of such experiments." Pointing out that it was impossible to discuss such a resolution then, the President asked those who were opposed to it to record their names and votes at the close of the meeting. The resolution was then adopted with loud cheers, and no hand was held up in opposition to it.

NOTES.

THE PLANTÉ AND FAURE BATTERIES.—Speaking of the relative merits of the two batteries, M. Faure says in a letter to "*The Electrician*," M. Planté has the merit of being clear in the exposition of his ideas and researches, and in his remarkable work, "Recherches sur l'Electricité," he tells us exactly how his battery is made, how it is "formed," and what it does when so made. Referring to this last point we read that a battery can furnish a constant current through fifty metres of copper wire one millimetre in diameter, say one ohm during one hour. Now, if we take the electromotive force at 2.20 volts we find for the work so given out $\frac{2.20^2}{1 \times 9.81} = .5$ kilogrammetres per second during one hour, or an absolute total of 1,800 kilogrammetres. And for the sake of comparison we may also say that the above battery would furnish a current of 2.2 webers for an hour. As Planté batteries may not be in the hands of everyone of your readers, and as I was fortunate enough to obtain an assorted supply before the scarcity set in, I will give a few figures which are the results of my experiments, and somewhat corroborate the above statements. The best cell that I could procure, and which had been nearly two years in formation at the makers in Paris, gave me, when properly charged, a current of twenty webers during five minutes. The two lead electrodes are each one millimetre in thickness and 65 millimetres long, by 20 centimetres deep. The amount of suboxide of lead which had been formed upon the positive electrode I found by drying and weighing to be 75 grammes. I will at once here make a comparison. In some of my round cells, having electrodes of the same size as the above, that is 65 x 20, I have placed upon the positive electrode 2,000 grammes of red lead (a similar quantity being also placed upon the *negative electrode*). The current which this arrangement furnished me was about equal to 20 webers during two hours and a half, or nearly proportionate to that furnished by the Planté battery, taking into account the relation $\frac{2000}{75}$ of lead oxide brought into action in both batteries. The least perfect of my Planté cells, which had been "formed" during three months only, gave me only about one-fourth of the above work. I state simply facts, but it is said that the above mentioned perfect Planté battery might have been made in three months instead of two years. Let it be so, and let us suppose that the Faure battery has no greater capacity of storage than three or four times that of some of the old Planté batteries in existence, still I beg to say that it exists, and is perfectly well covered by valid patents, and as such will be of great value to the electric industry. Upwards of twenty-five tons of Faure batteries have been made, and experiments on a commensurate scale carried out during a year of silence, and from trustworthy experimental work I have acquired the certitude that there are great things in it.

TESTS FOR COLOR-BLINDNESS.

A resolution received from the Ophthalmological Section, on the subject of the tests most applicable to be employed in working and observing signals by land or sea, where the lives of others are involved, was similarly carried unanimously, and the recommendations of the section ordered to be forwarded by the Hon. Secretary-General as the opinion of the Congress to the Foreign Secretary, the first Lord of the Admirality, and the President of the Board of Trade.

(Medical Congress, London, 1881.)

SATURDAY, OCTOBER 1, 1881.

TO OUR ENGLISH READERS.

We have received from Messrs. Deacon & Co., of 150 Leadenhall street, London, England, a standing order for a large supply of "Science," which will be forwarded weekly. We shall be obliged if our English readers will make this fact known to their friends.

The death of President James A. Garfield is regretted by the nation as a great national loss; but all friends of progress and those who desire to elevate the indifferent and ignorant to a higher grade of civilization, will mourn his sudden death as a calamity; for he was a living example of the wonderful power of education to raise a man from a humble position in society to a post of high honor and usefulness, developing powers which not only opened up a bright and brilliant career, but brought a peaceful and hopefnl serenity to his mind which was evident to all who enjoyed his society.

A NEW COMET.

Mr. E. E. Barnard, of Nashville, Tennessee, announced to the Smithsonian Institute, on the 21st instant, the discovery of a comet by him on the 20th, at two o'clock A. M., Washington mean time, in seven hours forty-six minutes right ascension, and thirteen degrees twenty-eight minutes north declension, with a daily motion of three degrees northeast.

On the 23d instant Professor Lewis Swift, of Rochester, made the following announcement in regard to this comet:

The position of Barnard's comet, as telegraphed from Washington, is so widely erroneous that nobody would be able to find it. Instead of being in cancer and having been discovered at two o'clock in the morning, it was near zeta virginis, low down in the Western horizon, and can be seen but a few minutes. It was discovered on the evening of the 19th, and at 7h. 46m., Washington mean time, of the 20th, was in right ascension 13h. 28m. 2s., declination north 3 deg. 47 min., with a daily motion of 3 degrees northeast.

In consequence of smoke I have not been able to find it.

We trust in our next issue to offer some explanation of these contradictory statements.

One of the most interesting and valuable reports that has been issued by the Board of Education at Washington, is that recently printed, which describes the opportunities for instruction in Chemistry and Physics which at present exists in the United States, together with statistical tables relating to this subject.*

The Department was fortunate in securing the services of Professor F. W. Clarke, Professor of Chemistry and Physics in the University of Cincinnati, to draw up this report, based on the mass of facts and figures bearing on this matter, which had been collected in reply to circulars issued by the Commissioner of Education towards the close of the year 1878. Professor Clarke appears to possess both executive and literary ability of a high order, and being himself a chemist and a teacher of science, was clearly in a position to do justice to the excellent intentions of Commissioner Eaton. We congratulate Professor Clarke on his success in compiling the technical part of his report, and we propose, on this occasion, to refer to some of his critical remarks aud suggestions, which, in scientific circles, will be considered the most valuable result of this investigation.

Before discussing the condition of scientific instruction in public schools, it may be well to consider first, at what age such instruction shall be commenced, and whether it should be considered as a part of primary education, or be reserved for high schools and universities, where special courses of training in the various branches can be advantageously advanced.

Professor Clarke claims that oral instruction in chemistry and physics can be made intelligible to children of ten years of age. He admits, however, that there is a tendency towards over-cramming the lower schools with a too great variety of subjects, which lead to results which are undesirable. He therefore suggests a compromise, and proposes, that in primary schools a taste for science should be cultivated among children "through the medium of the reading books, which might properly contain some short extracts relating to natural science." This plan Professor Clarke considers would be beneficial, and could not be injurious.

We can find no objection to such a course, provided a suitable reading book be written for the purpose, but before any discussion can be made as to the propriety of teaching the sciences in any form in the primary schools, a more thorough reform in the

*Circulars of Information of the Bureau of Education No. 6. 1881.

A report on the teaching of Chemistry and Physics in the United States, by Frank Wigglesworth Clarke, S. B., Professor of Chemistry and Physics in the University of Cincinnati. Washington, 1881.

whole system of public school education must be made. It appears superfluous to urge the teaching of science to children of ten years of age in public schools, where the elder scholars of fourteen and fifteen years are unable to read aloud intelligently or write an ordinary letter legibly. And yet, to our knowledge, such is the situation of too many of the scholars in our public schools in regard to these fundamental branches of education.

Professor Clarke's report shows that in high schools and academies the teaching of Chemistry and Physics varies between widely separated limits; in the majority of cases mere text book work is done, and only a few experiments performed by the teacher.

In our opinion the report offers excellent advice in regard to the teaching of Chemistry and Physics to such classes of students.

The following extract will explain Professor Clarke's views:

"That chemistry and physics are desirable branches to teach in schools of the grade now under discussion is pretty generally admitted, although a few educators still hold that such studies are fit only for technological institutes and colleges. But the greater number of pupils cannot go out into these higher grades, and must therefore either study the sciences now or do without them altogether. The latter alternative is clearly the wrong one to choose; at least, if we admit that education is anything other than a mere system of mental gymnastics. If subjects are to be learned quite independently of their relations to active life, then there is no ground for present argument; but if culture and utility are both to be considered we must recognize that some scientific training is indispensable. Nearly every pupil goes out of school into one of the great industries; and, whether he becomes a mechanic, manufacturer, railroad man, telegraph operator, farmer, miner, or tradesman, he is likely to encounter practical applications of the two sciences. In every avocation some knowledge of either physics or chemistry is almost certain to be directly useful; and this utility is often so great that the schools can better afford to err on the side of over-thorough teaching than in the opposite direction."

In answer to the inquiry how far these sciences can be carried in such schools without detriment to other interests, the report states:

"One high school has three years and another four years in its total course of study; the latter is plainly able to give more time to any particular subject than the former, Every variation in the character of a school must involve corresponding variations in the treatment of these two sciences. It may be safe to put half an academic year as the minimum time assignable to either subject. A year can usually be given to each without difficulty."

While as to the detail of such instruction Professor Clarke says:

"Instruction should be general rather than special. The attempt is too often made to teach applied science when there are no foundations of science to apply. Such foundations should be thoroughly laid in the high schools and academies, so that the pupil who passes on to a university or polytechnic course may have a genuine preparation for advanced work. Fundamental ideas, like those of the conservation of energy, the correlation of forces, the conceptions of atoms and molecules, &c., ought to be clearly inculcated. The scholar should be made to realize that each science is a coherent whole with definite relations to other sciences, that all its parts are vitally connected, and that certain general principles are universally applicable in all of its branches. In chemistry it is better to concentrate all efforts upon the inorganic portion of the science, leaving the complicated organic side for more advanced study. Along with the merely descriptive work should go a solid drill in chemical problems and chemical notation. Experiments made before classes ought to bear as far as possible upon main questions, and unavoidable details should be handled so as to illustrate clearly the great central ideas. When these have been fairly grasped, the scholar has gained something of both practical and intellectual value. His studies will have brought him not knowledge only, but also increased power."

For success, much depends on the teacher.

"He must have a vivid sense of what needs to be accomplished and enough special knowledge to render him in a measure independent of text books."

Text books, the report says:

"May be useful or injurious, according to circumstances. If they have been chosen by an average school committee, influenced by some publisher more energetic than his rivals, they are likely to be worthless, and the teacher must be prepared to make good their omissions and correct their blunders. No text book can be taken as sole guide and followed without variation; but a good treatise upon either science, prepared, not by a professional school-book maker, but by a trained specialist, may be of great help to teacher and pupils."

Professor Clarke wisely urges the value of laboratory work:

"In addition to classroom drill, laboratory practice should be an essential and prominent feature of every chemical or physical course. In the recitation or lecture, general principles are taught; in the laboratory, the student becomes familiar with methods and details. Three months of laboratory work will give more real insight into any science than a whole year's study of the printed page. To study chemistry from books alone is like learning a language from its grammar only, without attempting to translate or to write exercises. The pupil must learn to observe and to experiment for himself, in order to acquire any clear scientific knowledge."

One recommendation of the report is strongly in accord with our own views, and that relates to the advice to teachers and pupils, to construct as far as is practicable all apparatus used in the laboratory.

"The apparatus which a teacher contrives for himself

with the aid of his scholars is oftentimes the most useful for purposes of instruction. Many and many a school has invested in trifling electrical playthings a sum of money which would have gone far towards the establishment of a simple working laboratory.

"In physics the laboratory practice must needs be somewhat limited. The pupils may handle whatever apparatus happens to be available, learn its manipulation, and assist the teacher in the construction of simple appliances. The magnetization of needles, the electrolysis of liquids, the verification of the fixed points upon a thermometer, and rough determinations of specific gravity, boiling point, and melting point are among the many experiments which ought always to be possible.

"In the chemical laboratory a much greater variety of work is easily attainable. There are the ordinary experiments in manipulation, such as the bending of glass tubes, filtration, precipitation, distillation, &c., the preparation of the commoner gases, acids, and salts; the verification of the more obvious properties of the chemical elements; and lastly, the simpler reactions of qualitative analysis. To the last named subject some time may always be profitably assigned. No other class of exercises will do so much towards impressing the average beginner or towards making him realize the nature of chemical reasoning. At every step it calls his powers of judgment into play. It involves the use of no costly apparatus, and enough can be done for all school purposes with a very moderate supply of the cheaper chemicals. At an expense of a hundred dollars a year a great deal can be accomplished; and an outlay of only one-fifth of that sum may yield results which are by no means to be reckoned as trivial. Again let it be said that success depends upon the teacher and not upon the cost of materials."

We shall in our next issue continue our notice of this interesting report.

ON COMETARY APPEARANCES.[1]

By M. Jamin.

[Translated from the French by the Marchioness Clara Lanza.]

The question of comets seems at present to occupy the attention of all *savants*, and as M. Faye has prevailed upon physicists to take up the subject also, I have decided to enter into the discussion, not with the intention of creating any novel hypothesis, but rather to oppose that which M. Faye imagines to be the correct one. In the first place, it appears to me unnecessary. It contradicts in my opinion, the theory of the vibration of the ether. Besides, it deprives the law of gravitation of its generality and simplicity. In his first work, M. Roche determined, by means of calculation, the form of the horizontal strata of cometary atmospheres subject to the sun's attraction, but he omitted to note the variations of temperature occasioned by the solar rays on the two sides of the comet. In this way he was led to think that the latter must have two tails, one turned towards the sun, the other away from it, which supposition is contrary to reality, as it should be, in fact, inasmuch as it overlooks the cause which manifestly determines the unsymmetrical forms of the two sides. In a second paper, however, he makes a correction, by supposing the existence of a repulsive force diminishing the solar attraction about 1—to 1. ϕ, φ, being a force acting unequally upon different substances, and which is in reverse ratio to their density. This hypothesis admits of the calculation being achieved with facility, but it has no physical actuality. It is confined to replacing the warmth of the cometary atmosphere, which should be included in the calculations, but which has been forgotten, with a wholly imaginary action whose existence no experiments have ever confirmed. I shall endeavor to re-establish the effect due to the unequal warmth of the two sides by referring to analogous conditions which should exist between the Earth and comets.

Upon the Earth, every day throughout the year, the solar rays one after the other in regular succession strike normally all the points of a circle perpendicular to the axis of rotation and near the equator. These points on all portions of the globe are those that receive the maximum of heat at noon. They constitute what is termed the *ring of aspiration*. The air there really becomes rarified and ascends, advancing towards the north or the south, as the case may be, determining two gaseous currents called trade winds. These currents are permanent and regular; they come from temperate climates, grow warmed progressively in their course, carry with them an intense evaporation, are slightly deviated towards the west in consequence of the Earth's rotation, and finally meet obliquely upon the ring, to rise to the highest atmospheric limits. There they spread, then taking a contrary course, return, one towards the north, the other towards the south. These are the *counter trade winds*. There are, therefore, on the two sides of the ring of aspiration, two closed atmospheric currents completely enveloping the globe, coming cold from the poles, grazing the Earth, and then returning warm, by a higher route. There is no occasion to dwell upon the chief *rôle* played by this circulation. It is sufficient to merely demonstrate its necessity, its constancy and its extent, besides recalling the theory due to the famous Halley, which has never been contested.

This circulation would still exist although under changed conditions, if the Earth instead of turning on its axis always presented the same side to the Sun. The ring of aspiration would be reduced to a single point, the trade winds would converge in all directions, while the counter winds would diverge in the same way. All points of the Earth would send to this summit cold air which would grow warm there, *rise in the form of a cone toward the Sun, spread, become bent upon the edges like the chalice of a cyrathiform flower*, leave the Sun by a high route and after a more or less prolonged journey would return to the point of departure grazing the Earth's surface. It is very evident that this double movement would possess an increase of force proportionate to the Earth's approach to the Sun; that its atmosphere would be more extended, and that there would be a greater mass of water to be evaporated. This does not imply any particular repulsive force.

But let us get to the comets. In the long journey which they perform slowly until they are beyond the Solar world, they have plenty of time to lose all the heat received from the Sun, and to efface all traces of perturbation. The tail disappears, the matter is knit together by its own attraction and assumes a nebulous, spherical form. In the centre are the dense, solid substances, the nucleus, then the liquids and finally the gases. An enormous atmosphere and a very small nucleus. In Donati's comet the nucleus measured 1600 km., while the atmosphere was 20,000 km. The comet of 1881 was still more extraordinary. Its aureole measured 2,000,000 km., the nucleus was reduced to 680. This is just contrary to the Earth whose diameter amounts to 12,000 km., while its atmosphere is merely a thin pellicle of 18 or 20 leagues. Comets are so constituted that the most tremendous atmospheric movements are developed be-

[1] See *Comptes Rendus*, August 16, 1881.

neath the Solar action incomparably more accentuated than those exhibited by the Earth.

As no rotatory motion has ever been observed in comets or their atmospheres, we feel authorized in saying that if it does exist it is exceedingly slow, without taking into account the fact that comets always present the same side to the Sun. The second method of heating should therefore be produced. In every plain passing through the centre of the Sun and the nucleus, there will be a double atmospheric circulation. On the interior, the comets advance towards the Sun as though the gravitation there was intensified. On the exterior, they deviate as if the gravitation was diminished, or rather as though there existed some repulsive force emanating from the Sun, affecting the exterior surface of the cometary atmosphere, and acting solely upon it. In reality, this repulsive force does not exist. It seems as though it did, however, and under conditions analagous to those inferred by M. Faye. All the consequences therefore, which he deduced in order to explain the formation of the tails, are developed naturally. There is nothing here to be altered.

I do not think, however, that this theory is sufficient to account for cometary appearances. On the contrary, it is my opinion that electricity has a great deal to do with them. But before entering upon this let us first return to terrestial phenomena.

It has been satisfactorily proved that considerable electricity exists in atmospheric altitudes, and that it increases according to the height. It is admitted generally that atmospheric motion results; that it is developed by evaporation at the ring of aspiration; that it moves from the time it leaves this ring until it reaches the poles under the form of two currents in the rarified air which it illumines. Towards the sun it is the zodiacal light, invisible when close to this planet, but extending a sufficient distance to be perceived, especially near the equator. Close to the poles it is the aurora borealis, which we see obliquely and which appears more luminous than at the zenith, because it has greater density and is more concentrated.

Upon a comet the warmth occurs at the point where the trade winds come together opposite to the sun. But analogous electric actions should be manifested, illuminate the head and produce the appearance of effluviums succeeding each other like the stratifications in a Geissler tube, accompany the counter trade winds to the opposite side to illumine the tail, and be prolonged to a great distance like the luminous rays in Mr. Crookes's apparatuses. No doubt, matter would be contained in the tail, but rarified to an extreme degree and made visible by both the solar light and the electric current.

M. Flammarion would be quite right then to attribute this shining to electricity. On the other hand, M. Berthelot's observation would be justified, and the development of this electricity would be due to the phenomena of evaporation and movement situated in the atmosphere. We must insist upon this point.

The recent study of cometary spectra has shown us beyond the possibility of a doubt that the interior aureole and the tail contain carburetted gases which emit a light of their own. Now, they can only become luminous in two ways; either by combustion or by an electric effluvium. If by combustion, we have yet to explain how they take fire and how they continue to burn indefinitely, which seems very difficult. For in this case, all the materials of which the comet is composed would be red, and the spectrum would contain the bright spectral rays of the metals as we see them in the electric arc burning n mid air. Nothing of this kind occurs. The light is absolutely like that of the arc when the vaporous carbon is transported to the torpid gases without burning. It shows no brilliant metallic bands, any more than this arc. The light, therefore, cannot be the result of fire, but is due to illumination made by the currents.

I think that the Sun determines gaseous currents in cometary atmospheres analogous to terrestrial trade winds and counter trade winds; that this circulation produces near the Sun effluviums arising from the head of the nucleus and transports to the opposite side the substances which are on the exterior, producing upon these substances the effect of a repulsive force emanating from the Sun, a force which has absolutely no ***raison d'ètre***. Besides this, I think this circulation is accompanied by an electric movement which illumines the gases either towards the head or tail, as the case may be, making them visible to us notwithstanding the feebleness of their density, and precisely on account of this feebleness.

AMYLOSE: ITS CONSTITUENTS AND METHODS FOR THEIR ESTIMATION.

By H. W. Wiley, Lafayette, Indiana.

I propose the name Amylose for all the varieties of sugar and sugar-like substances derived from starch.

These substances are now known by many different appellations, and often the indiscriminate use of these terms gives rise to a great deal of misunderstanding and confusion. Among them I may mention grape sugar, starch sugar, dextrose, dextrine, glucose, maltose, fruit sugar, etc. These names do not always have the same signification in different localities. For instance, glucose and dextrose, in Europe, signify the same product, while in this country they embrace many other substances besides.

If we designate the starch sugar in general by amylose then the terms glucose, dextrose and maltose can be used to designate certain definite constituents of amylose.

Amylose is composed of three principal ingredients.

1st. Dextrine. Pure dextrine is very difficult to obtain. It is obtained almost pure by the dry roasting of starch. The temperature during torrefaction must not be carried too high, 210°–275°. Starch itself has a specific rotatory power of 214° (1). Bondonneau (*loc. cit.*), asserts that there are three dextrines, (*a*), in which aj (2) = 186°; (*β*), in which aj = 176°; (*γ*), in which aj = 164°. According to Musculus and Grubber (3), there are five dextrines; viz.: (*a*), soluble starch colored wine red by iodine aj = 218; (*b*), Erythro dextrine, red color with iodine; rotating power not given.

(*c*), *a* Achroodextrine, not colored by iodine, j = 210.

(*d*), *β* Achroodextrine, aj = 190.

(*e*), *γ* Achroodextrine, aj = 150.

Of these varieties the first and second do not reduce the alkaline copper solutions while the others do. If the reducing power of dextrose be taken at 100, that of the third of the above dextrines will be 12; the fourth 12 and the fifth 28.

O'Sullivan admits the existence of but one dextrine with a = 214.

Thomson (4) tries to show by history of multiples in the rotating power of the carbo-hydrates that there are at least three dextrines in which the value of aj is 186, 176 and 164 respectively.

I will not multiply authorities concerning the rotating power of dextrine. I have quoted enough to show the highly chaotic state of our knowledge on the subject.

The chemical properties of dextrine are equally as undeterminable.

Gentele (5) is quite confident that dextrine will reduce the alkaline copper solutions and on this he bases his method of separating dextrine from other reducing substances by ferricyanide of potassium.

Stommer (6), Bondonneau (7) and Rumpff (8), are equally

(1) Bondonneau, Ber. d. Deu. Chem. Gesel., IX, 69.
(2) a = specific rotatory power.

positive that dextrin does not reduce the copper solution except on prolonged boiling.

My own experience is that dextrine does not reduce Fehling's solution except on prolonged boiling and then by the dextrine being slowly converted into dextrose.

To secure the reduction of the dextrose and the reducible portion of maltose it is not necessary to boil the solution more than two minutes, and during this time the amount of dextrine reduced is wholly inappreciable.

Color with Iodine. Bondonneau ([9]) says, dextrine colors a solution of iodine a dark red, but that it is without effect on caustic soda. Musculus & Gruber ([9]), found that some varieties of dextrine colored iodine solution red, while others were without action on it.

In general it will be found that most substances purporting to be dextrine give a reddish color with iodine. For my part I do not know of any method by which absolutely pure dextrine can be prepared.

Fermentability. Respecting this property the most contradictory statements are found. The weight of authority leans to the non-fermentible doctrine. It is probable that before dextrine ferments it is first converted into dextrose.

Formation. In addition to the method by roasting, dextrine is always formed when diastase or dilute acids act on starch.

Some authorities maintain that dextrine in such cases is always the first transformation product and that the others are derived from it.

According to Musculus ([10]), dextrose and dextrin are formed synchronously by the action of sulphuric acid on starch and in the proportions of one part of the former to two of the latter. This proportion is maintained until all the starch disappears. The further action of the acid then tends to convert the dextrin into dextrose. O'Sullivan ([11]) states that by the action of diastase, both dextrine and maltose, and nothing else, are first produced from starch under certain conditions of temperature (below 63°), and in the proportions of one part of the former to two of the latter. The proportion, however, only obtains when the specific rotatory power of the mixed bodies is equal to 171°.

From a careful study of all the data I could obtain I concluded that very little is yet known of the real proportions of dextrine which amyloses formed by heating starch with dilute acids contain.

MALTOSE. Dubranfaut ([12]) first pointed out the probable existence of a third transformation product of starch in addition to the two which had long been known. But we must accord to O'Sullivan ([13]) the merit of having first isolated and studied the properties of this body. He has given in the *Journal of the Chemical Society*, within the last decade several papers on the properties of this important saccharide. He gives its specific rotatory power (a)= 150°. The same value is also given by Musculus and Gruber, ([14]),

Joshida[15] found a slightly higher number. For (a)j this would give 135.°36.

Maltose is formed chiefly by the action of diastase on starch at a temperature not exceeding 75°. But it is also formed, but in smaller quantities by the action of dilute acids.

It is well established that maltose has the power of reducing the alkaline copper solution and in the proportion of 65 to 100 compared with dextrose. We here find an easy explanation of the fact that so many chemists have affirmed that dextrine acted on copper solutions. In all these cases the dextrine doubtless contained maltose. Without citing further from the literature of maltose, which is all recent, I wish to call your attention again to the numbers representing its rotating and reducing power, viz. 150 and 65.

3d. DEXTROSE. This substance is the final product of a complete saccharification of starch. It has a slightly bitter taste, which is probably due to the development of a bitter principle on long boiling with acids. This bitter taste is not noticed in the products less perfectly converted.

Dextrose possesses in the highest degree the power of reducing the copper solutions. One gramme reduces 2.205 g. weighed as cupric oxide. Its specific rotatory power has been the subject of much controversy.

O'Sullivan gives 57°.6 = (a)
Tollens " 56 = "
" " 53.17 = (a) j. ([16]).

The differences in results which the above numbers show do not indicate so much errors of observation as they do the impurities which the purest dextrose is likely to contain. As a mean of these numbers, we may take (a) = 56 and (a) j. = 50.5 (by calculation).

Pure dextrose is almost insoluble in absolute alcohol, while it is very soluble in water. According to Anthon ([17]) 100 parts water dissolve 81.68 parts dextrose. To dissolve one part, 50 parts of alcohol, .83 sp. gr. are required. When subjected to fermentation, dextrose affords 48 per cent alcohol ([18]), while cane sugar and maltose each gives 51 per cent and dextrine none at all.

I have thought it useful to give the above brief *resume* of the literature of amylose, because the conclusions to be drawn from it will go far to explain the anomalies of the numbers which the following analyses and methods of analysis will show. The whole subject is a matter of considerable scientific interest on account of the immense production of amylose in this country and the laws which some of the States have passed to regulate its sale. In the present state of our knowledge I am at a loss to see how the real constitution of an amylose, or mixed sugar, can be established before a court of justice. To show this I will give synopses of a few of the

METHODS OF ANALYSIS

which have been proposed.

I shall not attempt to give an out-line of all the methods which have been proposed for determining the amount of dextrine and dextrose in amylose. Until within a few years they were all based upon the assumption that these were the only transformation products of starch—an assumption which we know to be false. Reduced to first principles, all the methods may be comprised under three heads.

1st. The reduction of certain metallic salts by the dextrose, and estimation of dextrine by difference.

2d. Fermentation of dextrose and estimation of dextrine by difference.

3rd. Precipitation of the dextrine by strong alcohol and estimation of the dextrose by difference.

Remembering the facts established in the first part of this paper, it will not be hard to show the fallacies of these several methods.

1st. Metallic salts, especially the compounds of copper, mercury and ferro-cyonigen, are all reduced by maltose as well as by dextrose, and on prolonged boiling in a slight degree by dextrine also. Thus the total reducing effect does not measure the amount of dextrose present only in case maltose is completely absent. In commercial amyloses this is never the case unless it be in rare instances of high pressure conversion.

2d. Fermentation not only converts dextrose into alcohol and carbonic dioxide, but acts in the same manner on maltose. For a given weight maltose gives even

(18). O'Sullivan loc. cit.

a higher percentage of alcohol than dextrose, and in the proportion of 51 to 48. Whether dextrine is fermentible or not has long been a subject of bitter discussion. The weight of authority seems to be in favor of its fermentability by a slow conversion into dextrose. Thus by fermentation we are not sure of getting the amount of dextrose present even when maltose is absent. From this it appears that the process of fermentation is likely to give less reliable results than reduction affords.

3d. Precipitation with alcohol is even less reliable than the method just given. Alcohol of 90 per cent ceases to give a precipitate long before the dextrine is all converted into dextrose, as every grape sugar maker well knows. If absolute alcohol is used, dextrose is also precipitated.

Anthon has shown[19] that fifty parts of alcohol of .83 sp. gr. will only dissolve 1 part of dextrose. Anything like an accurate separation, therefore, by this method is impossible.

As an illustration of the variations in the composition of different specimens of amylose I will cite the following analyses by Steiner[20]:

	I.	II.	III.	IV.
Water	15.50	6.00	13.30	7.60
Ash	.30	2.50	.40	1.10
Dextrose	45.40	26.50	76.00	...
Dextrine	9.30	15.90	....	39 80
Maltose	28.00	40.30	5.00	42.60
Carbo-hydrates	1.50	7.00	5.30	8.90

My own analyses have given results quite as puzzling as the above, although I have never been able to satisfy myself with such exact expressions of percents.

I have heretofore been glad when, by hard work and liberal guessing, I could come any way near the truth. The author of the above table leaves us in charming ignorance of the methods by which such accurate percents were obtained; at least, of methods which would stand the test of criticisms, while the bunching of all the unknowables as *carbo hydrates* is quite worthy of the reasoning of the Concord School of Philosophy. I have given enough, I think, to show the untrustworthiness of methods now in use, and of the results obtained by them. I am sorry that I have nothing very much, if any better, to propose as a substitute. What I have been able to accomplish I will now briefly describe.

THE ANALYSIS OF AMYLOSE.

Water. I have estimated water in a flat platinum dish. Only two or three grammes should be taken, though in many of my analyses I have used more. This dish is placed in a second one, and this in a paraffine bath heated to 150°–170°. The object of the second dish is to keep the wax from touching the dish which is to be weighed. After two hours the weight is sensibly constant, and the whole mass is quite brown. I believe the method will give the water to within one-half of one per cent.

Ash. There is only one method of determining the ash, *i. e.*, by incineration in a shallow platinum dish in a muffle. The per cent of ash in a strait amylose is extremely small. In most cases its quantity may be neglected as far as practical purposes are concerned. The determination of the ash is chiefly useful to furnish a clue to the purity of the sample.

Reducing Matter. I determine by Fehling's solution. It will be found most convenient to take 10 *g.* in 1000 *c. c.* In all cases the volumes of the solutions employed should be as nearly the same as possible.

Rotating Power is determined by using 10 *g.* of the amylose in 100 *c. c.* If 26,048 *g.* are taken the weight of cane sugar, which gives 100 divisions on most polariscopes, the rotation is so great that the neutral point is thrown entirely beyond the graduation. In many cases of high conversion, however, this would not be the case. If the solution is turbid it must be clarified by blood charcoal, or plumbic acetate. These substances, as I have shown ([21]), tend to diminish the rotating power. The clearer definition, however, of the neutral point in part compensates for this loss in gyratory power.

In the light of the foregoing *resumé* it is possible to explain the results of my own work, although I am far from thinking that anything better than approximate per cents can yet be obtained.

We have seen that an ordinary amylose, whether liquid or solid, contains about 86 per cent of material not water. One per cent, nearly, of this is ash and optically non-active matter. Ten grammes of amylose, therefore, will contain an average of 8.5 grammes optically active matter. If this were all dextrose it would give in 100 *c.c.* an angular rotation of 8°.67. This is obtained by the formula $a = \frac{\theta \times v}{\lambda \times w.}$

Here a_j. = sp. rot. power for yellow ray.
θ = angular rotation.
V = volume of solution in *c. c.*
λ = length of observation tube.
W = weight of substance in grammes.

In a large number of cases where I heated the amylose with dilute sulphuric acid from 4 to 6 hours, I obtained an average value of θ= 8°.85. This shows that prolonged boiling does not convert all the amylose into homogeneous dextrose.

If the substance under examination were all maltose the value of a_j would be 135.36 and θ would become 23° nearly. The highest number I ever obtained for an amylose was 22° .24. This shows that even this specimen, with such a high rotating power contained some matter in a weaker degree of optical activity.

Finally, if all the snbstances present were dextrine, I would not be able to tell theoretically what its rotating power would be, since we have just seen that dextrine is assigned different degrees of activity by different authors. As a mean of these I think we may place dextrine a_j =176°, although I do not wish to be understood as stating its real value.

This would give a total angular deflection of 29° nearly.

The problem of analysis is therefore at the present time in the following *status*:

1. In every amylose there are present at least three kinds of optically active matter, viz., dextrose, maltose and dextrine.
2. There are present in every amylose two kinds of reducing matter, viz., dextrose and maltose.
3. A high reducing power shows a high percentage of dextrose present.
4. A high rotating power, which is always shown when the reducing power is low, indicates a large percentage of maltose and dextrine.
5. From a very extended series of analyses, I will say that there is no method known which will give reliable, or rather exact, numbers for the percentage of the different constituents.
6. I propose to attempt the accomplishment of this very desirable result by first polarizing and then reducing the sample, and then repolarizing the residue. The difficulties of preserving a standard volume and of getting a solution sufficiently clear for polarization have prevented me hitherto from obtaining any results. I hope to overcome these troubles and to establish thereby a reliable optical method of determining the percentages of dextrose, maltose and dextrine in amylose.

Prof. Cantoni has been appointed director of the meteorological observatory, to be erected at Pavia. Observations are to be made on the influences of light, heat, and electricity upon vegatable growth, in addition to the ordinary meteorological and magnetical work.

A REMARKABLE INVASION OF NORTHERN NEW YORK, BY A PYRALID INSECT:*

Crambus vulgivagellus.

(Abstract.)

By J. A. Lintner.

About the middle of May, of the present year (1881), a serious invasion of St. Lawrence county, N. Y., and several of the adjoining counties, by the "Army Worm," was announced by the newspapers, and by letters addressed to me. It was stated that many pastures had been completely ruined, and the entire destruction of the pastures and meadows was feared. I had never witnessed the operation of the Army Worm—comparatively rare in the State of New York—and I at once visited the infested locality for personal observations.

The reports had not been exaggerated. The ravages were widespread and serious, already extending over eight of the northern counties. Hundreds of acres of grass presented a brown appearance, as if the grass had been winter-killed. A pasture lot of fifty acres, examined by me, which ten days before offered good pasturage, was now entirely brown from the complete destruction of the grass—so thorough, that in places not a blade could be discerned in an area of a square yard, by careful search. Numerous dead caterpillars were adhering to the dried stems of last year's grass, which, it is believed, had fallen victims to starvation.

Several interesting features characterized this attack. It appeared first on upland pastures, differing in this respect from the invasions of the Army Worm, *Leucania unipuncta.*

The progress was remarkably rapid. A browned patch would rapidly extend its area, until it overspread the entire field in ten or twelve days. It could not be ascertained if this was by the spread of the larvæ from certain points, or from the unequal hatching of the eggs, uniformly distributed over the field, as influenced by various conditions. The secresy of the depredation was unusual. The larvæ had seldom been seen and never observed in active feeding. It was believed that they fed at night, by drawing in the blades of grass to their subterranean retreats.

In two instances the larvæ were observed in immense numbers, collected on trunks of trees—so numerous that they could have been scooped up by handsfull. One of the reported localities was visited by me where the assemblage had been noticed three days before. The tree-trunk, at its base, was found to be enveloped by a web of silk, as was also an adjoining stump, of so firm a consistence that it could be lifted up in a sheet, like a piece of woven silk. The cause of the congregation at this point could only be conjectured, but it was thought it might have been for shade, after the complete destruction of the surrounding pastures. It was not for feeding on the foliage, for the grasses were alone eaten by the larvæ.

It was generally accepted throughout the entire region as an army-worm invasion, and the most disastrous consequences apprehended. The papers abounded with notices of it. Farmers commenced to dispose of their cattle, in the prospect of their ruined pastures and meadows. It became the one topic of village conversation, and general alarm prevailed.

The caterpillars observed and collected by me in Morley and Potsdam, by digging in the soil, and occasionally finding one on the surface, were slender, cylindrical, sixteen-footed, of a sordid or obscure greenish color, with a shiny black head. They were destitute of lines or other ornamentation than some verrucose spots on the dorsal portion. The average length was three-fourths of an inch.

I was unable to identify these with *Luecania unipuncta,* for they were quite unlike the mature form of that species which I had alone seen. Yet it was possible that they had additional moltings to undergo, which might result in a material change of appearance. Their habits seemed to be quite different from those of the army-worm, and it was nearly two months too early for an invasion of that species.

Of the larvæ which I had brought from Potsdam for rearing and ascertaining the species, nearly all died shortly thereafter. Only a single one developed, giving me a small Pyralid moth—*Crambus exsiccatus.* Additional ones were sent me, at my request, from Potsdam. They were quite different from those previously collected and observed by me, but it was believed by my correspondent, as the result of observations made, that the molting through which they had just passed had produced this change.

I suspected that two species were associated in the attack, but other pressing duties at the time prevented a decision upon this subject. Some of the examples received were submitted to Prof. Riley, who was able to identify them as the larvæ of a rather rare Noctuid—*Nephelodes violans,* which he had known in Missouri. The occurrence of the species in such numbers—more than a dozen in lifting a small piece of a rail—was an interesting discovery. In some communications contributed by me to some of the newspapers of Albany and Northern New York, I ascribed the above ravages to *Nephelodes violans.* Farther study led me to believe that I had been hasty in my reference.

Early in July, Mr. J. Q. Adams, of Watertown, N. Y., where the ravages of the same insect had also been observed, furnished me with information and material that convinced me that *N. violans* was only chargeable with a small portion of the above injuries, and that the principal depredator was the smaller larva observed and collected by me, which, from the cocoons forwarded to me at this time, undoubtedly belonged to the Pyralidæ. The cocoons were taken from the infested fields at Watertown, from just below the surface of the ground, where they were so numerous that a half dozen could be taken from a sod the size of a man's hand. On opening the cocoons, the larvæ were found lying within them, still unchanged, although they had been made over a month before, and they were identical with my Potsdam collections. Additional cocoons were opened by me early in July, when the larvæ were still in their untransformed state, in which they had at this time been remaining for from a month to a month and a half.

The delayed pupation is an interesting item in their history. It is known to occur in some of the Bombycidæ, among the Notodontas for example, when it extends over the winter, and the pupa state is assumed in the spring, a short time before the emergence of the perfect insect; but it was new to me at this season of the year.

Dr. Hagen, to whom I communicated the fact, was unable to find any record in the extensive library at Cambridge of such delayed pupation among the Pyralidæ, although Prof. Riley informs me that he had known of its occurrence in some of the species.

On the 6th of August, the first moth from the Watertown cocoons was disclosed, and it proved to be *Crambus vulgivagellus.* The interesting question as to which of our insect depredators was chargeable the ravages in Northern New York—more injurious in the extent of territory embraced than in an army worm invasion—was decided. The new enemy, the latest addition to our list of formidable insect pests, was found to be a modest, inconspicuous, hitherto unobtrusive little Crambus. It had long been known in our cabinets, but had never before presented itself as an injurious insect.

It is probable that several accounts of injuries to pasture lands, in New England States, during the last three or four years, which have been ascribed, either to the army-worm or an unknown depredator, are due to this

*Read before the A. A. A. S., Cincinnati, 1881.

species. In its subsequent appearance, hereafter, it may now be recognized.

The Crambidæ are small moths with narrow front wings, often marked with metallic spots and lines, which are frequently driven up for short staccato flights in our pastures and meadows during the fall months.

The paper concluded with a resumé of the history of the species, so far as known at present, which is omitted as not of general interest.

CAÑONS—THEIR CHARACTER AND ORIGIN.*

By Hon. William Bross.

To the professional geologist it may seem an impertinence for a layman to offer any opinions as to the character and the origin of cañons. He may, however, it is hoped, use his eyes without offense, and form such conclusions as the facts which he has observed, may appear to warrant. If they should not agree with the recognized principles of the science as now understood, he will be no worse off than scores of learned Professors in the past, for in this, as in almost every other science, nearly every conceivable absurdity was exhausted before theories were made to agree with acknowledged facts. And here, at the commencement, the conclusion to which the observations to be presented somewhat in detail have led, may as well be stated—viz.: that cañons were formed by some great convulsion of the earth's surface, or by the contraction of mountain chains from their igneous condition in the early history of the planet. Take, for instance, the cañon of the Saguenay—a vast fissure in the mountain chain that lies on the north side of and nearly parallel with the St. Lawrence. The fissure or cañon is some fifty or sixty miles long and lies nearly at right angles to the river. Something like a mile apart, the perpendicular rocks on the north side are, at some points, about 1,500 feet high, the water at their base being several hundred feet deep. No man in his senses, it seems to me, could possibly conceive that this gorge through the granite mountain could have been formed by the action of the insignificant river that empties into Ha-Ha Bay at the northern end of the cañon. The surface of the water, for the whole distance of sixty miles, is on a level with the St. Lawrence, in some places it is several hundred feet deep and the cañon is about a mile wide, through the solid granite rocks. And here another general principle may as well be stated, that, with a single exception, the width of this and the other cañons hereafter to be noticed, is scarcely ever more than a fraction of a mile; seldom a single mile—a fact that strongly indicates uniformity in their origin. And besides, the mountains on both sides are generally nearly of the same height.

TAKE THE CAÑON OF THE HUDSON,

where it passes through the Blue Ridge, above and below West Point. The channel is deep, the tide ebbing and flowing far upwards towards Albany; the mountains on both sides, though rounded off towards their summits, doubtless during the glacier period, are about of the same height, and there is a general correspondence in the dip and thickness of the vast strata of rocks on both sides of the river. With the exception that the cañon is far above tide water, the same general facts are witnessed in that of the Delaware at the water-gap through the same spur of the Allegheny Mountains. In this case there are two well-defined ledges corresponding with each other on both sides of the river; the water is deep and sluggish while passing through the gorge, and all the facts seem to point, with unerring certainty, to some great convulsion in Nature as the origin of the cañon. With the exception that the current of the Potomac is swift at Harper's Ferry, the break in the mountain there, so graphically described by Jefferson, is very similar to that of the Delaware. This gorge may not have been relatively as deep at its formation as those of the Hudson and the Delaware.

THE CAÑON OF THE NIAGARA

was confessedly formed by the action of the river; but, if the structure of the rocks forming the cañon between the falls and Lewistown be considered, the exception in this case, it is believed, will prove the rule enunciated at the beginning of this paper. The rocks underlying the country between Lewistown and Buffalo are nearly horizontal, and are, in round numbers, as indicated by the gorge below the falls, some 200 feet thick. The upper strata, for say half the distance, are solid limestone, underlaid for perhaps an unknown depth, by soft sandstone, scooped out with comparative ease by the great cataract. Hence, the support of the upper stratum of lime-rock is gradually worn away, and it falls into the gulf below. On the American side of Goat Island, where only a fraction of the river falls over the precipice, the lime-rock lies below in vast blocks, and a rapid is gradually forming, while on the Canada side, the immense river scoops out the sand-rock to a great depth, and the falling sections of the lime-rock are buried out of sight forever. Below the railway bridge, for a long distance, there is a terrible rapid, showing that some other rock at the bottom of the river was harder than the sandstone, or that the stream is partially damned up by the lime-rocks thrown down between the bridge and the present fall, forced to the position they now occupy by the water, débris, and ice pressing down from above as the river gradually receded towards Lake Erie. This recession will doubtless continue even back to Lake Erie, unless the sandstone dips deeper down into the earth, and the limestone strata become thicker or some other hard rock fills the entire face of the cataract. Then the fall would gradually wear away at the top and become a rapid of gigantic proportions. Now, if the Niagara River, with its vast volume of water at first falling over a lime-rock ledge, at Lewistown, underlaid by a friable sandstone base—a condition of things found, it is believed, in no other cañon upon the continent—has required untold ages to work its way up to its present location, how is it possible for the comparatively small rivers heretofore named, and those to follow, to wear away a pathway to the sea through great mountain ledges of the hardest rock? Such a conclusion would be absurd.

THE CAÑON OF THE MISSISSIPPI

extending, say from Dubuque to the head of Lake Pepin, some 200 miles or more, is an exception to the rule above proposed, mainly in its width, which is some five to seven miles. The sandstone bluffs on either side are generally perpendicular from the top downwards from 200 to 300 feet, when the débris slopes down to the bottom lands or to the majestic river as it sweeps through the alluvium from one side of this broad cañon to the other. There are doubtless good reasons for the opinion that the waters which now find their way from Lake Winnipeg to Hudson's Bay once flowed south and filled full the broad space between the beautiful bluffs of the Upper Mississippi.

THE GORGE OF THE UPPER MISSOURI,

situated about 100 miles below Fort Fenton, is one of the most marked, as it is one of the most beautiful, cañons on the continent. The walls are perpendicular, of white sandstone, scarcely a mile apart, and some eighty feet high. On the top of these walls there is a layer of clay, perhaps of the same thickness, rounded off gracefully by the winds and storms, while in some places it has been all worn away, and the tops of the white sandstone ledges appear as castellated forms, reminding one of the Milan Cathedral, or some of the old ruins

* Read before the A. A. A. S., Cincinnati, 1881.

scattered all over Europe. Between these sandstone walls the river flows smoothly, without giving the least suspicion that the cañon was formed by it. Only some great convulsion could have torn apart this immense sandstone deposit for some twenty or twenty-five miles. It will well repay a visit to the Upper Missouri to see it.

THE GRAND CAÑONS OF THE ARKANSAS,

the South Platte, Clear Creek and the Bowlder strongly resemble each other, and may, therefore, be disposed of in the same paragraph. Through the three first, in spite of the tremenduous obstacles they presented, railways have been built, and the saucy little locomotive rings out the echoes from their perpendicular granite walls on either side some 2000 to 3000 feet high. Small rivers—for they are small here—rush through them with angry roar; but it would be worse than idiotic to suppose that thev wore down the vast granite walls through which they run to the bed they now occupy. Only Nature's reserved forces, such as the world sees in earthquakes, could rend these granite mountains asunder, and, with perpendicular walls half a mile high, make a pathway for the tiny streams that surge and brawl between them.

THE CAÑON OF THE COLUMBIA

is, in some respects, one of the grandest upon the continent. From Cape Horn to perhaps some twenty miles or more above Celilo, at the head of the Dalles, a distance of sixty or seventy miles, the great river finds its way to the ocean through a gorge, the walls of which are from 500 to 4000 feet high. Even a cursory inspection will convince a practiced eye that for the entire height, and most of the distance, it is composed of nearly perpendicular basaltic rocks. No one series of columns where present reaches from the base to the top of the mountain; but at the foot of the cascades, on the south side of the river, their development is truly wonderful. Suppose before you there is a row of them 500 feet high and twice as long on the face of the mountain; at either end of that thousand feet another row, with their bases on a line with the tops of the first, shoots up another 500 feet, and so on from the base to the top, one row of columns above another, will convince the beholder that the entire mountain is composed of basalt. From the time of the Cæsars to the present all the world has been wondering at, or gazing with admiration at the Giant's Causeway, on the coast of Ireland. It, too, is composed of basaltic columns, and they are actually 300 feet high. Thus America furnishes to Great Britain a ratio in basalt of 3300 to 300; figures which I was wicked enough to write in 1879 would probably represent the influence of the two nations on the affairs of the world 100 years hence.

The Cascade Range, in Oregon and Washington Territory, corresponds with, and is virtually an extension of, the Sierra Nevada, in California. Near the western end of the cañon of the Columbia the Cascades form a splendid rapid, and the river falls thirty-five feet in two miles. From the head of the Cascades steamers run on the smoothly-flowing river for forty-five miles through the splendid cañon to the foot of the Dalles. Here, as the tourist glides along, Mount Hood, clad in a mantle of snow old as creation, peers down upon him through the lateral cañons, while the dark, frowning walls of basalt on either side almost make him shudder and forget for the moment how he can escape from this gloomy prison to the cheerful abodes of mankind. These stupendous basaltic walls, with the river flowing smoothly and beautifully between them, would never for a moment suggest the thought that this grand gorge was formed by the river. Only Nature herself, shaking as a reed this vast mountain-chain, could have rent it asunder and given us the sublime cañon of the Columbia. Only one other,

THE YOSEMITE VALLEY,

can be compared with it, and to that, as in some respects the grandest of them all, let us now turn our attention. A description of it will be most easily remembered by saying it is a gorge in one of the spurs of the Sierra Nevada Mountains, about twelve miles long, a mile wide, and a mile deep. As many, perhaps most of the members, have visited this grandest wonder of the world, only a brief description of it will be attempted. At El Capitan—or Tu-toc-a-nu-la, the granite wall—they are, on both sides, of the same material—is 3,300 feet high and very nearly perpendicular. At the grand arches, the height is about the same and the south dome is 6,000 feet—a very considerable fraction more than a mile—one-half of which is perpendicular. From either side the waterfalls are splendid. The Bridal Vail is 900 feet; the Yosemite, 2,634, more than half a mile; The Vernal Fall of the Merced River, at the head of the cañon, is 350 feet; and Nevada Fall is 700. The question is how was this vast gorge made through this mountain of granite? Prof. Whitney, if correctly reported, ascribes it to the dropping down towards the centre of the earth of a section of the mountain a mile wide. From this opinion, of this master of geological science, with all possible respect, I beg leave to differ. The facts of its structure, in my judgment, warrant the belief that, like all the other cañons above referred to—that of the Niagara alone excepted—it was formed by an upheaval of the mountain, at that particular point, sufficient to break it apart to the extent of a mile—the more probable cause; or the mountain, while intensely heated, contracted enough to do it. A few of my reasons for this opinion are as follows:

These solid granite mountains were once torn apart—on a smaller scale, it is true—for there are immense seams, perhaps two feet thick, of cream-colored feldspar, running through the walls of this valley; and it is believed that a correspondence can be observed in these seams on both sides of the gorge. If rent asunder to admit the injection of these seams of feldspar, why not on a larger scale? When this vast fissure was first made it was undoubtedly very deep, perhaps half a dozen miles or more. Where the break was in the line of the cleavage there the wall stands up perpendicularly, as at El Capitan, and the arches, and a few other points. Where it was not in the cleavage line, immense masses of rock were thrown into the abyss, and from this source and the débris brought down by the Merced river, the gorge gradually filled up to its present level. At El Capitan and the arches, the granite wall stands unbroken to the top, and you can ride right up to it and, from your saddle, put your hand on that wall rising sheer above you for more than three-fifths of a mile. Your horse stands on the fine disintegrated granite, the last contribution of the snowy range to the eastward. But after the valley was filled up to its present general level, at points where the cleavage was not in the line of the upheaval, as in the rear of Mr. Hutchins' hotel and some other places, the frost and perhaps earthquakes continued to throw down immense blocks, and hence there is at this point, a gradual slope to the top on the south side of the valley, with trees growing wherever they can find a ledge or a crevice to get root in. Another instance, showing how water, frost and other causes have broken the symmetry of the valley, may be seen at the Yosemite Fall. Both the height and the front of the escarpment, east and west of the Fall, are in the same line, while the ice and the stream have worn the wall back at the Fall perhaps a quarter of a mile from the front line. And yet the first perpendicular fall is 1,600 feet, or ten times the height of Niagara.

Such facts might be multiplied almost indefinitely, but

enough for this paper. This general remark, however, should be carefully weighed. The cañon of the Columbia, the Yosemite Valley, the Charquinez Strait connecting the Suisun and San Pablo Bays, and the Golden Gate itself, through which the waters of the Sacramento and the San Joaquin, draining the great Valley of California, find their way to the ocean, are all about a mile wide. With the exception of the cañon of the Mississippi, the same is true, it is here repeated, of all the cañons above referred to in the Rocky Mountains and east of them, noticed in this paper. It is submitted, therefore, that the main facts in regard to them, point almost unmistakably to a similar origin for them all. All these cañons I have myself visited, many of them several times. Several of them are splendid, even sublime, beyond the power of the most accomplished pen to describe. I dared not to attempt it, and have, therefore, simply stated what I have myself seen and drawn such conclusions as the facts seemed to warrant.

Let me add a very few words in conclusion upon a paper on the geological history of the Colorado River and the plateau of it, read at the St. Louis meeting by Col. E. C. Dutton, of Washington. This cañon, as described by Maj. Powell, who has the honor of braving almost incredible dangers to explore it and to give the world their first knowledge of its wonders, is some 1,500 miles long; the perpendicular walls are a mile or a fraction of it apart, and are from 1,000 to 5,000 feet high. They are composed of nearly all the series in the geological catalogue, from the granite all the way up to the highest igneous stratified rocks. Now this, by far the longest, and in some respects the most wonderful cañon in the world, Col. Dutton described as having been worn by the Colorado River. In view of the facts herein presented that conclusions seems supremely fanciful and absurd. Like all the others, it could only have been formed by some great convulsion of the earth's crust, and through it the drainage of nearly a thousand miles along the western slopes of the Rocky Mountains finds its way to the Gulf of California.

ADDRESS OF COL. GARRICK MALLERY, U. S. ARMY.

Chairman of the Subsection of Anthropology of the A. A. A. S. at the Opening of that Subsection.

THE GESTURE SPEECH OF MAN.

Anthropology tells the march of mankind out of savagery in which different people have advanced in varying degrees, but all started in progress to civilization from a point lower than that now occupied by the lowest of the tribes now found on earth. The marks of their rude origin, retained by all, are of the same number and kind, though differing in distinctness, showing a common origin to all intellectual and social development, notwithstanding present diversities. The most notable criterion of difference is in the copiousness and precision of oral speech, and connected with that, both as to origin and structure, is the unequal survival of gesture signs, which it is believed once universally prevailed. Where sign language survives it is, therefore, an instructive vestige of the prehistoric epoch, and its study may solve problems in philology and psychology. That study is best pursued by comparing the pre-eminent gesture system of the North American Indians with the more degenerate or less developed systems of other people.

EXAMINATION OF THE INDIAN SYSTEM.

The conditions and circumstances attending the prevalence, and sometimes the disuse, of sign language in North America were explained. The report of travelers that among Indians, as well as other tribes of men, some were unable to converse in the dark, because they could not gesture, is false. It is the old story of Βάρβαρος and ἀγλασσος applied by the Greeks to all who did not speak Greek, repeated by Isaiah of the "stammering" Assyrians, and now appearing in the term *slav* (speaker arrogated to themselves by a large division of the Aryan family), as contradistinguished by the Russians from the Germans, whom they stigmatize as *Njemez* (speechless.)

The theory that sign language was the original utterance of mankind does not depend upon such tales or prejudices. After the immeasurable period during which man has been upon the earth it is not probable that any existing peoples can be found among whom speech has not obviated the absolute necessity for gesture in communication between themselves.

The assertions made that the sign language of Indians originated from one definite tribe or region supposes its comparatively recent origin, whereas the conditions favorable to its development existed very long ago and were co-extensive with the territory of North America occupied by any of the tribes. Numerous evidences were presented as to its antiquity and generality. But the signs are not now, and from the nature of their formation never were, identical and uniform. The process is the same as among uninstructed deaf mutes when associated together, which was explained.

A comparison sometimes made of the diversities of the sign language of the Indians with the dialects and provincialisms of the English language is incorrect, as there is so small a proportion of the sign-using tribes which make identically the same signs to express the same ideas, and also because the signs are not absolute and arbitrary as are the words of English.

ARE SIGNS CONVENTIONAL OR INSTINCTIVE?

Sign language, as a product of evolution, has been developed rather than invented, but each of the separate signs had a definite origin arising out of some appropriate occasion, and the same sign may thus have had many different origins due to identity in the circumstances. No signs in common use were at first conventional. What may appear to be convention largely consists in the differing forms of abbreviation which have been adopted. Yet, while all Indians, as well as all gesturing men, have many signs in common, they use many others which have become conventional in the sense that their etymology and conception are not now known or regarded by those using them. The conventions by which such signs were established occurred during the long periods and under many differing circumstances. Our Indians, far from being a homogeneous race and possessing uniformity in their language, religions and customs, differ from each other more than do the several nations of Europe, and their semiotic conceptions have correspondingly differed.

PERMANENCE OF SIGNS.

Instances were presented of the ascertained permanence of some Indian signs, and of those of foreign peoples and deaf mutes. Though they, as well as words, animals and plants, have had their growth, development and change, those which are general among Indian tribes, and are also found in other parts of the world, must be of great antiquity. Many signs but little differentiated were unstable, while others that have proved to be the best modes of expression have survived as definite and established.

IS THE INDIAN SYSTEM SPECIAL AND PECULIAR?

The Indian system as a whole was compared with those of foreign peoples—the ancient Greeks and Romans, the modern Italians, the Turks, Armenians and Koords, the Bushmen of Africa, the Redjangs and Lelongs of Sumatra, the Fijians, the Chinese, Japanese, and the Australians. The result is that the so-called sign language of Indians is not, properly speaking, one language, but that it and the gesture systems of deaf-mutes and of all

peoples constitute together one language, the gesture language of mankind, of which each system is a dialect. The generic conformity is obvious, while the occasion of specific varieties can be readily understood.

ARCHÆOLOGIC RELATIONS.

The most interesting light in which Indians, as other lower tribes of men, are to be regarded, is in their present representation of the stage of evolution once passed through by our ancestors. Their signs, as well as their myths and customs, form a part of the paleontology of humanity. Their picture writings are now translated by working on the hypothesis that their rude form of graphic representation, when at the same time a system of ideographic gesture signs prevailed, would probably have been connected with the latter. Traces of the signs now used by the Indians are also found in the ideographic pictures of the Egyptian, Chinese and Aztec characters.

HISTORY OF THE GESTURE LANGUAGE.

From the records of the ancient classic authors, and also from the figures on Etruscan vases and Herculanean bronzes and other forms of Archaic art, it is certain that a system of gesture language is of great antiquity. Later, Quintilian gave elaborate rules for gesture, which are specially noticeable for the significant disposition of the fingers still prevailing in Naples. The ancient and modern pantomimes were discussed, and also the gestures of speaking actors in the theatres, the latter being seldom actually significant or self-interpreting even, in the expression of strong emotion. The same scenic gesture must apply to many diverse conditions of fact. Its fitness consists in being the same which the hearer of the expository words would spontaneously assume, if yielding to the same emotions, and which, therefore, by association, tends to induce sympathetic yielding. But the communication of the facts themselves depends upon the words uttered. A true sign language would express the exact circumstances, with or without any exhibition of the general emotion appropriate to them.

PRACTICAL APPLICATION OF SIGN LANGUAGE.

This was shown to be in successful use in cases cited by travelers skilled in it, and its powers were compared with those of speech. It finds actually in nature an image by which any person can express his thoughts and wishes on the most needful subjects to any other person. Merely emotional sounds may correspond with merely emotional gestures, but whether with or without them would be useless for the explicit communication of facts and opinions of which signs themselves are capable. Notwithstanding frequent denials, they are able to express abstract ideas. The rapidity of their communication is very great, and can approach to that of thought. Oral speech is now conventional, and with the similar development of sign language, conventional expressions could be made with hands and body more quickly than with the vocal organs, because more organs could be worked at once.

But such rapidity is only obtained by a system of preconcerted abbreviations and by the adoption of absolute forms, thus sacrificing self-interpretation and naturalness, as has been the case with all oral languages in the degree of their copiousness and precision.

RELATIONS IN PHILOLOGY.

Signs often gave to spoken words their first significance, and many primordial roots of language are found in bodily actions. Examples are given of English, Indian, Greek and Latin words in connection with gesture signs for the same meaning, and the structure of the sign-language was compared with the tongues of this continent, with reference also to old Asiatic and African languages, showing similar operations of conditions in the same psychologic horizon.

ORIGIN OF SPEECH.

It is necessary to be free from the vague popular impression that some oral language of the general character of that now used by man is "natural" to man. There is no more necessary connection between ideas and sounds, the mere signs of words that strike the ear, than there is between the same ideas and signs for them which are addressed only to the eye. Early concepts of thought were of a direct and material character. This is shown by what has been ascertained of the radicals of language, and there does not seem to be any difficulty in expressing by gesture all that could have been expressed by those radicals.

CONCLUSIONS.

It may be conceded that after man had all his present faculties, he did not choose between the adoption of voice and gesture, and never with those faculties, was in a state where the one was used, to the absolute exclusion of the other. The epoch, however, to which our speculations relate is that in which he had not reached the present symmetric development of his intellect and of his bodily organs, and the inquiry is: Which mode of communication was earliest adopted to his single wants and informed intelligence? With the voice he could imitate distinctively but few sounds of nature, while with gesture he could exhibit actions, motions, positions, forms, dimensions, directions and distances, with their derivations and analogues. It would seem from this unequal division of capacity that oral speech remained rudimentary long after gesture had become an efficient mode of communication. With due allowance for all purely imitative sounds, and for the spontaneous action of vocal organs under excitement, it appears that the connection between ideas and words is only to be explained by a compact between speaker and hearer which supposes the existence of a prior mode of communication. This was probably by gesture. At least we may accept it as a clew leading out of the labyrinth of philological confusion, and regulating the immemorial quest of man's primitive speech.

TRICHINÆ CYSTS.

The mode of formation of the cyst of trichina has been studied by M. Chatin and described in a communication to the Académie de Sciences. It was formerly said to be formed partly from the contractile tissue, and partly by a secretion from the nematoid, but this opinion was based only on some apparent differences in the thickness or aspect of the cyst wall, and not on any careful study of its formation, which necessitates the examination of animals dying or killed in different states of the affection. When it arrives in the muscles the worm forms adhesions with the interfascicular tissue in which rapid changes occur. The elements increase in size, and during the growth of the protoplasm it assumes the appearance of an amorphous mass, in which, however, nuclei and vacuoles can be seen, which seem to indicate that the mass consists really of aggregated cells. By the growth of this the primitive fibres are compressed. In the new protoplasm fine proteoid granulations are first observed, and then other granulations which present all the reactions of glycogen. Then follow important changes in the periphery of the granular mass, containing the trichina, now curled up in the interior; the outer surface becomes distinctly thickened and indurated, and may then become lamellated or present granulations or folds. The sarcolemma takes no part in the formation of the cyst except occasionally furnishing it with a purely adventitious layer. Moreover, when the nematoid contracts its first adhesions to sarcolemma, and not to the interfascicular tissue. it rapidly dies without determining a new formation.

BEFORE leaving New York, King Kalakaua called on Mr. Edison. He was accompanied on his visit by the Attorney-General of his island kingdom, Mr. Armstrong, and by an intimate friend residing in this city, whose acquaintance he made in Vienna. Punctually at nine o'clock in the evening his majesty alighted from the carriage of his friend in front of the Fifth-avenue mansion. He was introduced to Mr. Edison, who escorted him through the building, and by means of models, maps, drawings, and the 55 lamps in operation, explained the theory of the conversion of steam-power into electricity and the generation of light in the carbon loop.

Escorting his distinguished visitor to the library, Mr. Edison first explained the science of the light, and then, by reference to maps of the district that his engineers are preparing for the experiment, the application of his system to the practical requirements of a city. The region to be lighted will require 22,000 lights, all of which are to be supplied from a central station in Pearl street, where 12 engines of 185 horse power are to be placed. Ten of these will be in constant operation, the other two being held in reserve to meet the emergencies of accident. The engines will be run at a rate of speed equal to that of a locomotive at 60 miles an hour, and a new feature of the system is that no belts are employed to transmit the power to the dynamo-electric generators, and the power is applied directly, avoiding the irregularity and vibration arising from the slipping of the belt which seems inseparable from the old practice. The mains consist of large iron pipes, in which the crescent-shaped positive and negative conductors are carried, being insulated from such by means of a non-conducting material with which the pipes are filled when in a pasty condition, induced by heat, but which hardens like a concrete pavement in the process of cooling. These mains in their passage through the streets are all connected with each other by means of ingenious connection boxes, the whole forming a subterranean net-work of electrical conductors comparable to the capillary circulation in the skin of an animal body.

His Majesty listened with intense but almost silent interest, and examined the cross-sections of the electrical mains and the interior arrangement of the connection boxes with critical closeness, now and then asking a question in the purest English imaginable, and with a voice that was strikingly low, mellow, and muscial, and yet so sharply defined in the articulation of the consonants as to impress the ear at an unusual distance. He seemed particularly interested in the statement that after steam power had been transformed into electricity and carried to a great distance in that form it could again be converted into motive power by means of an electrical motor, and sold to customers for the purpose of running elevators or operating hoist-ways. His eyes lighted when he was told that one of the most profitable departments of the business of the company would be the sale of power to manufactories and business firms in quantities as small as a single horse-power, costing, under circumstances of ordinary use, not more than eight cents a day.

From the library Mr. Edison led the way to the front parlor, brilliantly lighted. Pressing the toe of his shoe upon a knob projecting from the floor, every lamp was instantaneously extinguished and as suddenly blazed out again. The inventor next turned the stop-cock of a single lamp among the group and extinguished it. The party then ascended to the upper floor, where more wonders were in store, and then descended two flights beneath the street level, where, in a low-ceiled vault, a small engine was operating, with nearly absolute silence, a generator whose cylinder performed 1200 revolutions per minute. After inspecting every detail, his Majesty took leave of the inventor, and repaired to his carriage. One of the points that appeared to impress him most was the steadiness of the light, and its freedom from vibration.—*N. Y. Times*.

TEACHING OF CHEMISTRY AND PHYSICS IN THE UNITED STATES.*

II.

In normal schools, the time which can be assigned to work in chemistry and physics is necessarily limited; it becomes then all-important that it should be of the right sort. As Professor Clarke points out, it is not the purpose of such schools to train specialists in any one department of learning, neither should they attempt to give a broad general education. The sole function of a normal school is to fit students for the profession of teaching.

The Bureau of Education has taken pains to enquire how far the scientific work in normal schools has complied with the plan which was originally formed to preserve them within their original functions.

On this point the report states that:

"An examination of the evidence presented in this report will show a great diversity among the various normal schools with respect to chemistry and physics. By far the larger number of them treat these sciences exactly as they are treated in secondary institutions and the smaller colleges; that is, they teach the elements of both subjects, partly by text books and partly by lectures; a few experiments are exhibited, and laboratory work on the part of the students is entirely ignored. In other words, the practice of these schools with reference to the sciences does not accord with the theory upon which they were originally founded."

A small number of normal schools, however,

"Adopt a more rational policy. Recognizing the fact that their students may be called upon to teach chemistry and physics, they endeavor to train them intelligently in methods of instruction."

Respecting instruction in chemistry and physics in universities, colleges and schools of science, much interesting matter is presented, giving in detail the actual work done in these branches of science at the most important institutions of this character.

The general conclusion drawn by Professor Clarke on the character of scientific instruction in universities and colleges is not favorable to such establishments. He says:

"Many high schools are actually doing more and better work with these sciences than is done in a very considerable number of colleges bearing good reputations."

The low standard of scientific work in universities and colleges is attributed by the report to persistent use "of the old-fashioned plan of a fix curriculum."

"Clearly these colleges could, if they would, build upon the work of the preparatory schools as a foundation, and, with no more cost of time, carry their pupils much further than they do now. The present subordinate position of scientific studies is undoubtedly due to the continuation in so many localities of the old-fashioned plan of a fixed curriculum. Given a college in which the latter still holds its own and in which the classics and mathematics have been for many years the dominant subjects of study, and we have an institution wherein but little time can be given to any one of the sciences. One term, from a third to half an academic year in length, is all that is usually allowed to chemistry. This is absurdly inadequate as one term in Latin or one term in mathematics, with no previous preparation, would be. By this system the sciences are not only underrated, but smattering is directly encouraged. The student trained in it can have no definite idea of scientific methods, scientific reasoning, or the scientific spirit. Even the professor in charge of the sciences may be himself a smatterer, teaching several branches without ever having received a systematic training in any one of them. Such teachers, who keep ahead of their classes by only a few lessons, are unfortunately very common, and with them the modern laboratory methods are simply impossible."

Professor Clarke may be correct in these general conclusions, but it is agreeable to refer to the many honorable exceptions, colleges where scientific instruction is offered on the most liberal and enlightened basis.

It would be difficult to take exception to the courses of study in Chemistry and Physics at Columbia College, New York City, where the collection of physical apparatus is the finest in the country, and three laboratories provided for the use of students.

The instruction in Physics and Chemistry at the school of mines of this college is thus described in the report:—

Physics.—Professor, O. N. Rood; mechanics is taught by Professor William G. Peck. The first year students, in the first term, take up the subject of heat, including the steam engine, and acoustics. In the second term they study optics, electricity and magnetism. The courses are illustrated by experiments and problems and are pre-

* Circulars of Information of the Bureau of Education No. 6. 1881.
A report on the teaching of Chemistry and Physics in the United States, by Frank Wigglesworth Clarke, S. B., Professor of Chemistry and Physics in the University of Cincinnati. Washington, 1881.

scribed for all students. To the third year class, lectures are delivered upon electro-statics, the mechanical theory of heat, mathematical optics, and the undulatory theory of light. Some of the lectures are accompanied by experimental demonstrations. This course is required of all students except those in chemistry, with whom it is optional.

Mechanics is taught in the third year to the students in mining engineering, civil engineering, and metallurgy. The mechanics of solids is studied in the first term and the mechanics of fluids in the second.

No physical laboratory work is mentioned in the handbook of information.

Chemistry.—Professor, C. F. Chandler; instructors, Elwyn Waller, Pierre De Peyster Ricketts, Alexis A. Julien, James S. C. Wells, Henry C. Bowen, Francis N. Holbrook, and Louis H. Laudy. General inorganic chemistry, stoichiometry, qualitative analysis, quantitative analysis, and blowpiping are required studies in all the courses. Assaying is taught to students in mining, metallurgy, and chemistry. In the geological and chemical courses, organic chemistry is studied. The chemical students have also a large amount of work in applied chemistry. Quantitative blowpipe analysis is an optional study in all of the courses.

In general chemistry the first year students attend three exercises a week throughout the year. This course is preliminary to practical instruction in the laboratory. The students are drilled upon the lectures, with free use of the best text books, and take notes which must be submitted to the professor. At the end of the year there is a rigid examination. The second class also attend three times a week during the year, and receive instruction in theoretical chemistry adapted to the needs of special scientific students.

For analytical chemistry there are three laboratories, one for qualitative analysis, one for quantitative analysis, and a third for assaying. Each of these is thoroughly equipped and is in the special charge of an instructor with an assistant. Every student is provided with a convenient table containing drawers and cupboards, and is supplied with a complete outfit of apparatus and reagents. The laboratories are open daily, except Saturdays, Sundays, holidays, and vacations, from 10 A. M. to 4 P. M.

During the second year, qualitative analysis is taught by lectures, blackboard exercises, and constant laboratory practice. The spectroscope is freely used. When the student shows, by written and experimental examination, that he is sufficiently familiar with qualitative work, he is allowed to enter the quantitative laboratory. In the third and fourth years, quantitative analysis is taught, the laboratory exercises being accompanied still by lectures and blackboard work. The laboratory course is graded after the usual manner, the student beginning with comparatively simple substances of known composition and passing on by degrees to the analysis of more complex bodies, such as coals, pig iron, various ores, slags, mattes, and so on. Both volumetric and gravimetric methods are employed. In the fourth year the student is admitted to the assay laboratory, where he is furnished with a suitable table and a set of assaying apparatus. Here he has access to crucible and muffle furnaces and to volumetric apparatus for the assay of alloys of gold and silver. The general principles and special methods of assaying are described in the lecture-room, and at the same time the ores of the various metals and their appropriate fluxes are exhibited and described. The student is then supplied with different ores and is required to assay each ore in duplicate under the supervision of the instructor.

Stoichiometry is taught, by lectures and blackboard exercises, as a part of the course in general chemistry, through the first and second years; and its practical applications are developed in lectures upon quantitative analysis and assaying.

In applied chemistry, the instruction extends through the third and fourth years and consists of lectures illustrated by experiments, diagrams, and specimens. The cabinet of industrial chemistry is very large and complete, containing several thousand specimens and materials and products.

It will be noticed that the course of study at this college is thorough, practical and technical, "the design being to train analysts and technologists." Professor Chandler has brought to bear in this work the full weight of his well-known administrative abilities, and the School of Mines of the City of New York may well be taken as a model for all future establishments of the same class on this continent.

A perusal of this report will make the fact evident, that in this country ample facilities exist for the most thorough instruction in both Physics and Chemistry, and the record shows that since the year 1865 the course of instruction in these departments of science has been one of continuous progress.

Of Columbia College, New York, we have spoken, but it might appear that we made an invidious selection if we did not refer to other prominent centres ot physical and chemical research. Among many of such we may name the Massachusetts Institute of Technology; the Stevens Institute, Hoboken; the Universities of Pennsylvania, Virginia and Cincinnati; Yale, Harvard and the Johns Hopkins University. To-day the higher chemistry can be studied in a score of places where twenty years ago no adequate facilities were offered, and the modern physics, with its mathematical methods and its laboratories, is rapidly coming into vogue.

One other feature of the new movement remains to be mentioned, namely, the spread of scientific teaching downward into the secondary schools. These, too, are organizing laboratories, teaching young scholars to see and experiment for themselves, preparing the way for higher work, and rendering the latter more easily possible. The "summer schools" of chemistry at Harvard and elsewhere, the Woman's

Laboratory at the Massachusetts Institute of Technology, and such-like enterprises are doing much in this direction. To-day Chemistry and Physics are taught in nearly all the academies and high schools of the land; so that the larger colleges, whenever they see fit, may easily require from the candidate for admission a wider knowledge of these sciences than they themselves taught a dozen years ago. When and in what manner the present scientific movement shall culminate, no one can say; but the fact of growth is evident everywhere. This report is an attempt to catch the present aspect of affairs and fix it in a permanent record.

ON THE SOURCES OF ENERGY IN NATURE AVAILABLE TO MAN FOR THE PRODUCTION OF MECHANICAL EFFECT.*

By Sir William Thomson, F. R. S.

During the fifty years' life of the British Association, the advancement of Science for which it has lived and worked so well has not been more marked in any department than in one which belongs very decidedly to the Mathematical and Physical Section—the science of Energy. The very name energy, though first used in its present sense by Dr. Thomas Young about the beginning of this century, has only come into use practically after the doctrine which defines it had, during the first half of the British Association's life, been raised from a mere formula of mathematical dynamics to the position it now holds of a principle pervading all nature and guiding the investigator in every field of science.

A little article communicated to the Royal Society of Edinburgh a short time before the commencement of the epoch of energy under the title "On the Sources Available to Man for the Production of Mechanical Effect,"† contained the following:

"Men can obtain mechanical effect for their own purposes by working mechanically themselves, and directing other animals to work for them, or by using natural heat, the gravitation of descending solid masses, the natural motions of water and air, and the heat, or galvanic currents, or other mechanical effects produced by chemical combination, but in no other way at present known. Hence the stores from which mechanical effect may be drawn by man belong to one or other of the following classes:

"I. The food of animals.

"II. Natural heat.

"III. Solid matter found in elevated positions.

"IV. The natural motions of water and air.

"V. Natural combustibles (as wood, coal, coal-gas, oils, marsh-gas, diamond, native sulphur, native metals, metoric iron.)

"VI. Artificial combustibles (as smelted or electrically-deposited metals, hydrogen, phosphorus).

"In the present communication, known facts in natural history and physical science, with reference to the sources from which these stores have derived their mechanical energies, are adduced to establish the following general conclusions:

"1. *Heat radiated from the sun* (sunlight being included in this term) *is the principal source of mechanical effect available to man.*‡ From it is derived the whole mechanical effect obtained by means of animals working, water-wheels worked by rivers, steam-engines, galvanic engines, wind-mills, and the sails of ships.

"2. The motions of the earth, moon, and sun, and their mutual attractions, constitute an important source of available mechanical effect. From them all, but chiefly no doubt from the earth's motion of rotation, is derived the mechanical effect of water-wheels driven by the tides.

"3. The other known sources of mechanical effect available to man are either terrestrial—that is, belonging to the earth, and available without the influence of any external body—or meteoric—that is, belonging to bodies deposited on the earth from external space. The terrestrial sources, including mountain quarries and mines, the heat of hot springs, and the combustion of native sulphur, perhaps also the combustion of inorganic native combustibles, are actually used; but the mechanical effect obtained from them is very inconsiderable, compared with that which is obtained from sources belonging to the two classes mentioned above. Meteoric sources, including only the heat of newly-fallen meteoric bodies, and the combustion of meteoric iron, need not be reckoned among those available to man for practical purposes."

Thus we may summarize the natural sources of energy as Tides, Food, Fuel, Wind and Rain.

Among the practical sources of energy thus exhaustively enumerated, there is only one not derived from sun-heat—that is the tides. Consider it first. I have called it *practical*, because tide mills exist, but the places where they can work usefully are very rare, and the whole amount of work actually done by them is a drop to the ocean of work done by other motors. A tide of two meters' rise and fall, if we imagine it utilized to the utmost by means of ideal water wheels doing, with perfect economy, the whole work of filling and emptying a dock basin in infinitely short times, at the moments of high and low water, would give just one metre-ton per square metre of area. This work done four times in the twenty-four hours, amounts to 1.1620th of the work of a horse-power. Parenthetically, in explanation, I may say that the French metrical equivalent (to which in all scientific and practical measurements we are irresistibly drawn, notwithstanding a dense barrier of insular prejudice most detrimental to the islanders),—the French metrical equivalent of James Watt's "horse-power" of 550 foot-pounds per second, or 33,000 foot-pounds per minute, or nearly 2,000,000 foot-pounds per hour, is 75 metre-kilogrammes per second, or 4½ metre-tons per minute, or 270 metre-tons per hour. The French ton of 1000 kilos, used in this reckoning, is 0.984 of the British ton.

Returning to the question of utilizing tidal energy, we find a dock area of 162,000 square metres (which is little more than 400 metres square) required for 100-horse power. This, considering the vast costliness of dock construction, is obviously prohibitory of every scheme for economizing tidal energy by means of artificial dock basins, however near to the ideal perfection might be the realized tide-mill, and however convenient and non-wasteful the acumulator—whether Faure's electric accumulator, or other accumulators of energy hitherto invented, or to be invented,—which might be used to store up the energy yielded by the tide mill during its short harvests about the times of high and low water, and to give it out when wanted at other times of six hours. There may, however, be a dozen places possible in the world where it could be advantageous to build a sea-wall across the mouth of a natural basin or estuary, and to utilize the tidal energy of filling it and emptying it by means of sluices and water-wheels. But if *so* much could be done, it would in many cases take only a little more to keep the water out altogether, and make fertile land of the whole basin. Thus we are led up to the interest-

* British Association, 1881.

† Read at the Royal Society of Edinburgh on February 2, 1852. (*Proceedings* of that date.)

‡ A general conclusion equivalent to this was published by Sir John Herschel in 1833. See his "Astronomy," edit. 1849, § (399.)

ing economical question, whether is 40 acres (the British *agricultural* measure for the area of 162,000 square metres) or 100 horse-power more valuable? The annual cost of 100 horse-power night and day for 365 days of the year, obtained through steam from coals, may be about ten times the rental of forty acres, at £2 or £3 per acre. But the value of land is essentially much more than its rental, and the rental of land is apt to be much more than £2 or £3 per acre in places where 100 horse-power could be taken with advantage from coal through steam. Thus the question remains unsolved, with the possibility that in one place the answer may be *one hundred horse power*, and in another *forty acres*. But, indeed, the question is hardly worth answering, considering the rarity of the cases, if they exist at all, where embankments for the utilization of tidal energy are practicable.

Turning now to sources of energy derived from sun-heat, let us take the wind first. When we look at the register of British shipping, and see 40,000 vessels, of which about 10,000 are steamers and 30,000 sailing ships, and when we think how vast an absolute amount of horse-power is developed by the engines of those steamers, and how considerable a proportion it forms of the whole horse-power taken from coal annually in the whole world at the present time, and when we consider the sailing ships of other nations, which must be reckoned in the account, and throw in the little item of windmills, we find that, even in the present days of steam ascendancy, old-fashioned wind still supplies a large part of all the energy used by man. But however much we may regret the time when Hood's young lady, visiting the fens of Lincolnshire, at Christmas, and writing to her dearest friend in London (both sixty years old if they are now alive), describes the delight of sitting in a bower and looking over the wintry plain, not desolate, because "windmills lend revolving animation to the scene," we cannot shut our eyes to the fact of a lamentable decadence of wind-power. Is this decadence permanent, or may we hope that it is only temporary? The subterranean coal stores of the world are becoming exhausted surely, and not slowly, and the price of coal is upward bound—upward bound on the whole, though no doubt it will have ups and downs in the future as it has had in the past, and as must be the case in respect to every marketable commodity. When the coal is all burned, or long before it is all burned—when there is so little of it left, and the coal mines from which that little is to be excavated are so distant and deep and hot that its price to the consumer is greatly higher than at present, it is most probable that wind-mills or wind motors in some form, will again be in the ascendant, and that wind will do man's mechanical work on land at least, in proportion comparable to its present doing of work at sea.

Even now, it is not utterly chimerical to think of wind superseding coal in some places for a very important part of its present duty—that of giving light. Indeed, now that we have dynamos and Faure's accumulator, the little want to let the thing be done is cheap windmills. A Faure cell containing 20 kilos. of lead and minium charged and employed to excite incandescent vacuum-lamps has a light-giving capacity of 60 candle hours (I have found considerably more in experiments made by myself; but I take sixty as a safe estimate). The charging may be done uninjuriously, and with good dynamical economy in any time from six to twelve hours or more. The drawing off of the charge for use may be done safely, but somewhat wastefully, in two hours, and very economically in any time of from five hours to a week, or more. Calms do not last often longer than three or four days at a time. Suppose, then, that a five-days storage capacity, suffices (there may be a little steam engine ready to set to work at any time after a four days' calm, or the user of the light may have a few candles or oil lamps in reserve and be satisfied with them when the wind fails for more than five days.) One of the 20-kilo. cells charged when the windmill works, for five or six hours at any time and left with its 60 candle-hours' capacity to be used six hours a day for five days, gives a 2-candle light Thus thirty-two such accumulator cells soused would give as much light as four burners of London 16-candle gas. The probable cost of dynamo and accumulator does not seem fatal to the plan, if the windmill could be had for something comparable with the prime cost of a steam engine capable of working at the same horse power as the wind mill when in good action. But wind mills as hitherto made are very costly machines; and it does not seem probable that without inventions not yet made, wind can be economically used to give light in any considerable class of cases, or to put energy into store for other kinds of work.

Consider, lastly, rain-power. When it is to be had in places where power is wanted for mills and factories of any kind, water-power is thoroughly appreciated. From time immemorial, water-motors have been made in large variety for utilizing rain-power in the various conditions, in which it is presented, whether in rapdidly-flowing rivers in natural waterfalls, or stored at heights in natural lakes or artificial reservoirs. Improvements and fresh inventions of machines of this class still go on; and some of the finest principles of mathematical hydrodynamics have, in the lifetime of the British Association, and, to a considerable degree with its assistance, been put in requisition for perfecting the theory of hydraulic mechanism and extending its practical applications.

A first question occurs: Are we necessarily limited to such natural sources of water-power as are supplied by rain falling on hill-country, or may we look to the collection of rain-water in tanks placed artificially at sufficient heights over flat country to supply motive power economically by driving water-wheels? To answer it: Suppose a height of 100 metres, which is very large for any practicable building, or for columns erected to support tanks; and suppose the annual rainfall to be three-quarters of a metre (30 inches). The annual yield of energy would be 75 metre-tons per square metre of the tank. Now one horse-power for 365 times 24 hours is 236,500 foot-tons; and therefore, dividing this by 75, we find 3153 sq. metres as the area of our supposed tank required for a continuous supply of one horse-power. The prime cost of any such structure, not to speak of the value of the land which it would cover, is utterly prohibirory of any such plan for utilizing the motive power of rain. We may or may not look forward hopefully to the time when windmills will again "lend revolving animation" to a dull flat country; but we certainly need not be afraid that the scene will be marred by forests of iron columns taking the place of natural trees, and gigantic tanks overshadowing the fields and blackening the horizon.

To use rain-power economically on any considerable scale we must look to the natural drainage of hill country, and take the water where we find it either actually falling or stored up and ready to fall when a short artificial channel or pipe can be provided for it at moderate cost. The expense of acqueducts, or of underground water-pipes, to carry water to any great distance—any distance of more than a few miles or a few hundred yards—is much too great for economy when the yield to be provided for is *power*; and such works can only be undertaken when the *water itself* is what is wanted. Incidentally, in connection with the water supply of towns, some part of the energy due to the head at which it is supplied may be used for power. There are, however, but few cases (I know of none except Greenock) in which the energy to spare over and above that devoted to bringing the water to where it is wanted, and causing it to flow fast enough for convenience at every opened tap in every house or factory, is enough to make it worth while to make arrangements for letting the water-power be used without wasting the water-substance. The cases in which water-power

is taken from a town supply are generally very small, such as working the bellows of an organ, or "hair-brushing by machinery," and involve simply throwing away the used water. The cost of energy thus obtained must be something enormous in proportion to the actual quantity of the energy, and it is only the smallness of the quantity that allows the convenience of having it when wanted at any moment, to be so dearly bought.

For anything of great work by rain-power, the water-wheels must be in the place where the water supply with natural fall is found. Such places are generally far from great towns, and the time is not yet come when great towns grow by natural selection beside waterfalls for power; as they grow beside navigable rivers, for shipping. Thus hitherto the use of water-power has been confined chiefly to isolated factories which can be conveniently placed and economically worked in the neighborhood of natural waterfalls. But the splendid suggestion made about three years ago by Mr. Siemens in his presidential address to the institution of Mechanical Engineers, that the power of Niagara might be utilized, by transmitting it electrically to great distances, has given quite a fresh departure for design in respect to economy of rain-power. From the time of Joule's experimental electro-magnetic engines developing 90 per cent of the energy of a Voltaic battery in the form of weights raised, and the theory of the electro-magnetic transmission of energy completed thirty years ago on the foundation afforded by the train of experimental and theoretical investigations by which he established his dynamical equivalent of heat in mechanical, electric, electro-chemical, chemical, electro-magnetic, and thermoclastic phenomena, it had been known that potential energy from any available source can be transmitted electro-magnetically by means of an electric current through a wire, and directed to raise weights at a distance, with unlimitedly perfect economy. The first large-scale practical application of electro-magnetic machines was proposed by Holmes in 1854, to produce the electric light for lighthouses, and persevered in by him till he proved the availibility of his machine to the satisfaction of the Trinity House and the delight of Faraday in trials at Blackwall in April, 1857, and it was applied to light the South Foreland lighthouse on December 8, 1858. This gave the impulse to invention; by which the electro-magnetic machine has been brought from the physical laboratory into the province of engineering, and has sent back to the realm of pure science a beautiful discovery—that of the fundamental principle of the dynamo, made triply and independently, and as nearly as may be simultaneously, in 1867 by Dr. Werner Siemens, Mr. S. A. Varley, and Sir Charles Wheatstone; a discovery which constitutes an electro-magnetic analogue to the fundamental electrostatic principle of Nicholson's revolving doubler, resuscitated by Mr. C. F. Varley in his instrument "for generating electricity;" patented in 1860; and by Holtz in his celebrated electric machine; and by myself in my "replenisher" for multiplying and maintaining charges in Leyden jars for heterostatic electrometers, and in the electrifier for the siphon of my recorder for submarine cables.

The dynamos of Gramme and Siemens, invented and made in the course of these fourteen years since the discovery of the fundamental principle, give now a ready means of realizing economically on a large scale, for many important practical applications, the old thermo-dynamics of Joule in electro-magnetism; and, what particularly concerns us now in connection with my present subject, they make it possible to transmit electro-magnetically the work of waterfalls through long insulated conducting wires, and use it at distances of fifties or hundreds of miles from the source, with excellent economy—better economy, indeed, in respect to proportion of energy used to energy dissipated than almost anything known in ordinary mechanics and hydraulics for distances of hundreds of yards instead of hundreds of miles.

In answer to questions put to me in May, 1879,* by the Parliamentary Committee on Electric Lighting, I gave a formula for calculating the amount of energy transmitted, and the amount dissipated by being converted into heat on the way, through an insulated copper conductor of any length, with any given electro-motive force applied to produce the current. Taking Niagara as example, and with the idea of bringing its energy usefully to Montreal, Boston, New York, and Philadelphia, I calculated the formula for the distance of 300 British statute miles (which is greater than the distance of any of those four cities from Niagara, and is the radius of a circle covering a large and very important part of the United States and British North America), I found almost to my surprise that, even with so great a distance to be provided for, the conditions are thoroughly practicable with good economy, all aspects of the case carefully considered. The formula itself will be the subject of a technical communication to Section A in the course of the meeting on which we are now entering. I therefore at present restrict myself to a slight statement of results.

1. Apply dynamos driven by Niagara to produce a difference of potential of 80,000 volts between a good earth connection and the near end of a solid copper wire of half an inch (1.27 centimetre) diameter, and 300 statute miles (483 kilometres) length.

2. Let resistance by driven dynamos doing work, or by electric lights, or, as I can now say, by a Faure battery taking in a charge, be applied to keep the remote end at a potential differing by 64,000 volts from a good earth-plate there.

3. The result will be a current of 240 webers through the wire taking energy from the Niagara end at the rate of 26,250 horse-power, losing 5250 (or 20 per cent) of this by the generation and dissipation of heat through the conductor and 21,000 horse-power (or 80 per cent of the whole) on the recipients at the far end.

4. The elevation of temperature above the surrounding atmosphere, to allow the heat generated in it to escape by radiation and be carried away by convection is only about 20° Centigrade; the wire being hung freely exposed to air like an ordinary telegraph wire supported on posts.

5. The striking distance between flat metallic surfaces with difference of potentials of 80,000 volts (or 75,000 Daniell's) is (Thomson's "Electrostatics and Magnetism." § 340) only 18 millimetres, and therefore there is no difficulty about the insulation.

6. The cost of the copper wire, reckoned at 8d. per lb., is £37,000, the interest on which at 5 per cent is £1900 a year, If 5250 horse-power at the Niagara end costs more than £1900 a year, it would be better economy to put more copper into the conductor; if less, less. I say no more on this point at present, as the economy of copper for electric conduction will be the subject of a special communication to the Section.

I shall only say, in conclusion, that one great difficulty in the way of economizing the electrical transmitting power to great distances, or even to moderate distances of a few kiloms., is now overcome by Faure's splendid invention. High potential—as Siemens, I believe, first pointed out—is the essential for good dynamical economy in the electric transmission of power. But what are we to do with 80,000 volts when we have them at the civilized end of the wire? Imagine a domestic servant going to dust an electric lamp with 80,000 volts on one of its metals? Nothing above 200 volts ought on any account ever to be admitted into a house or ship or other place where safeguard against accident cannot be made absolutely and forever trustworthy against all possibility of accident. In an electric workshop 80,000 volts is no more dangerous than a circular saw. Till I learned Faure's invention I could but think of step-down dynamos, at a main receiving station to take energy direct from the electic main

* Printed in the Parliamentary Blue-book Report of the Committee on Electric Lighting, 1879.

with its 80,000 volts, and supply it by secondary 200-volt dynamos or 100-volt dynamos, through proper distributing wires, to the houses and factories and shops where it is to be used for electric lighting, and sewing machines, and lathes, and lifts, or whatever other mechanism wants driving power. Now the thing is to be done much more economically, I hope, and certainly with much greater simplicity and regularity, by keeping a Faure battery of 40,000 cells always being charged direct from the electric main, and applying a methodical system of removing sets of 50, and placing them on the town-supply circuits, while other sets of 50 are being regularly introduced into the great battery that is being charged, so as to keep its number always within 50 of the proper number, which would be about 40,000 if the potential at the emitting end of the main is 80,000 volts.

ON THE ARRESTATION OF INFUSORIAL LIFE.*

By Prof. Tyndall.

Three years ago I brought with me to the Alps a number of flasks charged with animal and vegetable infusions. The flasks had been boiled from three to five minutes in London, and hermetically sealed during ebullition. Two years ago I had sent to me to Switzerland a batch of similar flasks containing other infusions. On my arrival here this year 120 of these flasks lay upon the shelves in my little library. Though eminently putrescible, the animal and vegetable juices had remained as sweet and clear as when they were prepared in London. Still an expert taking up one of the flasks containing an infusion of beef or mutton would infallibly pronounce it to be charged with organisms. He would find it more or less turbid throughout, with massive flocculi moving heavily in the liquid. Exposure of the flask for a minute or two to lukewarm water would cause both turbitity and flocculi to disappear, and render the infusion as clear as the purest distilled water. The turbidity and flocculi are simply due to the coagulation of the liquid to a jelly. This fact is some guarantee for the strength of the infusions. I took advantage of the clear weather this year to investigate the action of solar light on the development of life in these infusions, being prompted thereto by the interesting observations brought before the Royal Society by Dr. Downs and Mr. Blunt, in 1877. The sealed ends of the flasks being broken off, they were infected in part by the water of an adjacent brook, and in part by an infusion well charged with organisms. Hung up in rows upon a board, half the flasks of each row were securely shaded from the sun, the other half being exposed to the light. In some cases, moreover, flasks were placed in a darkened room within the house, while their companions were exposed in the sunshine outside. The clear result of these experiments, of which a considerable number were made, is that by some constituent or constuents of the solar radiation an influence is exercised inimical to the development of the lowest infusoria. Twenty-four hours usually sufficed to cause the shaded flasks to pass from clearness to turbidity, while thrice this time left the exposed ones without sensible damage to their transparency. This result is not due to mere differences of temperature between the infusions. On many occasions the temperature of the exposed flasks was far more favorable to the development of life than that of the shaded ones. The energy which in the cases here referred to prevented putrefaction was energy in the radiant form. In no case have I found the flasks sterilized by insolation, for on removing the exposed ones from the open air to a warm kitchen they infallibly changed from cleaness to turbidity. Four and twenty hours were in most cases sufficient to produce this change. Life is, therefore, prevented from developing itself in the infusions as long as they are exposed to the solar light, and the paralysis thus produced enables them to pass through the night time without alteration. It is, however, a suspension, not a destruction, of the germinal power, for, as before stated, when placed in a warm room life was invariably developed. Had I had the requisite materials I should like to have determined by means of colored media, or otherwise, the particular constituents of the solar radiation which are concerned in this result. The rays, moreover, which thus interfere with life must be absorbed by the liquid or by its germinal matter. It would therefore be interesting to ascertain whether, after transmission through a layer of any infusion, the radiation still possessed the power of arresting the development of life in the same infusion. It would also be interesting to examine how far insolation may be employed in the preservation of meat from putrefaction. I would not be understood to say that it is impossible to sterilize an infusion by insolation, but merely to indicate that I have thus far noticed no case of the kind.

* British Association, 1881.

PLANTÉ'S RHEOSTATIC MACHINE.*

Translated from the French by the Marchioness Clara Lanza.

Ruhmkorff's electric induction machine has proved in the most satisfactory manner that by the intermediary of inductive action, we can transform voltaic electricity into electricity of high tension. M. Bichat has likewise shown that by the same means, currents of high tension can be changed to currents of quantity, analogous to voltaic currents. M. Planté, with his secondary piles, has rendered this demonstration still more emphatic, and as his experiments demanded a greater tension than he was able to produce with his batteries, he undertook the manufacture of an apparatus by which he could obtain veritable discharges of static electricity, capable of forming at will, long thread-like sparks, or short, thick ones. In this way he was induced to make the battery of which we are about to speak, and which he calls the *rheostatic machine.*

Although this apparatus (fig. 1) was presented to the Academy of Sciences and exhibited to most of the physicians who witnessed M. Planté's fine experiments, it is as yet, but little known. Why this should be the case we are at a loss to understand, for it is one of the most perfect machines that can be employed in experiments of static electricity. Had the apparatus borne a foreign name, we are confident it would have attracted considerable attention long ago. It is much to be regretted that we are so constituted in France, that whatever is invented by an unknown man, a *savant* who does not rejoice in an established position or who is not a member of some scientific coterie originating from a celebrated school, is looked upon entirely as a matter of subordinate interest. "It is only an amateur's work," we hear on all sides for awhile and then the subject is dropped forever. In England it is quite different. Amateurs such as Grove, Gassiot, Warren, Delarue, Spottiswoode, Lords, Ross, Lindsay, Raleigh, Elphinstone and many others, find their efforts are appreciated as they deserve to be, and no one ever thinks of inquiring whether they are *savants* patented by the government or not.

M. Planté therefore, not being among the last-mentioned, was forced to meet with indifference which he forcibly overcame later by the fine work he performed with his accumulators. He was not so successful, unfortunately, with his rheostatic machine, and for this reason we shall dwell a little upon the important results it has afforded us.

M. Planté's machine consists of a series of condensers with mica plates, parallel one with the other and capable of being charged and discharged in a manner similar to his secondary batteries without any other alimentary electric source than these latter.

The various pieces composing the apparatus must be

* *La Lumière Electrique*, August 6th, 1881.

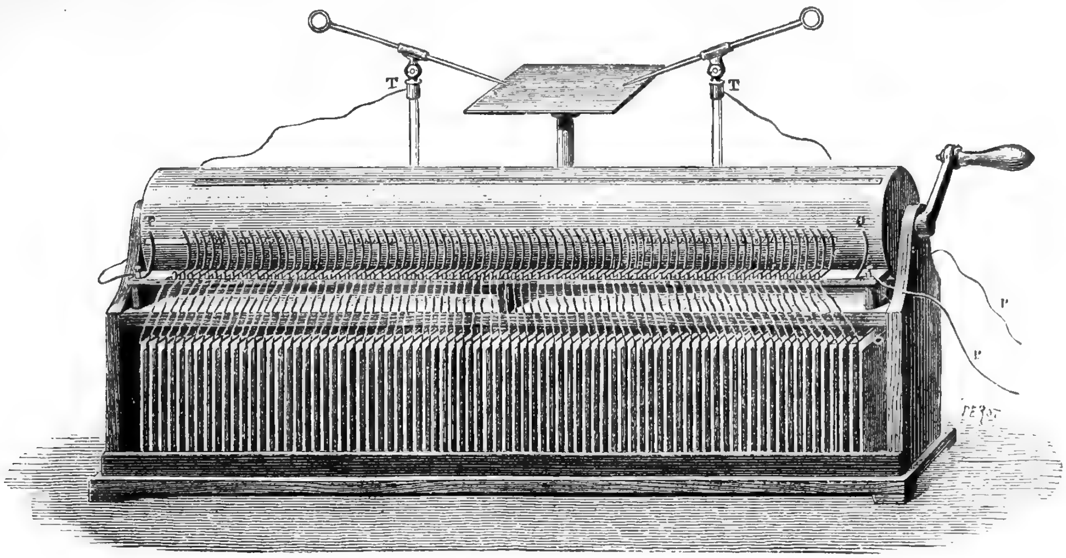

FIG. 1.

taken apart with great care. The commutator is formed of a long cylinder made of hard rubber. It is furnished with longitudinal metallic bands destined to connect the surface condensers, and crossed by pieces of copper wire bent at the ends, the object of the latter being to unite the condensers of tension. To this end, metallic wires, fashioned like springs, rest upon the cylinder and are associated with the two armatures of each condenser by very fine copper wires covered with gutta-percha. They are attached to an ebonite plaque on each side of the cylinder, and the latter can be made to rotate rapidly and continuously by means of a set of wheels. The final springs are separated considerably from those preceding them, in order to prevent the electric sparks from discharging between the tension poles of the rheostatic machine and those of the secondary battery.

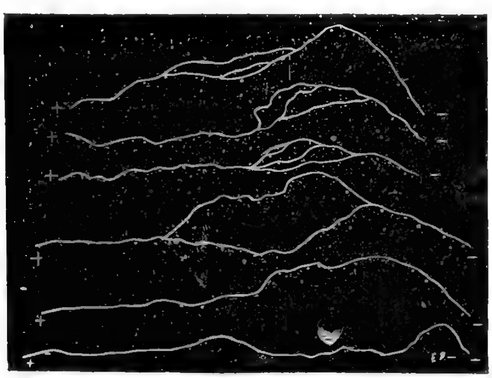

FIG. 2.

The mica plates in the condensers are 0^m 18 in length and 0^m 14 in breadth. The armatures are made of tinfoil. The edges of the condensers are rendered adherent by frames or simple ebonite plaques. These give them more rigidity and cause them more readily to maintain a vertical position, one beside the other, without coming in contact.

When the cylinder is so turned that the longitudinal metallic bands come in juxtaposition with the springs, the armatures in an even range with all the condensers unite on one side, while those in an uneven range are joined on the other, forming a single condenser of large surface. The armatures discharge by causing the right hand boundaries, which can be easily distinguished in the figure, to communicate with the poles of the battery.

When, on the contrary, the cylinder is so turned that its transversal pins are presented to the springs, all the charged condensers are connected in a series or in tension. The armature of the furthest condenser on the left, communicates with the last spring on the other side of the cylinder and ends at branch T of the excitant. The armature of the final condenser on the right communicates with the spring next to the last, and this spring unites with the last metallic pin traversing the cylinder. The last spring placed in the opposite side of the cylinder communicates with the other branch T′ of the excitant. While the condensers are thus connected, the pole, or battery, which charges the apparatus, is entirely beyond the circuit.

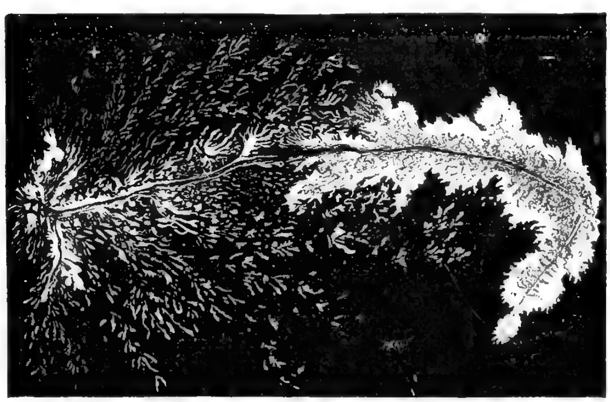

FIG. 3.

M. Planté has constructed rheostatic machines of different sizes. The one here represented is supplied with eighty condensers. The commutative cylinder is is one meter long and $0^m.15$ in diameter.

When this cylinder is put in motion and the machine connected with the battery of 800 secondary couples, we perceive, as the charge begins to act upon the commutator, long lines of sparks at those points where the metallic contact is effected. It becomes a tube of sparkling light and the effect is equally apparent when the discharge in tension occurs. At the same time we obtain a long spark at the excitant T T′.

Sparks produced by this machine attain, when fully exposed to the air, a length of 12 centimetres when influenced by the secondary battery of 800 couples. With less powerful machines, however, the length is reduced, and, according to M. Planté, it will be *in proportion to the number of condensers.* When a spark discharges across metallic filings it sometimes reaches the length of 70 centimetres.

We must remark here that discharges produced in this way have no alternate positive and negative sense, but are always the same. The loss of force resulting from the transformation should, therefore, be less than in induction machines; for as the Voltaic circuit is never closed upon itself for a single instant, no portion of the current is converted into a calorific effect. The machine, moreover, can be kept rotating for a long time and it produces a considerable number of discharges without any apparent weakness being visible on the part of the secondary battery.

The most interesting effects studied by M. Planté, by means of the sparks of this machine, were obtained by causing them to pass over pulverized sulphur in a compound of sulphur and minium. If these powders are spread upon a surface composed of resin and paraffine (1/10) the sparks, while passing over the sulphur, leave a bluish line distinctly visible, as though traced in black lead. This gives us an exact autograph, we may say, of the spark's course. It is easily effaced, however, by being rubbed. But if carefully followed and indented with some sharp pointed instrument it can be rendered intact. Afterwards we can study it thoroughly by tracing a drawing of it. The sparks represented by Fig. 2 were produced as above described.

When we come to investigate these sparks, we find, according to M. Planté, that when they have not the maximum of length which they are capable of attaining, they often display enclosed branches resembling *anastomoses*, and which are likely to escape while our attention is fixed upon the luminous track. Their sinuosities are always rounded, and that angular zig-zag, which is apparent in most electric sparks, is never seen. It is true that this form is sometimes indicated by effects of perspective when the flash is at the horizon. The sinuous shape, however, predominates, and frequently the spark resolves itself into two demi-undulations, forming a sort of S, which is also often seen in flashes of lightning that strike the ground. We find there particularly a very characteristic hook-shaped form, upon which M. Planté has long endeavored to attract attention, and which is produced at the negative pole in a constantly varying manner. M. Planté thinks the formation of this hook arises from the collision of two motions opposed to the ponderable matter drawn from the points of the excitant, an effect which always happens under an angle more or less pronounced, and with a more rapid movement on the side of the positive pole than the negative, doubtless because there is greater electric tension at the former. Our readers will probably recollect that I demonstrated this tension in several ways with the induced currents of Ruhmkorff's bobbin.[1]

If a portion of the sulphur spread upon the plate of the excitant is removed by giving the latter a few slight taps, the sparks change to luminous branch-like aigrettes which are truly magnificent. Fig. 3 represents one of these at its natural size, having a luminous track 15 centimetres in length. M. Planté calls these *arborescent sparks*, and he thinks they serve to explain those impressions of a vegetable appearance sometimes observed upon the bodies of persons struck by lightning, and which merely result from the ramifications of the fiery track made by the flash itself. He attributes these impressions to certain pulverulent particles which are in the course of the discharge, and which, after being projected into the air, heated or blazing, in various directions, fall upon the body that has been struck and produce a kind of cauterization if the particles are merely heated, and luminous impressions if they are blazing.

These experiments are extremely interesting, for they clearly show that the pretended reproduction of neighboring objects upon persons struck by lightning is purely imaginary.

If we neglect to give the taps, before mentioned, to the sulphur-powdered plate, the spark is displayed as represented by Fig. 4. We observe, in this case, that the size

FIG. 4.

of the track is increased on the side of the positive pole, and grows contracted as it advances towards the negative pole. Around the positive pole we see traces corresponding to branches or rays in proportion to the quantity of sulphur removed. On the side of the negative pole we find circular tracks of an entirely different kind, representing, probably, the luminous spots, generally blue, which appear at the negative pole simultaneously with the spark of Ruhmkorff's bobbin.

If the plaque of the excitant belonging to M. Planté's apparatus is arranged so as to produce Lichtenberg figures—that is to say, covered with a compound of pure powdered resin, pulverized sulphur and minium—magnificent arborescent sparks of yet another kind can be obtained, the most curious examples of which are shown by Figs. 5 and 6. Tracings of these sparks are made by placing a sheet of varnished black paper upon the plate.

The different effects produced by the aigrettes and the sparks are particularly marked. When the distance between the points of the excitant is too great to admit of the spark discharging, and merely an aigrette appears, the electric movement of ponderable matter which leaves the negative pole and is manifested by the powdered minium adhering to the resin, does not extend to the positive pole. The latter presents no traces of red powder in the sulphur wreath and divergent rays surrounding it, as may be seen in Fig. 5. If the spark has

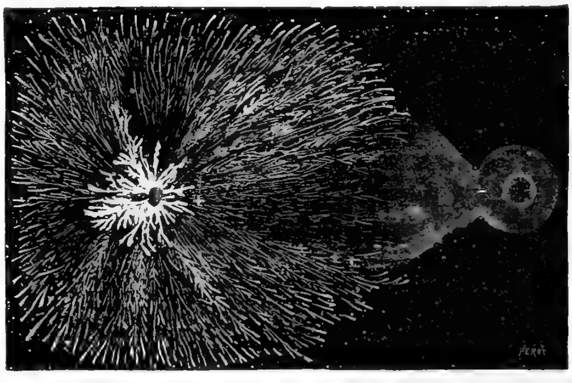

FIG. 5.

discharged, however, the wreath is open and the interior filled with red dust, showing that the electric movement proceeding from the negative pole, extends to the departing point of the positive electricity, as represented by Fig. 6.

[1] See Vol. II. of La Lumierè Electrique p. 439, and also a paper on *La nom homogénéité de l'étincelle d'induction*, p. 89.

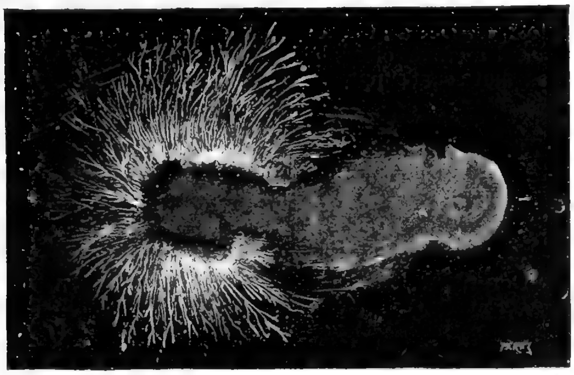

Fig. 6.

"With the spark," says M. Planté, "the distribution of negative electricity presents a curious crab-shaped appearance (Fig. 6.) With the aigrette, the electric movement around this same negative pole gives us the no less bizarre form of a polypus whose tentacles extend towards the positive pole, but do not reach it." (Fig. 5.)

From these results and other experiments quoted by M. Planté, he concludes that a blending of the two electricities may exist at each pole. This would infer that with electric currents of sufficient tension to obtain a continued series of discharges of static electricity, we could have a complete decomposition of the water at each pole and consequently a mixture of hydrogen and oxygen.

Pushing the study of these sparks still further, we find that the movement proceeding from the positive pole, externally, envelopes the negative electric movement like a bundle of curved sky-rockets. However, we often see at the same time an inward flux of positive electricity around the line of the spark between the positive current enveloping the exterior, and between both, the negative electric current which appears as though inhaled by the positive pole. This led M. Planté to suppose that the negative electricity, or else the ponderable matter which it carries with it, moves in an annular space furnished by the electrified matter proceeding from the positive pole. According to him, it would follow that the aspiratory or ascendant effects of the water obtained by electric currents of high tension might explain the ascension of water in a cloudy form as seen in water-spouts.

In a forthcoming article we will study other phenomena no less remarkable, which have been revealed by M. Planté's rheostatic machine. Among these are colored sparks and vibrations determined in a platinum wire traversed by a current of interrupted quantity, a phenomenon which can account for the effects produced in telephones by a simple wire crossed by a current.

Th. Du Marcel.

To be continued.

ON A PROCESS FOR UTILIZING WASTE PRODUCTS AND ECONOMIZING FUEL IN THE EXTRACTION OF COPPER.*

By J. Dixon (Adelaide, South Australia.)

This paper contains an account of a process for extracting copper from sulphurous ores, in which the heat generated by the combination of the oxygen of the air with the sulphur of the ore is utilized for the smelting of the ore. This process is based upon experiments, which, although the author regards as incomplete, show (1) that the charge grows visibly hotter by simply blowing air through it; (2) that the melting of the raw ore or regulus and its reduction can be carried on in the same furnace; (3) that if the ore is in lumps, and fed at the top whilst the air is admitted by the side, a practically clean slagg can be obtained; but if added in a coarse powder, as it is generally found in the market, it either blows out again or chokes the furnace; (4) that a rough copper of about 96 per cent pure metal can be obtained by the successful working of this process.

*British Association, 1881.

ON THE CHEMICAL ACTION BETWEEN SOLIDS.*

By Prof. Thorpe, Ph. D., F.R.S.

The author drew attention to the extremely rare instances of such action hitherto observed, showing how many of these might be explained on the supposition that combination actually occurred between the bodies either in solution or in a state of gas. For example, the formation of cement steel, by the combination of carbon with iron, which had long been adduced as an example of such combination between solids, was now explained by the fact that iron at a high temperature was permeable to gases, and that in the actual process of cementation oxides of carbon were formed, which were in reality conveyors of carbon to the metal. He then illustrated by experiments the formation of several compounds by bringing together the components in solid form, choosing as examples such as would manifest their formation by characteristic coloring. Thus, as instances, potassium iodide and mercuric chloride, potassium iodide and lead nitrate, and silver nitrate and potassium chromate, were powdered together in a mortar, and in each case evidence of an action was exhibited by the production of characteristic colors of the product of the reaction of these compounds. The author referred to the memoir of the Belgian phycisist, Prof. Spring, on the same subject, some of whose experiments he had repeated and in the main confirmed. One of the most remarkable results obtained by the Belgian professor was the formation of coal from peat by subjecting the latter material to a high pressure. Peat from Holland and Belgium, when exposed to a pressure of about 6,000 atmospheres, was, according to Spring, changed into a mass which in all physical characters resembled ordinary coal. Experiments of the same nature made by Dr. Thorpe with various samples of British peat yielded, however, a very dissimilar result. These experiments were made with pressures which were considerably less and more than those employed by Spring. Although solid, compact masses, hard and very much changed in structure, were attained, in no case was any product obtained which could be confounded with bituminous coal. He said it was highly improbable, on purely chemical grounds, that mere pressure had been little more than an important factor in the transformation of woody matter into coal.

A NEW DEMONSTRATION OF THE CARBONIC ACID OF THE BREATH.

By C. F. Cross.

Some time since I made the observation that the carbonic acid of the breath determines the liberation of iodine from a mixture of potassium iodide and iodate, and that the presence of starch renders the decomposition a very effective lecture-experiment, in demonstration of the presence of an active acid body in respired air. A friend to whom I lately communicated this result, threw doubt upon my interpretation, and while admitting the occurrence of the decomposition under the condition of respiring vigorously into the solution, preferred to attribute it to the action of the air or of acid vapors accidentally present. I therefore repeated the experiments

*British Association, 1881.

with special precautions, viz., washing the respired gases, and performing parallel experiments, in which, for the breath I substituted a rapid current of air, and lastly raising the latter to a temperature of 40° C. The result was to prove conclusively my original statement that the decomposition is brought about by a constituent of the respired air, and therefore by its carbonic acid. In performing this experiment it is only necessary to secure the neutrality of the solution; this being done, the development of a full purple color occupies from two to three minutes.

It is evident that this demonstration of the presence of *some* acid body precedes the lime-water test in the logical development of the complete proof of the presence of *carbonic* acid.—*Chemical News.*

THE BEST METHOD OF MOUNTING WHOLE CHICK EMBRYO.*

By Dr. Charles S. Minot.

The blastoderm is removed and cleaned in the usual manner, and then floated out on a glass slide, where it remains permanently. It is carefully spread out and allowed to dry until the edges become glued to the slide. It is then treated with a 0.5 per cent osmic acid solution, until a slight browning occurs. Stain with picro-carmine. The next step is particularly important, because it prevents the further darkening by the osmium, which otherwise injures or ruins the specimen. Pour Müller's fluid, or 0.5 per cent chromic acid solution, on the slide, and leave it over night. The next morning the blastoderm is ready for dehydration by alcohol, and mounting in the usual manner in balsam or dammar lac. Embryos prepared in this manner make particulary beautiful specimens.

ON THE ALLEGED DECOMPOSITION OF THE ELEMENTS.†

By Prof. Dewar, M.A., F.R.S.

In his remarks Prof. Dewar dealt chiefly with the spectroscopic work from which Mr. Norman Lockyer had drawn conclusions very different from those of Professors Liveing and Dewar, especially concerning the value of evidence on the subject. Prof. Dewar argued that Mr. Lockyer's views regarding the existence of carbon vapor in the corona of the sun would not bear scientific investigation, and that his views regarding the modification of the spectrum of magnesium were equally illusory, and gave no proof of the decomposition of elementary substances. Finally he discussed Mr. Lockyer's theory of "basic lines," and addressed himself to a refutation of the same. The results recorded, he said, strongly confirmed Young's observations, and left little doubt that the few as yet unresolved coincidences either would yield to a higher dispersion, or were merely accidental. It would indeed be strange if amongst all the variety of chemical elements and the still greater variety of vibrations which some of them were capable of taking up, there were no two which could take up vibrations of the same period. They certainly should have supposed that substances like iron and titanium, with such a large number of lines, must each consist of more than one kind of molecule, and that not single lines, but several lines of each, would be found repeated with the spectra of some other chemical elements. The fact that hardly a single coincidence could be established was a strong argument that the materials of iron and titanium, even if they be not homogeneous, were still different from those of other chemical elements. The supposition that the different elements might be resolved into simple constituents and even into a single substance had long been a favorite speculation with chemists; but however probable that hypothesis might appear *à priori*, it must be acknowledged, according to Prof. Dewar, that the facts derived from the most powerful method of analytical investigation yet devised, gave it but scant support.

ASTRONOMY.

Elements and Ephemeris of Comet (*d*), 1881.—Barnard.

Mr. S. C. Chandler, Jr., has computed the following elements and ephemeris of Comet (*d*), 1881—Barnard—which are published, by permission of Prof. E. C. Pickering, of Harvard College Observatory. The observations upon which the computation is based are the following: Washington Mean Time being given with the Nashville observation, which was obtained at Vanderbilt University, by Prof. O. H. Landreth, and Cambridge Mean Time with the two others:

							R. A.			Decl.		
		d.	*h.*	*m.*	*s.*		*h.*	*m.*	*s.*	°	′	″
1881.	Sept.	20	7	46		Nashville	13	28	2	+3	47	
		21	7	34	43	Harvard Obs.	13	30	20	4	54	
		25	7	17	52	Harvard Obs.	13	36	29.63	9	6	43.7

The observation of the 20th was received by telegraph, and that of the 21st depends on only two comparisons, taken when the comet was but one degree and a half above the horizon.

ELEMENTS.

T = 1881, September, 14.785. Washington Mean Time.

$$\left.\begin{array}{rll} & ° & ′ \\ \pi = & 271 & 22 \\ \Omega = & 260 & 43 \\ i = & 107 & 27 \end{array}\right\} \text{Mean Eq., 1881. 0.}$$

$$\log. q = 9.7053$$

EPHEMERIS.

Wash. midnight, 1881.	R. A. *h.*	*m.*	*s.*	Decl. °	′	Log. *r*.	Log. Δ.	Light
Sept. 29	13	41	36	+13	4	9.7894	0.1350	1.00
Oct. 3	13	45	28	16	26	9.8270	0.1467	.80
7	13	48	40	19	29	9.8648	0.1569	.65
11	13	51	32	22	18	9.9014	0.1628	.52

The light of the comet on September 29 is taken as unity, and in this scale its light at discovery, on September 17, was 1.85. The orbit does not resemble that of any known comet.

The comet is circular, not over one minute of arc in diameter, with a very decided central condensation. Its collective brightness is not more than equivalent to that of an 8½ mag. star. The comet is rapidly decreasing in light, and the moon is advancing, so that observations of it at once are very desirable. So far as is known, positions have been obtained only at Nashville and Cambridge, the early setting of the comet, and clouds, having greatly interfered. Under the circumstances, the orbit cannot be other than a rough one, and considerable latitude for error had better be allowed in searching for it.

MICROSCOPY.

The following method of hardening the spinal cord for microscopic sections has been highly recommended by Dr. M. Debove:

Place the cord in a 4 per cent solution of bichromate of ammonia for three weeks, then in a solution of phenic gum for three days, and for three days more in alcohol. Sections may then be cut with great facility. They should be placed in water to prevent curling. They are then immersed in a saturated solution of picric acid for twenty-four hours, and colored with carmine for about twenty minutes, the picric acid acting as a mordant.—*Archives de Neurologie.*

An era of microtomes appears to be approaching, and numerous are such devices which are advertised by the opticians. Mr. Thomas Taylor of the Agricultural de-

partment, Washington, has arranged a new microtome in which all the parts are reduced to their most simple form. Mr. Taylor described his invention as consisting essentially of a thin brass tube about one inch and a half strength by one inch in diameter. A ¼ inch brass tube secured within the large cylinder. This tube enters the bottom where it is secured, and proceeds to within a quarter of an inch of the inside surface of the top. To the outside open end of this tube a rubber tube is attached; the other end of the rubber tube is made to communicate with a freezing mixture composed of finely cut ice and salt in about equal proportions. The pail containing this mixture is placed over and about fifteen inches higher than the section cutter. The object of this arrangement is to fill the brass cylinder with a freezing liquid drained from the pail, and caused by the liquefying salt and ice, the temperature of which is about zero. On filling the cylinder with the liquid any object on the top of the cylinder becomes frozen in a short period and may then be cut to any degree of thickness. In order to preserve the low degree of temperature in the cylinder a second tube is secured in the cylinder to remove air and keep up a constant current of the freezing liquid. This tube enters the bottom of the cylinder, where it is fastened. It projects upwards to within an eighth of an inch of the top and has a diameter of about one-half of the supply tube. This microtome or freezing cylinder in other respects is arranged like other microtomes, such as are used for ether or rhigoline; and the same mathematical accuracy attained in cutting sections,

THE editor of the *American Monthly Microscopical Journal* devotes an article to the selection of microscopes, and expresses his belief that the microscope of the future will be an instrument of quite moderate size, and about the same dimensions as that of the forms used by the German student. We believe this to be a correct view of the microscopist's requirements, if the instrument is employed as often as it should be. The colossal instruments which have been recently constructed show no advance in the manufacture of microscopes, but rather a return to the monstrosities of 100 years ago, when their size was "prodigious," and the display of ornamentation profuse. We once saw the microscope "built" for George III., which was a marvel of the brass finisher's art, as elaborate as a Louis XIV. clock, and probably as useful, as an optical instrument.

We believe the form of microscope which will be accepted as a standard by future microscopists will be the "Stevenson" model. Five years ago we submitted drawings for an inexpensive instrument on this plan, but was met by a variety of objections from opticians.

We now find that two London makers are offering microscopes on this model, the Stevenson form having been modified, so as to considerably reduce the expense. The advantages of this model is very great. *First,* a horizontal stage. *Second,* the comfort of sloping tubes. *Third,* an erected image.

We notice in the new edition of "Carpenter" (page 86) that such an instrument (binoculen) can be sold complete, with objective, for $100, or simplified as a student's microscope (binoculen, with 2 objectives) for $64.

For those who merely practice the refinements of the microscope, such an instrument would present many objections, but for biological studies and ordinary microscopical work, we strongly advocate its use, and desire to find it manufactured in its new and cheaper form by American manufacturers of microscopes.

PROF. ALEXIS A. JULIEN has published a reprint from the Journal of the Amer. Chemical Society of his paper "*On the Examination of Carbon Dioxide in the Fluid Cavities of Topaz.*" He describes two simple and inexpensive apparatus for the microscopical determination of carbonic acid in the cavities of minerals; and a recent study of large numbers of cleavage slices from fifty pebbles of topaz from Minas Geraes, Brazil, has presented facts of some interest hitherto not recorded. In some of the slices many extremely angular, elongated, branching, and even reticulated forms of considerable size and novelty abound. Their outlines are at many points decidedly crystalline, with arms projecting at an angle of about 135 degrees, which seems to indicate that Brewster's generalization, that the cavities were generally "capriciously distributed when the substance of the crystal was in a soft or plastic state," may have been pressed too far. In general, the larger expansions of the cavities are mostly occupied by brine, while their attenuated extremities and fine tubular connections are filled by liquid carbonic acid, occasionally including a bubble due to contraction.

MR. C. M. VORCE has forwarded to us a drawing of the many forms of microscopical life found by him in water from Lake Erie, and used as a water supply for Cleveland City. This appears to be but the first instalment of the subject. He draws and names nearly two hundred specimens.

PRELIMINARY REMARKS ON THE MICROSCOPIC STRUCTURE OF COAL FROM EAST SCOTLAND AND SOUTH WALES, by Prof. Williamson, F. R. S., Owens College.—This subject will not be worked out until ten years, but he described layers of vascular tissue which can be separated layer by layer, while in other cases the charcoal layer on the surface of the coal and the organic structure is not capable of separation, and he stated that charcoal contains a tubular structure, like tissues of ordinary bark. The association of tissues resembles that of Cycadian plants; and referred to the genus *Cordaites* having been proved to belong to this group by M. Renault; the author has made nearly a thousand distinct observations on the structure of coal. Separates ordinary coal with large quantities of mineral charcoal, with macrospores of Lepidendroid plants filled up with myriads of microspores which were certainly not floated to the spots, from the *paraffine coals* which do not contain these large macrospores. He divides coal into "Iso-sporous" coals and "Heterosporous" coals; both abound in *Cordaites,* which form the mineral charcoal.

NOTE ON THE OCCURRENCE OF SELENIUM AND TELLURIUM IN JAPAN, by E. DIVERS, M. D.—The author draws attention to the fact that the presence of these two elements has been observed in Japanese sulphuric acid, and considers it probable that these substances occur in material quantities in Japan.

BREWING IN JAPAN, by R. W. ATKINSON, B.SC. (LOND.)—The Japanese brewing process is divided into two parts comparable with the malting and brewing processes of beer-making. The mode of preparation and the properties of the diastatic materials are different in the two cases. The Japanese equivalent of malt or "kōji" hydrates maltose in addition to cane-sugar, dextrin, and starch, and the ultimate products of its action on starch-paste are dextrose and dextrin, or perhaps dextrose alone. Kōji differs from malt in being rendered inactive by heat at a much lower temperature than malt. Kōji is prepared as follows: A mixture of steamed rice and water is allowed to remain in shallow tubs at a low temperature (0°–5° C.) until quite liquid; it is then heated, fermentation commences, and continues until nearly all the dextrine first formed is exhausted. This product is now used like yeast, and is added to fresh quantities of steamed rice and water, fermentation proceeding until the percentage of alcohol amounts to about 13 or 14 per cent by weight. After the greater part of the rice added has been used up, the mash is filtered and clarified by standing. The "saké" so produced requires very careful watching, and when summer approaches, or it exhibits signs of putrefactive fermentation, it is then heated in iron vessels; this operation has frequently to be repeated. Analyses of various specimens, fresh and diseased, are given in the paper.

BOOKS RECEIVED.

A TREATISE ON BRIGHT'S DISEASE AND DIABETES, WITH SPECIAL REFERENCE TO PATHOLOGY AND THERAPEUTICS. By JAMES TYSON, A. M., M. D., with Illustrations. Including a section on Retinitis in Bright's Disease. By WILLIAM F. NORRIS., A. M , M. D. Lindsay and Blackiston, Philadelphia. 1881.

Dr. Tyson needs no apology for publishing this work, and we express the hope that it will be extensively read by the medical profession.

It is true that many excellent treatises exist on this subject, but a mere glance at Dr. Tyson's work shows that in it the subject has been treated in a manner that is original, presenting all the facts in a concise form, and yet omitting no detail which is essential for the full comprehension of this intricate and difficult subject.

Those who have watched the course of recent literature relating to Diseases of the Kidneys and Glycosuria, are aware that we are very far from possessing precise knowledge in regard to such complications, and that while we are still ignorant of the precise pathology of some of these diseases, the very facts bearing on the subject are in a chaotic condition, and inaccessible to the majority of those who should be well informed.

The writer of this book is an accomplished writer, and one who has during the past fifteen years devoted his thoughts and studies to these subjects, and also engaged in practical work bearing on them. Surely the result of such an experience must be useful to both experts and students, if properly used and appreciated.

The number of calls made upon physicians by patients suffering from various forms of Bright's disease and Diabetes is daily on the increase, and no one knows better than the intelligent practitioner, that a large number of their confrères are miserably ignorant on the subject, unacquainted with the Pathology of these diseases, and disgracefully incompetent to treat them. We are not now speaking of quacks, but holders of medical diplomas.

Cases have come to our knowledge, where patients have succumbed on account of their physicians being unable to make a proper diagnosis of the diseases we refer to, or even to analyze or report on a sample of urine.

To such Dr. Tyson's work will probably still be a sealed book, but the advanced and intelligent physicians will, under our advice, procure a copy, for, although other works on this subject may have been studied with profit, we believe a perusal of the work before us will still contribute to his knowledge of this important and interesting subject.

SOLAR PHYSICS.—In concluding a series of lectures on Solar Physics, Professor J. Norman Lockyer said: "I am in honor bound to say, as the result of the work on our solar physics, in that small branch of the inquiry into solar matters with which I am more personally connected, that my belief is that the late work has changed the views which were held, say twenty years ago, to this extent: whereas twenty years ago, we imagined ourselves to be in full presence in the sun of chemical forms with which we are familiar here, I think in this present year, we are bound to consider that that view may be modified to a certain extent, and that we are justified in holding the view, that not these chemical forms with which we are acquainted here, but their germs really, are revealed to us in the hottest regions of the sun."

METEOROLOGICAL REPORT FOR NEW YORK CITY FOR THE WEEK ENDING OCT. 1, 1881.

ILLUSIONS.*

In reality this work might have been styled an essay on error, for the author deals, in his clear and masterly way, with other errors of the human judgment than those which are termed illusions in the narrower sense of that term. His essay loses nothing, and gains much by thus occupying a much broader field than the one, furnished by the sensory illusion, would constitute *per se.* Perhaps the most unfortunate part of the work, is the opening passage: "Common sense, knowing nothing of fine distinctions, is wont to draw a sharp line between the region of illusion and that of sane intelligence. To be the victim of an illusion is, in the popular judgment, to be excluded from the category of rational men. The term at once calls up images of stunted figures with ill-developed brains, half-witted creatures, hardly distinguishable from the admittedly insane. . . . . . The nineteenth century intelligence plumes itself on having got at the bottom of mediæval visions and church miracles, and it is wont to commiserate the feeble minds that are still subject to these self-deceptions."

We say this passage is an unfortunate one, and this particularly because of its position in the opening chapter of a book which, as we must particularly emphasize, is throughout one of the clearest and most readable psychological treatises that we have found in the English language; this passage on the other hand, is as full of wrong assumptions, misconstructions, and errors as a single paragraph can well be. The popular mind fails to contemn the bearer of an illusion, as it does the bearer of a delusion; the mediæval visions were not, even in popular parlance illusions, but hallucinations, and indeed the popular sense in which the term illusion is used, that is, the one employed by poets and classical writers, is anything but a reflection on the bearer of the illusion. The day-dream, the poetic illusion, and the constructions of a sanguine temperament, are the objects associated in the lay-mind with that term.

On the fourth page is further evidence that the author has failed to discriminate practically between delusions, hallucinations, and illusions. After stating that alienists have good reason to limit the word illusion to illusory perceptions, he adds "such illusions of the senses are the most palpable and striking evidences of mental disease." Inasmuch as illusions are common with the sane, it is incorrect to lay greater stress on the not very frequent illusions of the insane, than on the marked and characteristic hallucinations and the still more universal delusions of that class.

The author defines an illusion as a species of error which counterfeits the form of immediate, self-evident, or intuitive knowledge whether as a sense perception or otherwise. Further on he discriminates between the illusion and the fallacy, by characterising the former as a falsification of primary or intuitive knowledge, and the latter as a falsification of secondary or inferential knowledge. It must be admitted that the author is happier in his discrimination than in his definition, and an illustration of the difficulty under which definers labor recurs in the peroration of the same chapter, where he says that the illusion is seen to arise through "some exceptional feature in the situation or condition of the individual, which, for the time, breaks the chain of intellectual solidarity which under ordinary circumstances binds the single member to the collective body." The greater portion of this passage would constitute an excellent nucleus for a definition of insanity, but at the same time it seems to us that it fails to cover those common illusions, which involve the visual apparatus, and of which familiar illustrations are furnished in most physiological text books. The dividing line between the delusion, the hallucination, and the illusion, should have been strictly drawn at the outset, by our author. We have offered the following as showing the difference between the hallucination and the illusion: While a hallucination is a subjective perception of an object as a real presence, without a real presence to justify the perception, and a memory is the subjective per-

* *Illusions, a psychological study.* By JAMES SULLY. New York, D. Appleton and Co.—Volume XXXIII. of the International Scientific Series.

ception of an object not actually present, involving the recognition of its absence, an illusion is the subjective perception of an object actually present, but in characters which the object does not really possess. With appropriate alterations these definitions will cover the abstract hallucination and phantastic illusion of Wundt as well.

In his second chapter, the author ably, but we believe unsuccessfully, endeavors to defend his refusal to recognize the distinction between illusion and hallucination as the leading principle of classification, though he admits the necessity of making this distinction in accordance with the leading alienists. Wundt, an authority whose teachings in psychological physiology the author of the present volume has most successfully assimilated, has drawn attention to the numerous connecting links existing between illusions and hallucinations, and yet strongly insists on utilizing their general differences as a basis of classification. We find the chief drawback to the otherwise great value of the work, in its failure to give adequate space to the anatomical mechanism concerned in false registrations of the perceptional and conceptional sphere. If it be borne in mind that while even hallucinations may be based on actual impressions, the latter are not the determining factor of the hallucination, the difficulty in discriminating between these perversions is overcome; this is illustrated by the occasional persistence of dream-images in the waking state, and the moving of certain hallucinated images consonant with the movements of the eye-ball. If an actual or subjective impression, say in the shape of *chromatopsia* and *tinnitus*, be granted to exist in a subject hallucinating the vision and voice of the Virgin Mary, it will be instantly recognized by every observant alienist, that the real determining factor is here centrifugal, while in the illusion, which constructs, out of a ball rolling in an ill-lighted apartment, a mouse, the determining factor takes a centripetal course. In the former instance, the misinterpretation lies ready made in the Cortex, and seizes on the slight external pretext, whose existence we only admit for the sake of the argument, to incorporate it, in its substance; in the latter, it is based upon an imperfect registration and a gradual constructive interpreting process. Nothing could more forcibly illustrate the correctness of these propositions than the very case cited from Wundt by Mr. Sully of a forester who saw the real objects of the outer world, (furniture and tapestry, for example,) through the wood piles which formed the subjects of his hallucinations.

With these remarks on the propositions of the opening chapters, our criticism ceases to be adverse. In the last twelve chapters of the book, the author gives a concise review of the chief theories held by alienists and metaphysicians on the perceptional illusion, the introspective illusion, dreams illusions of memory, and those of belief. We refrain from again pointing out places where the author encroaches on the fields of delusion and hallucination, as he has given a wider scope to his definition of the illusion, than we are inclined to consider proper. It is but just to say that he gives a just interpretation to the views of alienists, an interpretation which only occasionally manifests that tincture of uncertainty which is unavoidable on the part of one devoid of a practical knowledge of the insane.

The perusal of this work cannot fail to be profitable to the student of mental pathology as well as of metaphysics. More reliable in the latter field, than in the former, it is yet a successful attempt to present the modern German ideas on the subject, and to combine the teachings of the practical and the abstract psychologists. To the general reader we can only repeat, what we said at the outset, it is the clearest rendition of a difficult yet fascinating theme, to be found in our language.

E. C. SPITZKA, M. D.

ON THE DISCOVERIES OF THE PAST HALF-CENTURY RELATING TO ANIMAL MOTION.

By J. BURDON-SANDERSON, M.D., LL.D., F.R.S.

The two great branches of Biology with which we concern ourselves in this section, Animal Morphology and Physiology, are most intimately related to each other. This arises from their having one subject of study—the living animal organism. The difference between them lies in this, that whereas the studies of the anatomist lead him to fix his attention on the organism itself, to us physiologists it, and the organs of which it is made up, serve only as *vestigia*, by means of which we investigate the vital processes of which they are alike the causes and consequences.

To illustrate this I will first ask you to imagine for a moment that you have before you one of those melancholy remainders of what was once an animal—to wit, a rabbit—which one sees exposed in the shop of poulterers. We have no hesitation in recognising that remainder as being in a certain sense a rabbit; but it is a very miserable vestige of what was a few days ago enjoying life in some wood or warren, or more likely on the sand-hills near Ostend. We may call it a rabbit if we like, but it is only a remainder—not the thing itself.

The anatomical preparation which I have in imagination placed before you, although it has lost its inside and its outside, its integument and its viscera, still retains the parts for which the rest existed. The final cause of an animal, whether human or other, is muscular action, because it is by means of its muscles that it maintains its external relations. It is by our muscles exclusively that we act on each other. The articulate sounds by which I am addressing you are but the results of complicated combinations of muscular contractions—and so are the scarcely appreciable changes in your countenances by which I am able to judge how much, or how little, what I am saying interests you.

Consequently the main problems of physiology relate to muscular action, or as I have called it, animal motion. They may be divided into two—namely (1) in what does muscular action consist—that is, what is the process of

which it is the effect or outcome? And (2) how are the motions of our bodies co-ordinated or regulated? It is unnecessary to occupy time in showing that, excluding those higher intellectual processes which, as they leave no traceable marks behind them, are beyond the reach of our methods of investigation, these two questions comprise all others concerning animal motion. I will therefore proceed at once to the first of them—that of the process of muscular contraction.

The years which immediately followed the origin of the British Association exceeded any earlier period of equal length in the number and importance of the new facts in morphology and physiology which were brought to light; for it was during that period that Johannes Müller, Schwann, Henle, and, in this country, Sharpey, Bowman, and Marshall Hall, accomplished their productive labors. But it was introductory to a much greater epoch. It would give you a true idea of the nature of the great advance which took place about the middle of this century if I were to define it as the epoch of the death of "vitalism." Before that time, even the greatest biologist—*e.g.* J. Müller—recognized that the knowledge they possessed, both of vital and physical phenomena, was insufficient to refer both to a common measure. The method, therefore, was to study the process of life in relation to each other only. Since that time it has become fundamental in our science not to regard any vital process as understood at all, unless it can be brought into relation with physical standards, and the methods of physiology have been based exclusively on this principle. Let us inquire for a moment what causes have conduced to the change.

The most efficient cause was the progress which had been made in physics and chemistry, and particularly those investigations which led to the establishment of the doctrine of the Conservation of Energy. In the application of this great principle to physiology, the men to whom we are indebted are, first and foremost, J. R. Mayer, of whom I shall say more immediately; and secondly to the great physiologists still living and working among us, who were the pupils of J. Müller—viz.; Helmholtz, Ludwig, Du Bois-Reymond, and Brücke.

As regards the subject which is first to occupy our attention, that of the *process* of muscular contraction, J. R. Mayer occupies so leading a position that a large proportion of the researches which have been done since the new era, which he had so important a share in establishing, may be rightly considered as the working out of principles enunciated in his treatise [1] on the relation between organic motion and exchange of material. The most important of these were, as expressed in his own words: (1) "That the chemical force contained in the ingested food and in the inhaled oxygen is the source of the motion and heat which are the two products of animal life; and (2) that these products vary in amount with the chemical process which produces them." Whatever may be the claims of Mayer to be regarded as a great discovery in physics, there can be no doubt, that as a physiologist, he deserves the highest place that we can give him, for at a time when the notion of the correlation of different modes of motion was as yet very unfamiliar to the physicist, he boldly applied it to the phenomena of animal life, and thus re-united physiology with natural philosophy, from which it had been rightly, because unavoidably, severed by the vitalists of an earlier period.

Let me first endeavor shortly to explain how Mayer himself applied the principle just enunciated, and then how it has been developed experimentally since his time.

The fundamental notion is this: the animal body resembles, as regards the work it does and the heat it produces, a steam-engine in which fuel is continually being used on the one hand, and work is being done and heat produced on the other. The using of fuel is the chemical process, which in the animal body, as in the steam engine, is a process of oxidation. Heat and work are the useful products, for as, in the higher animals, the body can only work at a constant temperature of about 100° F., heat may be so regarded.

Having previously determined the heat and work severally producible by the combustion of a given weight of carbon, from his own experiments and from those of earlier physicists, Mayer calculated that if the oxidation of carbon is assumed to represent approximately the oxidation process of the body, the quantity of carbon actually burnt in a day is far more than sufficient to account for the day's work, and that of the material expended in the body not more than one-fifth was used in the doing of work, the remaining four-fifths being partly used, partly wasted in heat production.

Having thus shown that the principles of the correlation of process and product hold good, so far as its truth could then be tested, as regards the whole organism, Mayer proceeded to inquire into its applicability to the particular organ whose function it is "to transform chemical difference into mechanical effect"—namely muscle. Although, he said, a muscles acts under the direction of the will, it does not derive its power of acting from the will, any more than a steamboat derives its power of motion from the helmsman. Again (and this was of more importance, as being more directly opposed to the prevalent vitalism), a muscle, like the steamboats use in the doing of work, not the material of its own structure, or mechanism, but the fuel—*i. e.* the nutriment—which it derives directly from the blood which flows through its capillaries. "The muscle is the instrument by which the transformation of force is accomplished, not the material which is itself transformed." This principle he exemplified in several ways, showing that if the muscles of our bodies worked, as was formerly supposed, at the expense of their own substance, their whole material would be used up in a few weeks, and that in the case of the heart, a muscle which works at a much greater rate than any other, it would be expended in as many days—a result which necessarily involved the absurd hypothesis that the muscular fibres of our hearts are so frequently disintegrated and reintegrated that we get new hearts once a week.

On such considerations Mayer founded the prevision, that, as soon as experimental methods should become sufficiently perfect to render it possible to determine with precision the limits of the chemical process, either in the whole animal body or in a single muscle, during a given period, and to measure the production of heat and the work done during the same period, the result would show a quantitative correlation between them.

If the time at our disposal permitted, I should like to give a short account of the succession of laborious investigations by which these previsions have been verified. Begun by Bidder and Schmidt in 1851,[1] continued by Pettenkofer and Voit,[2] and by the agricultural physiologists[3] with reference to herbivora, they are not by any means completed. I must content myself with saying that by these experiments the first and second parts of this great subject—namely, the limits of the chemical process of animal life and its relation to animal motion under different conditions—have been satisfactorily worked out, but that the quantitative relations of heat production are as yet only insufficiently determined.

Let me sum up in as few words as possible how far what we have now learnt by experiment justifies Mayer's anticipations, and how it falls short of or exceeds them. First of all, we are

[1] J. R. Mayer, "Die organische Bewegung in ihrem Zusammenhange mit dem Stoffwechsel; ein Beitrag zur Naturkunde,' Heilbronn, 1845.

[1] Bidder and Schmidt, "Die Verdauungssäfte und der Stoffwechsel," Leipzig, 1852.

[2] Pettenkofer and Voit, *Zeitschr. f. Biologie*, passim, 1866–80.

as certain as of any physical fact that the animal body in doing work does not use its own material— that, as Mayer says, the oil to his lamp of life is food; but in addition to this we know what he is unaware of, that what is used is not only not the living protoplasm itself, but is a kind of material which widely differs from it in chemical properties. In what may be called commercial physiology —*i.e.*, in the literature of trade puffs—one still meets with the assumption that the material basis of muscular motion is nitrogenous; but by many methods of proof it has been shown that the true "Oel in der Flamme des Lebens" is not proteid substance, but sugar, or sugar-producing material. The discovery of this fundamental truth we owe first to Bernard (1850-56), who brought to light the fact that such material plays an important part in the nutrition of every living tissue; secondly, to Voit (1866), who in elaborate experiments on carnivorous animals, during periods of rest and exertion, showed that, in comparing those conditions, no relation whatever shows itself between the quantity of proteid material (flesh) consumed, and the amount of work done; and finally to Frankland, Fick, and his associate Wislicenus, as to the work-yielding value of different constituents of food, and as to the actual expenditure of material in man during severe exertion. The subjects of experiment used by the two last-mentioned physiologists were themselves; the work done was the mountain ascent from Interlaken to the summit of the Faulhorn; the result was to prove that the quantity of material used was proportional to the work done, and that that material was such as to yield water and carbonic acid exclusively.

The investigators to whom I have just referred aimed at proving the correlation of process and product for the whole animal organism. The other mode of inquiry proposed by Mayer, the verification of his principle in respect of the work-doing mechanism—that is to say, in respect of muscle taken separately—has been pursued with equal perseverance during the last twenty years, and with greater success; for in experimenting on a separate organ, which has no other functions excepting those which are in question, it is possible to eliminate uncertainties which are unavoidable when the conditions of the problem are more complicated. Before I attempt to sketch the results of these experiments, I must ask your attention for a moment to the discoveries made since Mayer's epoch, concerning a closely related subject, that of the Process of Respiration.

I wish that I had time to go back to the great discovery of Priestley (1776), that the essential facts in the process of respiration are the giving off of fixed air, as he called it, and the taking in of dephlogisticated air, and to relate to you the beautiful experiments by which he proved it; and then to pass on to Lavoisier (1777), who, on the other side of the Channel, made independently what was substantially the same discovery a little after Priestley, and added others of even greater moment. According to Lavoisier, the chemical process of respiration is a slow combustion which has its seat in the lungs. At the time that Mayer wrote, this doctrine still maintained its ascendency, although the investigations of Magnus (1838) had already proved its fallacy. Mayer himself knew that the blood possessed the property of conveying oxygen from the lungs to the capillaries, and of conveying carbonic acid gas from the capillaries to the lungs, which was sufficient to exclude the doctrine of Lavoisier. Our present knowledge of the subject was attained by two methods—viz., first, the investigation of the properties of the coloring matter of the blood, since called "hæmoglobin," the initial step in which was made by Prof. Stokes in 1862; and secondly, the application of the mercurial air-pump as a means of determining the relations of oxygen and carbonic acid gas to the living blood and tissues. The last is a matter of such importance in relation to our subject that I shall ask your special attention to it. Suppose that I have a barometer of which the tube, instead of being of the ordinary form, is expanded at the top into a large bulb of one or two litres capacity, and that, by means of some suitable contrivance, I am able to introduce, in such a way as to lose no time and to preclude the possibility of contact with air, a fluid ounce of blood from the artery of a living animal into the vacuous space—what would happen? Instantly the quantity of blood would be converted into froth, which would occupy the whole of the large bulb. The color of the froth would at first be scarlet, but would speedily change to crimson. It would soon subside, and we should then have the cavity which was before vacuous occupied by the blood and its gases—namely, the oxygen, carbonic acid gas, and nitrogen previously contained in it. And if we had the means (which actually exist in the gas-pump) of separating the gaseous mixture from the liquid, and of renewing the vacuum, we should be able to determine (1) the total quantity of gases which the blood yields, and (2), by analysis, the proportion of each gas.

Now, with reference to the blood, by the application of the "blood-pump," as it is called, we have learned a great many facts relating to the nature of respiration, particularly that the difference of venous arterial blood depends not on the presence of "effete matter," as used to be thought, but on the less amount of oxygen held by its coloring matter, and that the blood which flows back to the heart from different organs, and at different times, differs in the amount of oxygen and of carbonic acid gas it yields, according to the activity of the chemical processes which have their seat in the living tissues from which it flows.[1] But this is not all that the blood-pump has done for us. By applying it not merely to the blood, but to the tissues, we have learned that the doctrine of Lavoisier was wrong, not merely as regards the place, but as regards the nature of the essential process in respiration. The fundamental fact which is thus brought to light is this, that although living tissues are constantly and freely supplied with oxygen, and are in fact constantly tearing it from the hæmoglobin which holds it, yet they themselves yield no oxygen to the vacuum. In other words, the oxygen which living protoplasm seizes upon with such energy that the blood which flows by it is compelled to yield it up, becomes so entirely part of the living material itself that it cannot be separated even by the vacuum. It is in this way only that we can understand the seeming paradox that the oxygen, which is conveyed in abundance to every recess of our bodies by the blood-stream, is nowhere to be found. Notwithstanding that no oxidation-product is formed, it becomes latent in every bit of living protoplasm; stored up in quantity proportional to its potential activity—*i. e.*, to the work, internal or external, it has to do.

Thus you see that the process of tissue respiration—in other words, the relation of living protoplasm to oxygen—is very different from what Mayer, who localized oxidation in the capillaries, believed it to be. And this difference has a good deal to do with the relation of Process to Product in muscle. Let us now revert to the experiments on this subject which we are to take as exemplification of the truth of Mayer's forecasts.

If I only desired to convince you that during the last half-century there has been a greater accession of knowledge about the function of the living organism than during the previous one, I might arrange here a small heap at one end of the table the physiological works of the Hunters, Spallanzani, Fontana, Thomas Young, Benjamin Brodie, Charles Bell, and others, and then proceed to cover the rest of it with the records of original research on physiological subjects since 1831, I should find that, even if I included only genuine work, I should have to heap my table up to the ceiling. But I apprehend this would not give us a true answer to our question. Although, etymologically, Science and Knowledge mean the same thing, their real meaning is different. By science we mean, first of all,

that knowledge which enables us to sort the things known according to their true relations. On this ground we call Haller the father of physiology, because, regardless of existing theories, he brought together into a system all that was then known by observation or experiment as to the processes of the living body. But in the "Elementa Physiologiæ" we have rather that out of which science springs than science itself. Science can hardly be said to begin until we have by experiment acquired such a knowledge of the relation between events and their antecedents, between processes and their products, that in our own sphere we are able to forecast the operations of nature, even when they lie beyond the reach of direct observation. I would accordingly claim for physiology a place in the sisterhood of the sciences, not because so large a number of new facts have been brought to light, but because she has in her measure acquired that gift of prevision which has been long enjoyed by the higher branches of natural philosophy. In illustration of this I have endeavored to show you that every step of the laborious investigations undertaken during the last thirty years as to the process of nutrition, has been inspired by the provisions of J. R. Mayer, and that what we have learnt with so much labor by experiments on animals is but the realization of conceptions which existed two hundred years ago in the mind of Descartes as to the mechanism of the nervous system. If I wanted another example I might find it in the provisions of Dr. Thomas Young as to the mechanism of the circulation, which for thirty years were utterly disregarded, until, at the epoch to which I have so often adverted, they received their full justification from the experimental investigations of Ludwig.

But perhaps it will occur to some one that if physiology founds her claim to be regarded as a science on her power of anticipating the results of her own experiments, it is unnecessary to make experiments at all. Although this objection has been frequently heard lately from certain persons who call themselves philosophers, it is not very likely to be made seriously here. The answer is, that it is contrary to experience. Although we work in the certainty that every experimental result will come out in accordance with great principles (such as the principle that every plant or animal is both, as regards form and function, the outcome of its past and present conditions, and that in every vital process the same relations obtain between expenditure and product as hold outside of the organism), these principles do little more for us than indicate the direction in which we are to proceed. The history of science teaches us that a general principle is like a ripe seed, which may remain useless and inactive for an indefinite period, until the conditions favorable to its germination come into existence. Thus the conditions for which the theory of animal automatism of Descartes had to wait two centuries, were (1) the acquirement of an adequate knowledge of the structure of the animal organism, and (2) the development of the sciences of physics and chemistry; for at no earlier moment were these sciences competent to furnish either the knowledge or the methods necessary for its experimental realization; and for a reason precisely similar Young's theory of the circulation was disregarded for thirty years.

I trust that the examples I have placed before you today may have been sufficient to show that the investigators who are now working with such earnestness in all parts of the world for the advance of physiology, have before them a definite and well-understood purpose, that purpose being to acquire an exact knowledge of the chemical and physical processes of animal life, and of the self-acting machinery by which they are regulated for the general good of the organism. The more singly and straightforwardly we direct our efforts to these ends, the sooner we shall attain to the still higher purpose—the effectual application of our knowledge for the increase of human happiness.

The Science of Physiology has already afforded her aid to the Art of Medicine in furnishing her with a vast store of knowledge obtained by the experimental investigation of the action of remedies and of the causes of diseases. These investigations are now being carried on in all parts of the world with great diligence, so that we may confidently anticipate that during the next generation the progress of pathology will be as rapid as that of physiology has been in the past, and that as time goes on the practice of medicine will gradually come more and more under the influence of scientific knowledge. That this change is already in progress we have abundant evidence. We need make no effort to hasten the process, for we may be quite sure that, as soon as science is competent to dictate, art will be ready to obey.

METEORIC DUST.

By Prof. Schuster.

A committee of the British Association was appointed for the double purpose of examining the observations hitherto recorded on the subject of meteoric dust and of discussing the possibility of future more systematic investigations. With regard to the first point we note that in a paper presented to the Royal Astronomical Society in 1879, Mr. Ranyard has given what appears to be a pretty complete account of the known observations as to the presence of meteoric dust in the atmosphere. It appears that in the year 1852 Prof. Andrews found native iron in the basalt of the Giant's Causeway. Nordenskjöld found particles of iron which in all probability had a cosmic origin in the snows of Finland and in the ice-fields of the Arctic regions. Dr. T. L. Phipson, and more recently Tissandier, found similar particles deposited by the winds on plates exposed in different localities. Finally, Mr. John Murray discovered magnetic particles raised from deposits at the bottom of the sea by H. M. S. *Challenger*. These articles were examined by Prof. Alexander Herschel, who agreed with Mr. Murray in ascribing a cosmic origin to them. For fuller details and all references we must refer to Mr. Ranyard's paper. There cannot be any doubt that magnetic dust, which in all probability derives it origin from meteors, has often been observed, and the question arises, in what way we can increase our knowledge on these points to an appreciable extent. A further series of occasional observations would in all probability lead to no result of great value, unless they were carried on for a great length of time in suitable places. Meteoric dust, we know, does fall, and observations ought if possible to be directed rather towards an approximate estimate of the quantity which falls within a given time. Difficulties very likely will be found in the determination of the locality in which the observations should be conducted. The place ought to be sheltered as much as possible against any ordinary dust not of meteoric origin. The lonely spots best fitted for these observations are generally accessible to occasional experiments only, and do not lend themselves easily to a regular series of observations. Nevertheless experiments continued for a few months at some elevated spot in the Alps might lead to valuable results. The Committee would like to draw attention to an instrument which is well fitted for such observations. It was devised by Dr. Pierre Miquel for the purpose of examining, not the meteoric particles, but organic and organized matters floating about in the air. A description, with illustrations, will be found in the *Annuaire de Montsouris* for 1879. Two forms of the instrument are given. In the first form, which is only adapted to permanent places of observations, an aspirator draws a quantity of air through a fine hole. The air impinges on a plate coated with glycerine, which retains all solid matter. By means of this instrument we may determine the quantity of solid particles within a given volume of air.

The second, more portable form, does not allow such an accurate quantitative air analysis. The instrument is attached to a weathercock, and thus is always directed against the wind, which traverses it, and deposits, as in the other permanent form, its solid matter on a glycerine plate. An anemometer placed in the vicinity serves to give an approximate idea of the quantity of air which has passed through the apparatus. These instruments have been called aëroscopes by their inventor. It is likely that the second form given to the apparatus will be best fitted for the purpose which the Committee has in view.

THE NEW ASTRONOMER ROYAL.

Mr. William Henry Mahony Christie, who has succeeded Sir George Airy in the office of Astronomer Royal at the Royal Observatory, Greenwich Park, was born on October 1, 1845, at Woolwich. He is a younger son of the late Professor S. H. Christie, of the Royal Military Academy, Woolwich, and formerly Secretary to the Royal Society. Mr. W. H. M. Christie was educated at Kings College School, London; and at Trinity College, Cambridge, which he entered in 1864, having won a Minor's Scholarship of that College; he subsequently gained a Foundation Scholarship and was afterwards elected a Fellow of Trinity College. He took his degree of B.A. in 1868, as fourth wrangler in the Mathematical Tripos, and in 1871 proceeded to the M. A. degree. In 1870, Mr. Christie was appointed Chief Assistant at the Royal Observatory; and he has, during the past ten years, done special good service by contriving and introducing several valuable improvements in the scientific apparatus there in use; a new form of spectroscope, an instrument for determining the colors and brightness of the stars, a recording micrometer, and a polarising solar eye-piece, are to be mentioned as his inventions. In the recent address of the President of the British Association, at York, a passing reference was made to Mr. Christie's work in verifying the results obtained by Dr. Huggins, with regard to the motions of stars, as inferred from spectroscopic observations. The new Astronomer Royal has directed particular attention, at the Royal Observatory, both to spectroscopy and to photography, as a means of recording the observations. He is a fellow of the Royal Society, and was elected Secretary of the Royal Astronomical Society last year. He contributed to the proceedings of the Royal Society, in March, 1877, a paper "on the magnifying power of the half-prism, as a means of obtaining great dispersion, and on the general theory of the half-prism spectroscope." To the monthly notices of the Royal Astronomical Society, he has furnished these: in June, 1873, a paper on the recording micrometer; in January, 1874, on the color and brightness of stars, as measured with a new photometer; in May, 1875, on the determination of the scale in photographs of the Transit of Venus; in 1876, (January) on a new form of solar eye-piece; (May) on the displacement of lines in the spectra of stars; (November) on the effect of wear in the micrometer screws of the Greenwich Transit Circle; same year (December) on the gradation of light on the disk of Venus; in 1878 (January) on specular reflection from Venus; (June) on the existence of bright lines in the solar spectrum; in 1879 (January) on a phenomeno seen in the occultation of a star by the moon's bright limb; in 1880, November, on the spectrum of Hartwig's comet of that year; in 1881 (January) on Mr. Stone's alterations of Bessel's refractions; (May) on the flexure of the Greenwich transit circle, and some further remarks on Mr. Stone's alterations of Bessel's refractions; besides various papers on the Greenwich spectroscopic and photographic observations, communicated by the late Astronomer Royal; and a paper which will be found in the Memoirs of the Royal Astronomical Society, published in January, 1880, on the systematic errors of the Greenwich North Polar distances. Mr. Christie is also the founder and editor of a journal entitled "*The Observatory*, a Monthly Review of Astronomy," which has been published during the past four years; and he is author of the "Manual of Elementary Astronomy," published in 1875 by the Society for Promoting Christian Knowledge.

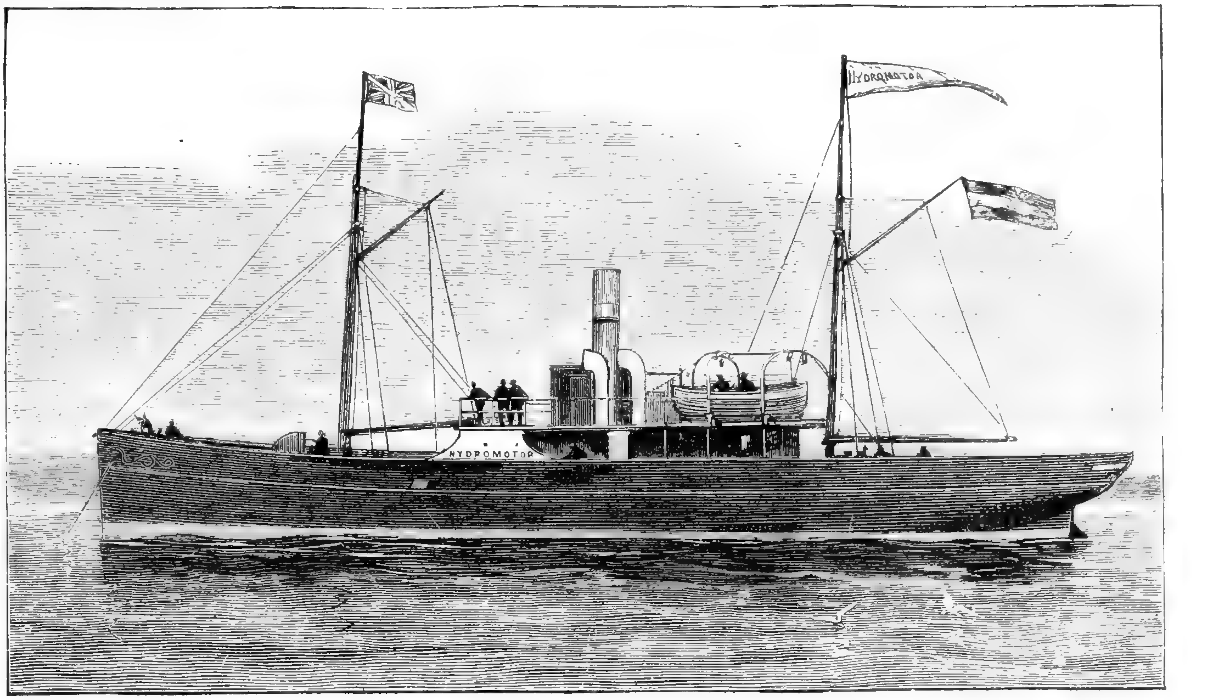
WILLIAM H. M. CHRISTIE.

ON THE ELECTRIC CONDUCTIVITY AND DICHROIC ABSORPTION OF TOURMALINE.*

By Prof. SILVANUS P. THOMPSON.

The electric conductivity of tourmaline differs in different directions; being, according to the author's experiments, a minimum along the optic axis. Tourmaline also possesses the optical property of dichroism, its absorption being a maximum for rays parallel to the axis, and greater for blue rays than for red, equal thicknesses of crystal being considered. According to the electro-magnetic theory of light, bodies which are good conductors of electricity should be opaque to light. The author has in the August number of the *Philosophical Magazine* rewritten the equations of Maxwell's electro-magnetic theory for the case of crystalline media possessing different conductivities in different directions. From these equations it appears that in tourmaline and negative uniaxial crystals electric displacements at right angles to the axis will be more absorbed than electric displacements parallel to the axis. This accounts for the well-known greater absorption of the ordinary ray, provided the views of Stokes and Fresnel are correct, that these displacements are at right angles to the so-called plane of polarization. The difference of velocity between the rays of different color accounts for the difference of absorption being greater in that direction in which the conductivity is a minimum. It was also pointed out that in positive uniaxial crystals, in which the electric conductivity is a maximum along the axis, there will be maximum absorption of the extraordinary ray, and there will be least opacity along the axis. Smoky quartz and magnesic platinocyanide fulfil the latter condition. Specimens of tourmaline cut into cubes to show the colors in different directions were shown, and also specimens of magnesic platinocyanide and of herapathite. Mechanico-optical models were also shown illustrating the theory; a tourmaline being represented by a cube built up of layers of glass and wire-gauze. In conclusion it was shown that crystals in which the electric conductivity differs in three different directions will exhibit *trichroism;* and that di- or trichroic absorption is a general property of all colored crystals other than those of the cubical system.

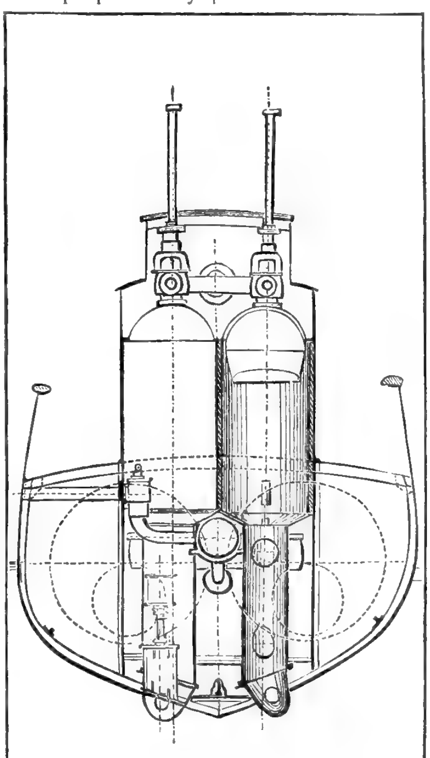
* British Association, 1881.



THE VESSEL AS IT APPEARS AFLOAT

THE HYDROMOTOR SHIP.

We present a drawing of a vessel propelled by hydraulic reaction, and recently constructed at Kiel by Dr. Emil Fleischer, of Dresden.



Machines propelled on the reactive principle are by no means a novelty, but hitherto have been attended with indifferent success. Nearly 40 years ago a model boat, which used to travel up and down a tank propelled by such means, was exhibited in London. But Dr. Fleischer's hydromotor allows of as much as 90 per cent. of the indicated steam power being applied to the production of the outflowing water stream, while not more than 30 per cent. has been secured with the reaction machines hitherto constructed. In his vessel the usual ship's engines, worked by means of wheel or screw, are replaced by hydraulic reaction, by the drawing in and shooting out of a stream of water. The steam power acts immediately on the water, without any loss of such power in conveyance from steam engines and pumps. The manœuvring capabilities of the vessel are greatly increased, and the usual complicated machinery is replaced by a remarkably simple contrivance.

The professional men who took part in a short trip with the hydromotor, expressed the most unqualified appreciation of the invention, and of every detail of its execution. The easy manœuvring of the vessel, its small consumption of coal, and the practicability of adapting the system to all rates of speed were clearly shown, and the simplicity of its construction was regarded as particularly valuable for war ships. The hydromotor is undergoing further tests in English waters.

HYDRODYNAMIC ANALOGIES TO ELECTRICITY AND MAGNETISM.

From a scientific and purely theoretical point of view there is no object in the whole of the Electrical Exhibition at Paris of greater interest than the remarkable collection of apparatus exhibited by Dr. C. A. Bjerknes, of Christiania, and intended to show the fundamental phenomena of electricity and magnetism by the analogous ones of hydrodynamics. I will try to give a clear account of these experiments and the apparatus employed; but no description can convey any idea of the wonderful beauty of the actual experiments, whilst the mechanism itself is also of most exquisite construction. Every result which is thus shown by experiment had been previously predicted by Prof. Bjerknes as the result of his mathematical investigations.

It has long been known that if a tuning-fork be struck and held near to a light object like a balloon it attracts it. This is an old experiment, and the theory of it has been worked out more than once. Among others, Sir William Thomson gave the theory in the *Philosophical Magazine* in 1867. In general words the explanation is that the air in the neighborhood of the tuning-fork is rarefied by the agitation which it experiences. Consequently the pressure of the air is greater as the distance from the tuning-fork increases. Thus the pressure on the far side of the balloon is greater than that on the near side, and the balloon is attracted.

Dr. Bjerknes has followed out the theory of this action until he has succeeded in illustrating most of the

fundamental phenomena of electricity and magnetism. He causes vibrations to take place in a trough of water about six inches deep. He uses a pair of cylinders fitted with pistons which are moved in and out by a gearing which regulates the length of stroke and also gives great rapidity. These cylinders simply act alternately as air-compressers and expanders, and they can be arranged so that both compress and both expand the air simultaneously, or in such a way that the one expands while the other compresses the air, and *vice versa*. These cylinders are connected by thin india-rubber tubing and fine metal pipes to the various instruments. A very simple experiment consists in communicating pulsations to a pair of tambours, and observing their mutual actions. They consist each of a ring of metal faced at both sides with india-rubber and connected by a tube with the air-cylinders. One of them is held in the hand; the other is mounted in the water in a manner which leaves it free to move. It is then found that if the pulsations are of the same kind, *i.e.* if both expand and both contract simultaneously, there is attraction. But if one expands while the other contracts, and *vice versa*, there is repulsion. In fact the phenomenon is the opposite of magnetical and electrical phenomena, for here like poles attract, and unlike poles repel.

Instead of having the pulsation of a drum we may use the oscillation of a sphere; and Dr. Bjerknes has mounted a beautiful piece of apparatus by which the compressions and expansions of air are used to cause a sphere to oscillate in the water. But in this case it must be noticed that opposite sides of ths sphere are in opposite phases. In fact the sphere might be expected to act like a magnet; and so it does. If two oscillating spheres be brought near each other, then, if they are both moving to and from each other at the same time, there is attraction; but if one of them be turned round, so that both spheres move in the same direction in their oscillations, then there is repulsion. If one of these spheres be mounted so as to be free to move about a vertical axis, it is found that when a second oscillating sphere is brought near to it, the one which is free turns round its axis and sets itself so that both spheres in their oscillations are approaching each other or receding simultaneously. Two oscillating spheres, mounted at the extremities of an arm, with freedom to move, behave with respect to another oscillating sphere exactly like a magnet in the neighborhood of another magnetic pole. I believe that these directive effects are perfectly new, both theoretically and experimentally. The professor mounts his rod with a sphere at each end in two ways: (1) so that the oscillations are along the arm, and (2) so that they are perpendicular. In all cases they behave as if each sphere was a little magnet with its axis lying along the direction of oscillation.

Dr. Bjerknes looks upon the water in his trough as being the analogue of Faraday's medium; and he looks upon these attractions and repulsions as being due, not to the action of one body on the other, but to the mutual action of one body and the water in contact with it. Viewed in this light, his first experiment is equivalent to saying that if a vibrating or oscillating body have its motions in the same direction as the water, the body moves away from the centre of disturbance, but if in the opposite direction, towards it. This idea gives us the analogy of dia- and paramagnetism. If, in the neighborhood of a vibrating drum, we have a cork ball, retained under the water by a thread, the oscillations of the cork are greater than those of the water in contact with it, owing to its small mass, and are consequently *relatively* in the same direction. Accordingly we have repulsion, corresponding to diamagnetism. If, on the other hand, we hang in the water a ball which is heavier than water, its oscillations are not so great as that of the water in its vicinity, owing to its mass, and consequently the oscillations of the ball relatively to the water are in the opposite direction to those of the water itself, and there is attraction, corresponding to paramagnetism. A rod of cork and another of metal are suspended horizontally by threads in the trough. A vibrating drum is brought near to them; the cork rod sets itself equatorially, and the metal rod axially.

If a pellet of iron be floated by a cork on water and two similar poles (*e. g.* both north) be brought to its vicinity, one above and the other below the pellet, the latter cannot remain exactly in the centre, but will be repelled to a certain distance, beyond which, however, there is the usual attraction. The reason is that when the pellet is nearly in the line joining the two poles the north pole of the pellet (according to our supposition) is further from this line than the south one. The angle of action is less; so that although the north pole is further away, the horizontal component of the north pole repulsion may be greater than that of the south pole attraction. Dr. Bjerknes reproduces this experiment by causing two drums to pulsate in concord, the one above the other. A pellet fixed to a wire, which is attached by threads to two pieces of cork, is brought between the drums, and it is found impossible to cause it to remain in the centre.

Dr. Bjerkes conceived further the beautiful idea of tracing out the conditions of the vibrations of the water when acted upon by pulsating drums. For this purpose he mounted a sphere or cylinder on a thin spring and fixed a fine paint-brush to the top of it. This is put into the water. The vibrations are in most cases so small that they could not be detected, but by regulating the pulsations so as to be isochronous with the vibrations of the spring, a powerful vibration can be set up. When this is done a glass plate mounted on four springs is lowered so as to touch the paint-brush, and the direction of a hydrodynamic line of force is depicted. Thus the whole field is explored and different diagrams are obtained according to the nature of the pulsations. Using two drums pulsating concordantly, we get a figure exactly like that produced by iron filings in a field of two similar magnetic poles. If the pulsations are discordant it is like the figure with two dissimilar poles. Three pulsating drums give a figure identical with that produced by three magnetic poles. The professor had previously calculated that the effects ought to be identical, and I think the same might have been gathered from the formulæ in Sir William Thomson's "Mathematical Theory of Magnetism," but this only enhances the beauty of the experimental confirmation.

Physicists have been in the habit of looking upon magnetism as some kind of molecular rotation. According to the present view it is a rectilinear motion. Physicists have been accustomed to look upon the conception of an isolated magnetic pole as an impossibility, but here, while the oscillating sphere represents a magnetic molecule with north and south poles, the pulsating drum represents an isolated pole. These are new conceptions to the physicists, let us see whither they lead us. The professor shows that if a rectilinear oscillation constitutes magnetism, a circular oscillation must signify an electric current, the axis of oscillation being the direction of the current. According to this view what would be the action of a ring through which a current is passing? If the ring were horizontal the inner parts of the ring would all rise together and all fall together, they would vibrate and produce the same effect as the rectilinear vibrations of a magnet. This is the analogue of the Amperian currents.

To illustrate the condition of the magnetic field in the neighborhood of electric currents, Dr. Bjerknes mounted two wooden cylinders on vertical axes, connecting them by link-work, which enabled him to vibrate them in the same or opposite ways. To produce enough friction he was forced to employ syrup in place of water. The figures which are produced on the glass plate are in every case the same as those which are produced by iron filings in the neighborhood of electric currents, including the

case of currents going in parallel and in opposite directions.

The theory is carried out a step further to explain the attraction and subsequent repulsion after contact of an electrified and a neutral substance and the passage of a spark. But it is extremely speculative, and is not as yet experimentally illustrated, and I think that at present it is better to pass it by,

I believe that the professor will exhibit his experiments and give some account of his mathematical investigations, which have occupied his time for five years, to the Académie des Sciences this afternoon. His results have not been published before. GEORGE FORBES.

THE ELECTRIC DISCHARGE THROUGH COLZA OIL.*

By A. MACFARLANE, D. SC., F. R. S. E.

The electrical properties of colza oil which I have examined are its dielectric strength and some phenomena which accompany the passage of the spark. By the dielectric strength of a substance I mean the ratio of the difference of potential required to pass a spark through air under the same conditions. The electrodes used were two parallel brass plates each four inches in diameter. When comparing the gases the standard distance of the plate chosen was 5 mm. In the case of liquids it is convenient to observe for a shorter distance, and reduce the result by the law which previous experiments of mine have established, namely, that in the case of the discharge between parallel plates through a liquid dielectric, the difference of potential required is proportional to the distance between the plates. (*Trans.* R. S. E., vol. xxix. p. 563). One set of observations gave the ratio for colza oil to be 2.7, another gave 2.5. Hence 2.6 may be taken. I have now obtained the following table of dielectric strengths for liquids (1 being unity).

Substance.	Dielectric Strength.
Paraffine oil	3.7
Oil of turpentine...........	4.0
Paraffine liquefied..........	2.4
Olive oil..................	3.5
Colza oil..................	2.6

The specific gravity of the colza oil is .91. The passage of the spark was accompanied by the formation of gas bubbles, but there was no deposition of solid particles. As the 4-inch plates were placed horizontally in the oil a bubble produced by the discharge was prevented from escaping by the upper plate. When the upper plate is again electrified such a bubble behaves in the following manner. If it is large enough it will extend itself somewhat like an hour-glass between the plates, but if it is smaller it takes the form of an acorn with a flat base, the base resting on one or other of the plates. When the upper plate is charged positively the bubble is repelled so as to place its base on the lower plate; when the electricity is changed to negative the bubble remains with its base on the upper plate. A reversal of the order of charging did not change the effect. After a few electrifications a sufficient number of solid particles collect to form a chain, and thus interfere with the phenomenon, the bubbles then being lengthened out in a remarkable manner, but never repelled to the lower plate. When the upper plate was charged negatively, gas bubbles appeared to me to rise from the lower plate, as if they had been formed there. To test this point further I took some sparks between two smaller disks placed vertically in the oil. The gas-bubbles were observed to rise up at the negative surface as if they had been formed at the positive surface, and had been repelled or carried straight across, and then rose up at the negative surface. When the spark was taken between two points bent at right angles to two rods dipping into the oil, the bubbles were observed to shoot out in the direction from the positively charged point, and to circulate round the earth-rod some time before rising to the surface. These phenomena indicate that the bubble is positively electrified.

ASTRONOMY.

ON THE POSSIBILITY OF THE EXISTENCE OF INTRA-MERCURIAL PLANETS.*

By BALFOUR STEWART, LL.D., F.R.S.

It is a somewhat frequent speculation amongst those who are engaged in sun-spot research to regard the state of the solar surface as influenced in some way by the positions of the planets.

In order to verify this hypothesis observers have tried whether there appear to be solar periods exactly coinciding with certain well-known planetary periods. This method has been adopted by the Kew observers (Messrs. De La Rue, Stewart, and Loewy), who had an unusually large mass of material at their disposal, and they have obtained from it the following results :—

1. An apparent maximum and minimum of spotted area approximately corresponding in time to the perihelion and aphelion of Mercury.

2. An apparent maximum and minimum of spotted area approximately corresponding in time to the conjunction and opposition of Mercury and Jupiter.

3. An apparent maximum and minimum of spotted area approximately corresponding in time to the conjunction and opposition of Venus and Jupiter.

4. An apparent maximum and minimum of spotted area approximately corresponding in time to the conjunction and opposition of Venus and Mercury.

The Kew observers make the following remarks upon these results :—

"There appears to be a certain amount of likeness between the march of the numbers in the four periods which we have investigated, but we desire to record this rather as a result brought out by a certain specified method of treating the material at our disposal than as a fact from which we are at present prepared to draw conclusions. As the investigation of these and similar phenomena proceeds, it may be hoped that much light will be thrown upon the causes of sun-spot periodicity.

The Kew observers have likewise produced evidence of a different kind in favor of the planetary hypothesis, for they have detected a periodicity in the behavior of sun-spots with regard to increase and diminution apparently depending upon the positions of the two nearer planets, Mercury and Venus. The law seems to be that as a portion of the sun's surface is carried by rotation nearer to one of these two influential planets, there is a tendency for spots to become less and disappear, while on the other hand, when it is carried away from the neighborhood of one of these planets, there is a tendency for spots to break out and increase.

But whatever truth may be in these conclusions, it appears to be quite certain that periodical relations between the various *known* planets will not account for *all* the sun-spot inequalities with which we are acquainted. They may account for some, but certainly not for all. For there are solar inequalities of short duration which presuming them to be real, can only be accounted for on the planetary hypothesis, by supposing the existence of several unknown intra-Mercurial planets.

Indeed these short-period inequalities in sun-spots and the allied phenomena of terrestrial magnetism and meteorology have so augmented in number of late years as to make some observers inclined to question their reality; while others again resort to the above-mentioned hypothesis, and attribute them to intra-Mercurial planetary agency.

The method to be pursued in detecting the existence

* British Association, 1881.

of inequalities will be easily understood by an illustration. Suppose we had in our possession extensive records of the temperature of the earth's atmosphere at some one place in middle latitudes, and that, independently of astronomical knowledge, we were to make use of these for the purpose of investigating the natural inequalities of terrestrial temperature. We should begin by grouping the observations according to various periods taken, say, at small but definite time-intervals from each other. Now if our series of observations were sufficiently extensive, and if some of our various groupings together of this series should correspond to a real inequality, we should expect it to exhibit a well-defined and prominent fluctuation, whose departures above and below the mean should be of considerable amount.

Suppose, for instance, that we have twenty-four points in our series, and that we group a long series of temperature observations in rows of twenty-four each, the time distance between two contiguous members of one row being one hour. The series would thus represent the mean solar day, and we should, without doubt, obtain from a final summation of our rows a result exhibiting a prominent temperature fluctuation of a well-defined character, which we might measure (as long as we keep to twenty-four points) by simply adding together all the departures of its various points from the mean, whether these points lie above or below; in fine, by obtaining the area of the curve, which is the graphical representation of the inequality above and below the line of abscissæ taken to represent the mean of all the poiuts. Suppose next that, still keeping to rows of twenty-four, we should make the time interval between two contiguous members of a row somewhat different from one hour, whether greater or less, we should now in either case obtain a result exhibiting, when measured as above, a much smaller inequality than that given when the interval was exactly one hour; and it is even possible that, if our series of observations were sufficiently extensive, we should obtain hardly any traces of an inequality whatever.

In fine, when each row accurately represented a solar day, the result would be an inequality of large amount; but when each row represented a period either slightly less or greater than a day, the result would be an inequality of small amount. This process, as far as I have described it, is not new, inasmuch as something of this kind must be pursued in all attempts to detect inequalities. In the present instance we should by its means, after bestowing enormous labor in variously grouping, in accordance with a great number of periods taken at small intervals from each other, obtain definite results. These might be graphically represented in the following manner:—

The line of abscissæ might be taken to denote the exact values of the various periods, forming a time-scale, in fact, while the ordinates might represent the areas or summations obtained as above by employing these various periods. There would thus be in the case now used for illustration a very prominent peak, corresponding to twenty-four hours, which would fall off very rapidly on either side.

By means of the process now described we should at length, after enormous labor, obtain a graphical result, showing the exact position in the time-scale of the observed maximum inequality. In conjunction with Mr. William Dodgson, I have devised a method by which this labor is very greatly reduced, and the process so modified has been applied by us in order to determine whether there be inequalities of short period in the observed areas of the sun-spots occurring on the visible hemisphere of the sun. We have detected an inequality of this nature corresponding in period to 24.011 days, which, when subjected to a certain purifying treatment, appears to us to exhibit the marks of a true periodicity. But it has been suggested by Prof. Stokes that a method of this nature for detecting inequalities might with greater propriety be employed as a crucible for testing the value of some hypothesis introduced into it from without.

Acting upon this suggestion I have ventured to introduce the planetary hypothesis, and to ask whether the above sun-spot inequality of short period may not in reality be caused by an intra-Mercurial planet. It is quite easy to put this hypothesis to a test, taking for our guidance the results obtained by the Kew observers. For what do these results exhibit? In the first place they exhibit the probability of a sun-spot inequality corresponding to the period of Mercury round the sun; and in the next they exhibit the probability of similar inequalities corresponding to the synodic period of Mercury and Venus, and to the synodic period of Mercury and Jupiter.

Now if there be an intra-Mercurial planet of period 24.011 days, it will have the following synodic periods:—

With Mercury................33.025 days.
With Venus.................26 884 days.
With Jupiter................24.145 days.

In conjunction with Mr. Dodgson I have applied the above method of analysis with the view of ascertaining whether there be well-marked sun-spot inequalities nearly corresponding to these periods, and we have obtained the following results:—

A very prominent inequality of period......32.955 days.
A very prominent inequality of period......26.871 days.
A less prominent inequality of period......24.142 days.

It will thus be noticed that there are prominent sun-spot inequalities, the periods of which agree very well with the synodic periods of the supposed planet with Mercury, Venus, and Jupiter, more especially if we bear in mind that this is only a first approximation.

The test, however, is not yet complete. Referring once more to the results of the Kew observers, it will be noticed that we have approximately maxima of sun-spot areas when Mercury and Venus, or when Mercury and Jupiter are in conjunction. Now if we assume that there is an intra-Mercurial planet of period 24.011 days, we are as yet unable to assign its exact position in ecliptical longitude at any moment. We know its period, and we may presume that it has considerable eccentricity, but we know nothing else. We may, however, assume as most probable that the maximum point of the inequality of period 32.955 days corresponds to the conjunction of the planet with Mercury, the maximum point of the inequality of period 26.871 days to its conjunction with Venus, and the maximum point of the inequality of period 24.142 days to its conjunction with Jupiter. On this assumption, and knowing the average rate of motion of the planet in its orbit, we may deduce approximately its position at a given epoch independently from each of the three synodic periods above mentioned, and these positions ought to agree together, if our hypothesis be correct.

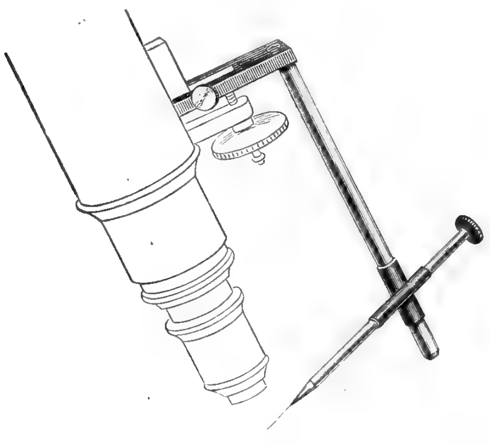
I have done this approximately, but am not able to bring exact figures before this meeting. The agreement is as great as can be expected, bearing in mind that we know only the average rate of motion of the planet, and not the variations of its rate, inasmuch as we are ignorant of its eccentricity. I think I may state that three independent values of its position corresponding to January 1, 1832, will be obtained, and that the mean difference of a single value from the mean of the whole will probably not be more than twenty degrees. It would thus appear from this investigation that the evidence is in favor of the sun-spot inequality of 24.011 days being due to an intra-Mercurial planet. Of course a single research of this nature is insufficient to establish a theory of this importance, but as there are several short-period solar inequalities, the same method may be pursued for each, an operation which demands nothing but time and labor. It appears to me of great importance that these short-period solar inequalities should be systematically examined after this method.

MICROSCOPY.

Mr. C. Henry Kain thus describes in the August number of *The American Journal of Microscopy*, his new mechanical finger for the microscope, which will be found a useful addition to the instrument.

A glance at the engraving will render the working of it intelligible to all. It consists essentially of a slotted bar which may be firmly clamped to the upper (immovable) bar of the fine adjustment by means of a milled-headed screw. Through the end of this is fastened a round rod, at such a distance from the objective that, when lowered, the end will not strike the stage. Over this rod slips a split tube, to which is soldered at an angle, a smaller tube. Through the small tube passes a rod carrying a glass hair at its extremity. This rod is easily rotated by means of a milled head. The capillary glass thread is attached to the extremity by means of beeswax. The arrangement of split tubes was suggested by Mr. Edward Pennock, to take the place of a binding screw which I had intended; it is a very neat and convenient affair, and much less clumsy than the arrangement I originally proposed. It will be noticed that the finger has no revolving collar, as it is quite unnecessary, especially when the microscope is provided with a revolving stage. By dispensing with the revolving collar and making all movements depend entirely upon the adjustments of the microscope, greater stability and accuracy in working are secured.

To use the finger, the point of the glass thread is first brought into the focus of the objective, or nearly so, by sliding the tube on the vertical rod and pushing or pulling the rod carrying the glass thread until the desired position is attained. It is not difficult to do this, and, having once been done by hand, it does not have to be repeated, as all further movements are made by the adjustments of the microscope. Supposing now the point of the glass thread



A NEW MECHANICAL FINGER.

to be in focus; by means of the fine adjustment throw the focus *ahead* of the point, then, by means of the coarse adjustment, rack down and search for the object you wish to pick up. Having found the object desired, again bring the point of the thread into focus by means of the fine adjustment; then rack down with the coarse adjustment and pick it up. Now rack back with the coarse adjustment, remove the slip on which the material is spread, and place your prepared slip or cover upon the stage. Again, by means of the fine adjustment, throw the focus ahead of the object, rack down with the coarse adjustment and search for the spot where you wish to deposit the object, and, having found it, again focus the object, then rack down with the coarse adjustment, and, when the object touches the slide and has been placed in proper position, fix it by means of a very gentle breath. There are many other devices by which this useful little instrument may be used for a variety of purposes, for a description of which we refer the reader to Professor Phin's journal.

PENNOCK'S OBLIQUE DIAPHRAGM.—The accompanying engravings show a new form of oblique diaphragm devised by Mr. E. Pennock, and described by him in *The American Journal of Microscopy* (August, 1881). It is designed to be attached to the under side of the stage for shutting off all light except a small pencil from the mirror. Its function is the same as Smith's >-shaped diaphragm. It is an adaptation of Mr. Mayall's spiral diaphragm, which was originally designed for use with condensers of wide aperture, and was described in a recent number of the *Journal of the Royal Microscopical Society*.

It may be mounted in either of two forms: the one to fit into the usual tube, which, in the cheaper microscopes, is attached to the under side of the stage; the other to screw directly into the stage aperture.

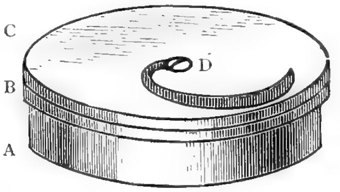


FIG. 1.

A. Tube 1½ inch in diameter, fitting into accessory tube beneath stage.

B. Upper plate (shown as under) having radial slot.

C. Under plate, having spinal slot.

D. Screw joining the plates.

The manner of using it to obtain pencils of varying degrees of obliquity will be sufficiently manifest from the construction.

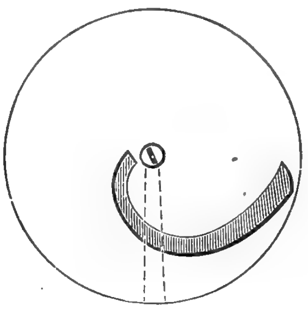

FIG. 2—PLAN OF UPPER AND LOWER PLATES MOVING FULLY ON EACH OTHER.

CORRESPONDENCE.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. No notice is taken of anonymous communications.*]

To the Editor of "SCIENCE."

I do not like to see so great an authority as Faraday misunderstood, as he evidently is by your correspondent on page 459 of your journal, and that too, in a way which he took particular care to caution against—as to the law of gravitating action. That it acts inversely as the square of the distance he fully believed and admitted; or, to use his own words, "I know it is so."

If your correspondent finds difficulty to account by this law for the return of the earth from aphelion to perihelion, let him try to account for the return of a stone to the earth when thrown up into the air; for precisely the same explanation applies to both, the highest point of the stone's path being "aphelion." The resistance of the air need not be regarded, for, though it modifies the stone's path, it does not affect the theory of the action of gravity.

GEO. B. MERRIMAN.

RUTGERS COLLEGE.

To the Editor of "SCIENCE:"

I have no desire to make any rejoinder to Dr. Rogers' reply (see SCIENCE, p. 459), but am willing to leave his answer with your readers just as he has given them.

I desire, however, to make the following corrections in my published letter:—

On p. 458, next to last paragraph, for "author of above question" read "author of above quotation." Same page, last paragraph, for "As to the law of inertia" read "As by the law of inertia." And on p. 459, last line of first paragraph, for "centrifugal" read "centripetal."

DES MOINES, *Sept.* 26, 1881. J. E. HENDRICKS.

BOOKS RECEIVED.

CELESTIAL OBJECTS FOR COMMON TELESCOPES, by the REV. T. W. WEBB, M. A., F. R. A. S.—Fourth Edition — Revised and greatly enlarged — The Industrial Publication Company, No. 14 Dey street, New York. Price $3.00.

From the number of inquiries we have received respecting the expected issue of a fourth edition, we believe it will be welcome intelligence to our readers, to learn that the work can now be obtained.

As the third edition was an enlargement of its predecessors, so the present and latest edition has been re-written and again enlarged. Mr. Webb thus states his reasons for remodeling his work, and at the same time indicates many of the improvements that he has introduced.

"The unprecedented diffusion of a taste for astronomical observation during the last seven years has brought with it such a corresponding increase in the optical capacity of telescopes in private hands that the very title of this treatise would convey an inaccurate impression unless its contents were modified in accordance with the requirements of the time.

Without abandoning that elementary character which may still make it serviceable to beginners, its compass must now be greatly extended, if it may hope for acceptance as a manual by the more advanced student; and with this object, as the increase of telescopic range chiefly affects the sidereal portion, recourse has been had for additional Double Stars to the great catalogue of Struve I., as well as in a lesser degree to those of his son and Burnham, and as regards Nebulæ to that of Herschel II., with a total increase of about 1500 objects, some of which are chosen as tests worthy of the finest instruments, but occasionally, as is well known, within reach of those of more moderate dimensions."

The present edition of Mr. Webb's will soon find purchasers, and we advise all those who desire to possess a copy, to be prompt in securing it. The work is an indispensable manual to all who possess a telescope, or have a taste for astronomical studies.

A CORRECTION.—Professor Edward S. Morse desires to withdraw the first part of the last paragraph of the abstract of his paper on "Changes in Mya and Lunatia since the Deposition of the New England Shell Heaps," and substitute the following:—

"A comparison of the common beach cockle (Lunatia) from the shell heaps of Marblehead, Mass., showed that the present form living on the shore to-day had a more depressed spire than the ancient form; and this variation," etc., etc.

METEOROLOGICAL REPORT FOR NEW YORK CITY FOR THE WEEK ENDING OCT. 8, 1881.

SATURDAY, OCTOBER 22, 1881.

TO OUR ENGLISH READERS.

We have received from Messrs. Deacon & Co., of 150 Leadenhall street, London, England, a standing order for a large supply of "Science," which will be forwarded weekly. We shall be obliged if our English readers will make this fact known to their friends.

THE REVELATIONS OF THE AUTOPSY HELD ON THE BODY OF THE LATE PRESIDENT.

The *Medical Record* of October 8th contains an account by Dr. Bliss, the late President's attending surgeon, of the life history of his illustrious patient, as well as the *post mortem* observations recorded at the time of the autopsy, and also at a later period, by those who examined the specimens preserved in the Army Medical Museum.

Inasmuch as the various diagnoses, made during Mr. Garfield's life, as to the location of the bullet, and the injury sustained by various organs, were all of them erroneous, and as the secular and medical journals have already discussed those topics *ad nauseam*, we shall limit ourselves to a relation of the leading features in the light of the anatomical findings.

For similar reasons, we shall give no space to a discussion of the views expressed by a physician, who, after incurring considerable ridicule at the hands of the medical profession, and much obloquy at the hands of the public, on account of his sensational experiments on dead bodies, and whose claimed results no doubt misled the eminent surgeons at the President's bed-side, publishes a *post mortem* diagnosis of the case in the same issue of the *Record.* In it he seeks to prove that if the bullet *was* found in an entirely different locality from the one his experiments induced him to surmise, it *would*, had it have gone a little further, infallibly have dropped into a similar situation on the *opposite* side! One of the leading medical journals has no other comment to make on this performance, and, as far as we can learn, that comment expresses the general opinion of the medical profession, than to announce that a leading circus company has engaged the services of Dr. Fanueil D. Weisse to repeat his celebrated experiments in the course of the programme.

We subjoin the essential portions of Dr. Bliss' report:—

The depressed cicatrix of the wound made by the pistol-bullet was recognized over the tenth intercostal space, three and one-half inches to the right of the vertebral spines. A deep linear incision (made in part by the operation of July 24, and extended by that of August 8) occupied a position closely corresponding to the upper border of the right twelfth rib. It commenced posteriorly about two inches from the vertebral spines, and extended forward a little more than three inches. At the anterior extremity of this incision there was a deep, nearly square abraded surface about an inch across.

On *inspection of the abdominal viscera in situ*, the transverse colon was observed to lie a little above the line of the umbilicus. It was firmly adherent to the anterior edge of the liver. The greater omentum covered the intestines pretty thoroughly from the transverse colon almost to the pubes. It was still quite fat, and was very much blackened by venous congestion. On both sides its lateral margins were adherent to the abdominal parietes opposite the eleventh and twelfth ribs. On the left side the adhesions were numerous, firm, well organized and probably old.

These adhesions, and the firm ones on the right side, as well as those of the spleen, possibly date back to an attack of chronic dysentery, from which the patient is said to have suffered during the civil war. On the right side there were a few similar adhesions, and a number of more delicate and probably recent ones.

A mass of black, coagulated blood covered and concealed the spleen and the left margin of the greater omentum. On raising the omentum it was found that this blood-mass extended through the left lumbar and iliac regions and dipped down into the pelvis, in which there was some clotted blood and rather more than a pint of bloody fluid. The blood-coagula having been turned out and collected, measured very nearly a pint. It was now evident that secondary hemorrhage had been the immediate cause of death, but the point from which the blood had escaped was not at once apparent.

The adhesions between the liver and the transverse colon proved to bound an *abcess-cavity* between the under-surface of the liver, the transverse colon, and the transverse mesocolon, which involved the gall-bladder, and extended to about the same distance on each side of it, measuring six inches transversely and four inches from before backward. This cavity was lined by a thick pyogenic membrane, which completely replaced the capsule of that part of the undersurface of the liver occupied by the abscess. It contained

about two ounces of greenish yellow fluid—a mixture of pus and biliary matter. This abscess did not involve any portion of the substance of the liver except the surface with which it was in contact, and no communication could be detected between it and any part of the wound.

Some recent peritoneal adhesions existed between the upper surface of the right lobe of the liver and the diaphragm. The *liver* was larger than normal, weighing eighty-four ounces; its substance was firm, but of a pale yellowish color on its surface and throughout the interior of the organ, from fatty degeneration. No evidence that it had been penetrated by the bullet could be found, nor were there any abscesses or infarctions in any part of its tissue.

The *spleen* was connected to the diaphragm by firm, probably old, peritoneal adhesions. There were several rather deep congenital fissures in its margins, giving it a lobulated appearance. It was abnormally large, weighing eighteen ounces; of a very dark lake-red color both on the surface and on section. Its parenchyma was soft and flabby, but contained no abscesses or infarctions.

There were some recent peritoneal adhesions between the posterior wall of the *stomach* and the posterior abdominal parietes. With this exception no abnormities were discovered in the stomach or *intestines*, nor were any other evidences of general or local peritonitis found besides those already specified.

The *right kidney* weighed six ounces, the *left kidney* seven. Just beneath the capsule of the left kidney, at about the middle of its convex border, there was a little abscess one-third of an inch in diameter, and there were three small serous cysts on the convex border of the right kidney, just beneath the capsule; in other respects the tissue of both kidneys was normal in appearance and texture.

The *urinary bladder* was empty.

Behind the right kidney, after the removal of that organ from the body, the dilated *track of the bullet* was dissected into. It was found that from the point at which it had fractured the right eleventh rib (three and one-half inches to the right of the vertebral spines) that missile had gone to the left, obliquely forward, passing through the body of the first lumbar vertebra and lodging in the adipose connective tissue immediately below the lower border of the pancreas, about two and one-half inches to the left of the spinal column, and behind the peritoneum. It had become completely encysted.

The track of the bullet between the point at which it had fractured the eleventh rib and that at which it entered the first lumbar vertebra was considerably dilated, and the pus had burrowed downward through the adipose tissue behind the right kidney, and thence had found its way between the peritoneum and the right iliac fascia, making a descending channel which extended almost to the groin. The adipose tissue behind the right kidney, and thence had found its way between the peritoneum and the right iliac fascia, making a descending channel which extended almost to the groin. The adipose tissue behind the kidney in the vicinity of this descending channel was much thickened and condensed by inflammation. In the channel, which was almost free from pus, lay the flexible catheter introduced into the wound at the commencement of the autopsy; its extremity was found doubled upon itself, immediately beneath the peritoneum, reposing upon the iliac fascia, where the channel was dilated into a pouch of considerable size. This long descending channel, now clearly seen to be caused by the burrowing of pus from the wound, was supposed, during life, to have been the track of the bullet.

The last dorsal, together with the first and second lumbar vertebra and the twelfth rib, were then removed from the body for more thorough examination.

When this examination was made, it was found that the bullet had penetrated the first lumbar vertebra in the upper part of the right side of its body. The aperture by which it entered involved the intervertebral cartilage next above, and was situated just below and anterior to the intervertebral foramen, from which its upper margin was about one-fourth of an inch distant. Passing obliquely to the left, and forward through the upper part of the body of the first lumbar vertebra, the bullet emerged by an aperture, the centre of which was about one-half inch to the left of the median line, and which also involved the intervertebral cartilage next above. The cancellated tissue of the body of the first lumbar vertebra was very much comminuted and the fragments somewhat displaced. Several deep fissures extended from the track of the bullet into the lower part of the body of the twelfth dorsal vertebra. Others extended through the first lumbar vertebra into the intervertebral cartilage between it and the second lumbar vertebra. Both this cartilage and that next above were partly destroyed by ulceration. A number of minute fragments from the fractured lumbar vertebra had been driven into the adjacent soft parts.

It was further found that the right twelfth rib also was fractured at a point one and one-fourth inch to the right of the traverse process of the twelfth dorsal vertebra; this injury had not been recognized during life.

On sawing through the vertebra, a little to the right of the median line, it was found that the spinal canal was not involved by the track of the ball. The spinal cord, and other contents of this portion of the spinal canal, presented no abnormal appearances. The rest of the spinal cord was not examined.

Beyond the first lumbar vertebra, the bullet continued to go to the left, passing behind the pancreas to the point where it was found. Here it was enveloped in a firm cyst of connective tissue, which contained, besides the ball, a minute quantity of inspissated, somewhat cheesy pus, which formed a thin layer over a portion of the surface of the lead. There was also a black shred adherent to a part of the cyst-wall, which proved, on microscopical examination, to be the remains of a blood-clot. For about an inch from this cyst the track of the ball behind the pancreas was completely obliterated by the healing process. Thence, as far backward as the body of the first lumber vertebra, the track was filled with coagulated blood, which extended on the left into an irregular space rent in the adjoining adipose tissue behind the peritoneum and above the pancreas. The blood had worked its way to the left, bursting finally through the peritoneum behind the spleen into the abdominal cavity. The rending of the tissues by the

extravasation of this blood was undoubtedly the cause of the paroxysms of pain which occurred a short time before death.

This mass of coagulated blood was of irregular form, and nearly as large as a man's fist. It could be distinctly seen from in front through the peritoneum, after its site behind the greater curvature of the stomach had been exposed by the dissection of the greater omentum from the stomach, and especially after some delicate adhesions between the stomach and the part of the peritoneum covering the blood-mass had been broken down by the fingers. From the relations of the mass as thus seen, it was believed that the hemorrhage had proceeded from one of the mesenteric arteries, but as it was clear that a minute dissection would be required to determine the particular branch involved, it was agreed that the infiltrated tissues and the adjoining soft parts should be preserved for subsequent study.

On the examination and dissection made in accordance with this agreement, it was found that the fatal hemorrhage proceeded from a rent, nearly four tenths of an inch long, in the main trunk of the splenic artery, two and one-half inches to the left of the cœliac axis. This rent must have occurred at least several days before death, since the everted edges in the slit in the vessel were united by firm adhesions to the surrounding connective tissue, thus forming an almost continuous wall bounding the adjoining portion of the blood-clot. Moreover, the peripheral portion of the clot in this vicinity was disposed in pretty firm concentric layers. It was further found that the cyst below the lower margin of the pancreas, in which the bullet was found, was situated three and one-half inches to the left of the cœliac axis.

Besides the mass of coagulated blood just described, another, about the size of a walnut, was found in the greater omentum, near the splenic extremity of the stomach. The communication, if any, between this and the larger hemorrhage mass could not be made out.

The examination of the *thoracic viscera* resulted as follows:

The *heart* weighed eleven ounces. All the cavities were entirely empty except the right ventricle, in which a few shreds of soft, reddish, coagulated blood adhered to the internal surface. On the surface of the mitral valve there were several spots of fatty degeneration; with this exception the cardiac valves were normal. The muscular tissue of the heart was soft, and tore easily. A few spots of fatty degeneration existed in the lining membrane of the aorta just above the semilunar valves, and a slender clot of fibrin was found in the aorta, where it was divided, about two inches from these valves, for the removal of the heart.

On the right side slight pleuritic adhesions existed between the convex surface of the lower lobe of the lung and the costal pleura, and firm adhesions between the anterior edge of the lower lobe, the pericardium, and the diaphragm. The *right lung* weighed thirty-two ounces. The posterior part of the fissure, between its upper and lower lobes, was congenitally incomplete. The lower lobe of the right lung was hypostatically congested, and considerable portions, especially toward its base, were the seat of broncho pneumonia. The bronchial tubes contained a considerable quantity of stringy muco-pus; their mucous surface was reddened by catarrhal bronchitis. The lung-tissue was œdematous, but contained no abcesses or infarctions.

On the left side the lower lobe of the lung was bound behind to the costal pleura, above to the upper lobe, and below to the diaphragm, by pretty firm pleuritic adhesions. The *left lung* weighed twenty-seven ounces. The condition of the bronchial tubes and of the lung-tissue was very nearly the same as on the right side, the chief difference being that the area of the broncho-pneumonia in the lower lobe was much less extensive in the left lung than in the right. In the lateral part of the lower lobe of the left lung, and about an inch from its pleural surface, there was a group of four minute areas of gray hepatization, each about one-eighth of an inch in diameter. There were no infractions and no abcesses in any part of the lung tissue.

The surgeons assisting at the autopsy were unanimously of the opinion that, on reviewing the history of the case in connection with the autopsy, it is quite

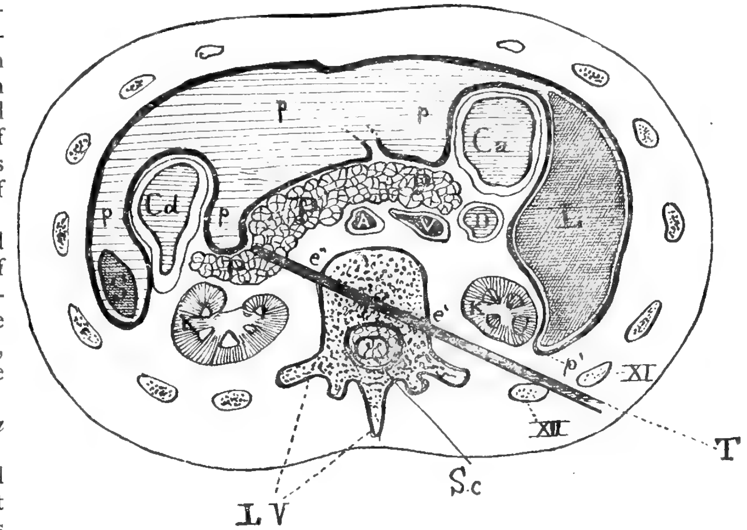

Diagram of a Horizontal Section through a Frozen Human Cadaver at the Level of the Pancreas.

evident that the different suppurating surfaces, and especially the fractured spongy tissue of the vertebra furnish a sufficient explanation of the septic conditions which existed during life.

The accompanying diagrams (page 503) from the *Medical Record* illustrate the course of the bullet very aptly. Fig. 6 is, in our opinion, valueless as a diagram, and it is difficult to harmonize the statements about the track of the ball, and the figure reference, "injury to artery" in the latter illustration. The figure reference, "Point of impact of ball *and deflection*," may be also taken with some allowance.

We have added a schematic drawing taken from a plate representing a frozen section through the human

body, in the horizontal plane (supposing the body standing), and figured of the life size in Braune's magnificent "Atlas." Such a diagram more accurately represents the course of the bullet topographically, than the ones selected by Dr. Bliss seem to us to do.

It is a noteworthy fact, that on marking the topographical projection of the fracture of the 11th rib, that is the point of impact (XI), the fracture of the 12th rib (XII), the aperture of entry into the lumbar vertebra (c'), the aperture of exit (c"), and the terminus of the bullet track, where the bullet was found encysted, on this frozen section, and *connecting all these points by a line, that line is found to be perfectly straight!* It will be seen on examining the figures 4 and 5 furnished by the President's physician, that the bullet track was as straight as an arrow in its frontal projection, and as far as it involved the bony structures.

Now, a line which appears as a straight line in two projections of space, is a straight line in fact, and from this point of view, the case merits renewed discussion.

It must be recollected that our diagram represents a horizontal plane of the body, and the one where the bullet was found encysted. The point of impact lies much higher, the liver in that higher level occupies a greater area of the section, and the bullet in passing the peritoneum seems to have grazed the latter. It could hardly have done so without "nicking" the lower part of the pleural cavity, which descends to this level as a fine slit. The pleuritic adhesions found at the lower part of the right lung, sustain this view.

In the light of modern surgery, an examination of this wound could have presented no difficulties. It is illustrative of the unfortunate position in which the President's physicians find themselves placed, when attempting to defend their course, that the only examination of the wound, which they are able to refer to, is that made by the Surgeon General of the Navy, who was checked in his examination, and excluded from the President's bed-side by those later in charge of the patient. That the fracture of the ribs was not recognized by the attendants, until suppuration near the point of impact necessitated the removal of dead and decaying fragments of bone, is also a remarkable feature of the case. The course of the bullet from the point of impact, being a direct one to the lumbar vertebra, it is difficult to conceive how a thorough digital and instrumental examination could have failed to detect the irregularity produced on the vertebral body by the entrance of the bullet.

None of the procedures necessary to have determined the bullet track from the point of impact to the point of entry into the spinal column, would have been unwarrantable to the most conservative surgeon. *None of these procedures would have been more risky than the one later resorted to in the case, when the false bullet track was repeatedly probed to a distance of twelve inches.*

At this point criticism must necessarily pause, with reference to the question of the examination of the wound. The perforation of the lumbar vertebra having been detected, a bold surgeon might shrink from passing his probe further and following up the bullet-track into the regions beyond, through a perforated segment of the spinal column. What now, in the light of the *post mortem* seems perfectly feasable, during the President's life would have been considered as "heroic" a surgery, as can well be conceived. That a surgeon endowed with the necessary amount of daring, and that great essential the *tactus eruditus*, could have passed a probe through the vertebra and touched the bullet, *without injuring any important organ*, must be admitted by every impartial expert who bears in mind the directness of the bullet track.

This question, however, represents rather a side-issue, when it is recollected that it was not the location of the ball, or its presence in the body, that killed the President. It is only as an illustration of the extent to which the public was misled, and we fear intentionally misled, by some of the President's physicians, that it merits being referred to.

One of the consulting surgeons stated in an ironical way that the bullet could have been removed if its situation had been known, provided the surgeon had, as a preliminary, removed several lumbar vertebræ, and groped his way among the great nerves, the thoracic duct, the Aorta and the Vena Cava. This assertion is stated by no less a one than Dr. Hammond, to be an intentional deception of the people, as it was made through the columns of the daily papers. The reader will see in our diagram that the Aorta and Vena Cava have absolutely no relations to the bullet-track or to the seat of the bullet. Had the situation of the latter been appreciated during life, an incision on the left side of the spinal column would have been in order. This incision and the entire operation *would have been the strict counterparts of certain of the legitimate operations of modern surgery*, namely of *nephrotomy* and *lumbo-colotomy*. It is bad surgery which insists that in every bullet wound, the bullet has to be extracted through its own track. A bullet perforating the thigh to within an inch of the surface on the other side, is to be extracted from the point where it is nearest the surface.

The reader will find the left kidney indicated at K, this is operated on in the operation of nephrotomy, he will find the descending colon at (C. d.), this is opened into in the operation of lumbo-colotomy;

The same risks would have to be taken in the extraction of the bullet that are familiar to the surgeon who performs the latter operation.

Leaving aside all speculative issues, let us trace out the symptoms of the heroic and patient sufferer and their basis, as inferable from the autopsy.

When first struck by the bullet, the President suffered from Surgical Shock. The wound was so severe that his death might have taken place in a few hours; death so occurs to soldiers on the field of battle, who receive similar wounds. His treatment, which consisted in the administration of stimulants and opium, was eminently proper, and doubtless aided by the powerful constitution, overcame the tendency to a fatal collapse.

A tendency to such a collapse recurred at a later period, when Dr. Wales thought the President dying. The primary hemorrhage from the wound was insignificant, no important blood vessels were injured, and the hemorrhage seems to have been mainly external. At a later period an escape of dark venous blood from the wound seems to us to have indicated necrotic usure of the large veins running in the substance of the injured vertebral body.

The painful sensations experienced in the distribution of all the nerves, originating from the crural and particularly the sacral plexus, are attributable to the sudden shock acting on the vertebral column. There is no evidence that any hemorrhage occurred around the nerve roots, or any inflammatory disturbance of the cord or its membranes. The spontaneous disappearance of these nervous symptoms proves conclusively that they were due to the kind of shock, frequently occurring in the practice of military surgeons, and well described by Mitchell, Morehouse and Keene in their work on nerve-injuries. That the nerves on the right side suffered more than those of the left, is attributable to the greater nearness of the right vertebral bullet aperture to the inter-vertebral foramen, where the nerves concerned in the tegumentary supply of the most painful region in this case emerge.

The main injury done by the bullet in its further course, consisted in the irritation of important nerve filaments connected with the Solar Plexus of the Sympathetic System. Irritation of this Plexus, or its derivative branches, accounts for the obstinate and frequently recurring spells of nausea and vomiting, as well as for the great acceleration of the pulse rate, so marked a feature of the President's history. These same symptoms, through the same mechanism, occur with peritonitis, and some of our best physicians suspected the existence of this trouble, from these two symptoms alone. It cannot be said that the imperfect and ambiguous post-mortem record quoted, proves them to have been wrong in their surmise.

In view of the great irritability of the alimentary canal, it is to be considered highly unfortunate that the President's dietary was not properly attended to. At least two of his relapses were due to the undue massing of food in his stomach, at what were considered convalescent periods. Though it is denied that he was allowed improper articles, yet in view of the fact that much of what occurred in the sick-chambers, was rigidly ignored or suppressed by the medical staff, and that on their own confession he was fed on so injurious a combination as milk and lemon-juice for the first few days after the injury, we can not consider that assertion as an invention, until a more authoritative denial be made, than the one vouchsafed by Dr. Bliss.

Several days after the injury, when that examination of the wound was made, which should, in the opinion of ninety-nine out of a hundred surgeons, whom we have consulted or heard opinions from, been made in the first place, a canal was found extending downward to the pelvis. This is now known as the fistulous tract represented on the body-diagram. It was due to burrowing of the pus originating, be it borne in mind, not from the bullet, not from the perforated vertebra, but from the neglected fragments of the eleventh rib. The surgeons did all in their power for a long period to oppose Nature's attempt to close this passage. Thus the pus-absorbing surfaces were largely increased, and with it the dangers of pyæmia.

Without entering into the details of the management of the case, let us conclude with an examination as to the cause of death. The immediate cause of death is stated by the attending surgeon to have been hemorrhage from a dissecting aneurism of the splenic artery. The evidence offered as to the existence of such an aneurism is exceedingly feeble. It is founded on an examination of the specimen after it had lain in alcohol. Under such circumstances laminated layers, as well as membranous precipitates are very apt to form, and on the existence of these the diagnosis appears to rest. A far more natural explanation suggests itself. Every medical student knows that when the dead subject is injected for anatomical purposes masses of blood or of the injecting material are very apt to be found in the abdominal cavity, having escaped through rents in the arteries artificially produced. The pressure used by the embalmer when injecting the President's body was so great that in several places Dr. Bliss is constrained to speak of cavities, a large part of the fluid contained in which had probably transuded from the injecting material of the embalmer. The existence of other clots in the omentum, and elsewhere in the peritoneal cavity, shows that vessels altogether unconnected with the

wound were ruptured by the injecting pressure. The autopsy should have been made before the injection, and then we should have known whether a heart-clot as an accompanying factor of death from post-pyæmic exhaustion was present or not. A physician might well blush for a profession, a member of which could in the face of the criticism waiting to hang on every expression that fell from his lips, deliberately state that the President died of "Neuralgia of the Heart."

The primary cause of death was unquestionably pyæmia. The attending surgeons persist in speaking of septicæmia, and their apologist in the *Medical Record*, Dr. Shrady, ably shields their diagnosis by saying that strictly speaking there is no such thing as pyæmia. It should be known, he claims, as metastatic septicæmia. The attending surgeons knew and know what is meant by pyæmia, and deliberately denied, and still deny, that the condition passing under that name existed. The abscess of the parotid gland, the abscess in the kidneys, and the foci in the lungs are stubborn facts; but they do not appear to exist for those who seem interested in placing their critics in the wrong.

In the conclusion of the report it is stated:—

"The surgeons assisting at the autopsy were unanimously of the opinion that, on reviewing the history of the case in connection with the autopsy, it is quite evident that the different suppurating surfaces, and especially the fractured spongy tissue of the vertebra, furnish a sufficient explanation of the septic conditions which existed during life."

This is admitted to be a correct inference by all those competent to form an opinion. Probably many will cavil at the term "especially" as destined to make light of the responsibility involved in keeping up that largest suppurating area in the President's body, the fistulous tract.

The lessons to be drawn from this surgical case, and it must be borne in mind that just such a case is reported as recovered in Dr. Hamilton's text book, are the following:—

1st. Experiments with projectiles on the dead body do not constitute any guide applicable to given living cases of gun-shot wound."

2d. Surgeons will sin less by being bold in probing and examining wounds, even when near the great cavities of the body, than by being over-conservative and taking chances.

3d. With a constitution like that of Mr. Garfield, almost any operative procedure would be preferable to a conservatism which, through its efforts to keep up a false tract, increases the fatal chances of pyæmia.

Those interested in the mechanism of the impingement of projectiles, will scarcely credit the claim that the bullet was deflected at its impinging point on the eleventh rib. A bullet which crushes through two ribs, cuts clean through a vertebra, and penetrates altogether over eight inches of bony, muscular and fatty tissue in a straight line, and fired at so short a range, can scarcely have been deflected by the very rib it crushed to pieces. The simplest explanation of its course is, that the assassin fired at the President in a line directly continuous with the bullet track in the latter's body. That is, he fired while the plane of the President's back was oblique to the plane of the mouth of the revolver. With this the account given by the assassin himself, the coolest and most unmoved witness of the deed, is in accord throughout.

It should be recollected, what seems to have been overlooked by most or all of those who have criticized this case, that the relations of the parts into which the bullet was fired, were altogether different at the time of the assassination than when the autopsy was performed. At that time large, fatty and muscular masses had to be traversed by the ball, which, in the course of the wasting process ensuing, had nearly disappeared.

It is unfortunate that the brain was not examined. The continual delirious state of the sufferer suggests some metastatic affection of that organ. Probably the reason this organ was not examined was the desire to avoid disfigurement, but the brain can be removed in even a bald person without the latter.

It may be here urged that the early performance of the autopsy should not have interfered with the subsequent embalming. The embalming procedure resorted to in the President's case was of the most routine and imperfect character, and not remotely comparable to the perfected processes employed by the German and Italian anatomists and embalmers.

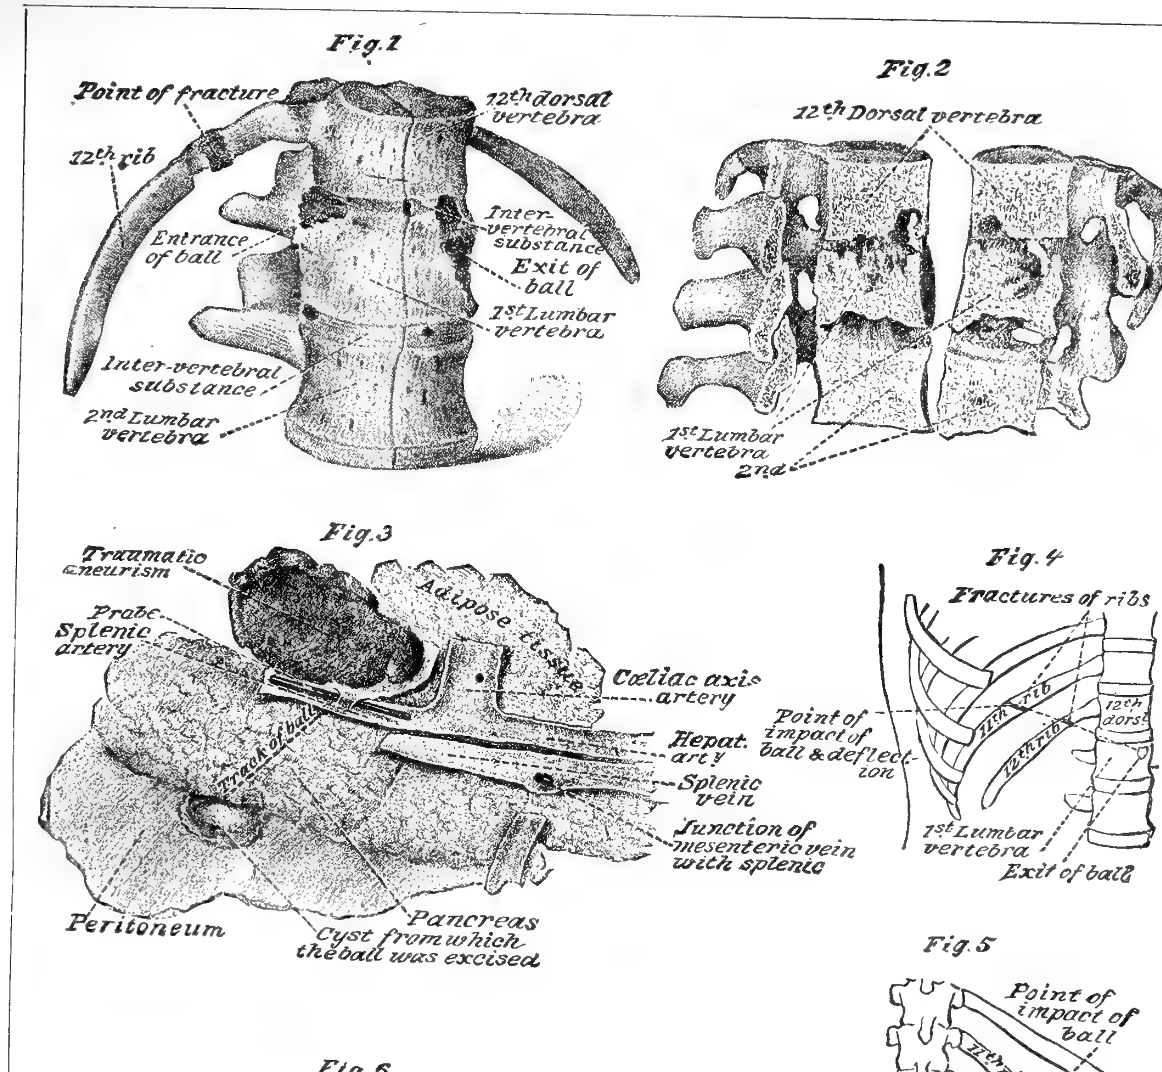
PROTOPLASM STAINED WHILST LIVING.—Mr. L. F. Henneguy publishes the result of some experiments made on living infusoria, in which he confirms the observations of Brandt, made in 1879, that an aqueous solution of aniline brown, known in commerce as Bismarck brown, will give an intense brownish-yellow color to the protoplasm of the infusoria without in any way interfering with their enjoyment of life. The coloration first appears in the vacuoles of the protoplasm, then this latter is itself stained, the nucleus being most generally not at first colored, and so being made more conspicuous. Experiments made on vegetable protoplasm seemed to exhibit the same result.



DRAWINGS ILLUSTRATING AUTOPSY ON THE BODY OF THE LATE PRESIDENT GARFIELD.

THE AMERICAN CHEMICAL SOCIETY.

The October meeting of the American Chemical Society was held Friday evening, the 7th inst., with Dr. A. R. Leeds in the chair. The following new members were declared elected: H. C. Heipe, Wm. L. Leman, Dr. H. Von Bauer, Lewis Habel, Dr. Lauber, Dr. P. Radenhauser, and Mr. A. L. Colby. The first paper announced was by Prof. Leeds "On the Comparative Purity of City Water." In consideration of the recent litigation in regard to the pollution of the water of the Passaic river, Prof. Leeds was appointed to investigate the purity of the water from a chemical standpoint. The water supply of the cities of Newark, Jersey City and Hoboken is taken from the above mentioned river. Before it reaches Newark, the sewerage of Paterson, a city of 50,000 inhabitants, is emptied into it: besides this, along the river, the stream receives the refuse from a number of factories.

A short distance beyond Paterson, at a paper mill where carbolized paper was manufactured, the entire refuse was dumped into the river. In consequence of the dissolving of the carbolic acid, its presence was soon detected at Jersey City and Hoboken, and it became so objectionable that the water could not be used for drinking purposes. Legal measures were at once adopted, and the nuisance stopped. Simultaneous collection of specimens of the drinking water of the leading cities of the United States were collected, and a comparative examination of the organic matter (estimated according to the permanganate method) undertaken. Without any other special reference to the data given by Prof. Leeds, his results were as follows:—

. The purity of drinking water:—

1, Brooklyn; 2, Rochester; 3, Philadelphia; 4, Baltimore; 5, New York; 6, Washington; 7, Newark, Jersey City and Hoboken; 8, Cincinnati; 9, Boston; 10, Oswego; 11, Wilmington, Del.

In answer to questions which arose during the discussion of the paper, it was stated that during the past summer an excessive amount of chlorine was found in the analysis of the Passaic river, a fact contrary to all previous experience, and one which was considered as due to the extreme drought of the past summer so diminishing the amount of fresh water that the sea water had extended quite a ways back up the river. A similar circumstance was stated in regard to the Hudson river this year, the salt water being detected higher than usual. In regard to the statements recently made by Prof. Huxley in reference to the spread of disease by germs in the water, a very significant fact was mentioned by Prof. Leeds, in commenting on the rags used in the paper mills, who stated that they were imported from the plague stricken regions of Smyrna, and yet not one case of analogous disease had been observed from those who used the water, in which these rags were cleansed, for drinking purposes. The desirable property of precipitating out organic material from water by the use of the basic chloride of iron was remarked by Dr. E. R. Squibb. This fact has been used to advantage by one of the large hotels at Coney Island.

"Upon some new Salts of Thymole Sulpho Acid, and some new facts concerning the same," was the title of the second paper. It was by Mr. James H. Stebbins, Jr., and was essentially a resumé of some recent salts prepared by him and description of their important characteristics.

The third paper was by Dr. W. Hempel, who gave in the German language a descriptive "Exhibition of some new Gas Apparatus." Not only were they exhibited, but Dr. Hempel, in the presence of the Society, made analysis of the illuminating gas (which he considers superior to that used in Europe) and of the air. To those who are especially interested in this branch his recently published book will give the requisite information, and for the average reader a general description is almost impossible without cuts.

M. B.

MOUNDBUILDER SKELETONS.*

I.

By W. C. Holbrook, Coleta, Ill.

The skeletons found in the mounds of Rock River Valley, although always partially decomposed, present the following anatomical peculiarities:—

The *cranium* is small, low and broad. The superciliary ridges are very large and cause the forehead to appear even lower than it really is.

The malar process and the zygoma small and low.

Traces of a *frontal suture* are sometimes found in adult skulls. In the skull of a child about six years old, the suture was well developed. It appears that the two lateral portions of the frontal bone did not then unite as early in life as they now do, and that the traces of this suture remained through life in some persons. In one adult skull I found ten bones, viz.: two occipital, two parietal, two frontal, two temporal, sphenoid and ethnoid. The occipital was divided into two lateral portions by an *occipital suture.*

The *frontal suture* was also well developed. The *sagittal suture*, therefore, extended from the glabella over the vertex to the *foramen magnum.*

The *sagittal suture* is usually quite short. In one skull it measured only 4 67-100 inches, and the frontal and the occipital bones in this specimen were normal.

The supraorbital foramen is usually large and about one-eighth of an inch above the orbit. I never saw a supraorbital notch in a moundbuilder skull. *Ossa triquetra* are very uncommon and are confined to the lambdoid suture. This suture, together with traces of an occipital suture sometimes form one or two large triangular *ossa triquetra* in the superior angle of the occipital bone.

The posterior half of the synamus-suture is often completely grown up and the adjacent part of the temporal and parietal bones completely united.

The grooves for the *arterie menigea media* are very deep, while the foresæ that correspond to the brain are shallow and indistinct. The frontal sinus large and triangular in shape. The lower joint was large, massive and broad. The teeth are usual remarkably sound. I have never found but two or three "decayed teeth" in all of my explorations. Toothache was not, therefore, one of the troubles that beset the moundbuilders.

The humerus presents one marked peculiarity. About midway between the external and the internal condyloid ridges, and in the center of the fossa for the coronoid process of the ulwa, there is sometimes a well developed foramen.

In some mounds that contained fifteen or twenty persons this foramen was found in more than fifty per cent. of the humeri. I sometimes found it in both the right and the left arms. When only present in one arm, traces of an obliterate or grown up foramen were sometimes found in the opposite arm. Traces of this foramen are quite frequent, and in all moundbuilder humeri, the flat portion of bone between the condyloid ridges are very thin. This foramen is usually small and circular. Sometimes, however, it is large and triangular in shape, the base of the triangle parallel with the trochlea and the sides parallel with the condyloid ridges. A nutritious foramen sometimes enters the lower end of the shaft of the humerus at the superior angle of this triangular foramen. I believe that the moundbuilders were slowly outgrowing this Simian characteristic, for the humeri containing the triangular foramens are found in the oldest mounds, and are associated with the lowest foreheads and the smallest crania. In both the right and the left humerus of the skeleton whose skull contained ten bones, I found this foramen well developed. In the more modern mounds this foramen is less frequently found, and when present, is small and circular. The

* American Association for the Advancement of Science, 1881.

partition of bone between the two fossæ is also thicker.

The elimination of this "degraded affinity" is but one instance of the general evolution that has shaped or moulded all of the innumerable forms of animal and vegetable life. The vertebral column is always so badly decayed that anatomical comparison is impossible. The parts that "resist decay" indicate great physical perfection and strength. The Sacrum presents different forms in respect to curvature. Sometimes it is very slight, while in other specimens it is considerable. This curvature of the Sacrum is a more constant sexual characteristic in mound-builder skeletons than in the Caucasian or the African races, but I have not examined specimens enough to tabulate the difference. The only constant sexual characteristic of the Sacrum among all races of men is its greater breadth in the female, and this characteristic is well developed in the mound-builder skeletons. Comparing portions of almost every one of the larger bones of the mound-builder skeletons with several Caucasian and one Negro, and two Indian skeletons, it is certain that the primitive people of the Rock River Valley were strong, broad-shouldered, muscular men, with broad, round faces, and low receding foreheads. Exostosis, or foreign growth of bone, has been found. One, I remember, was found in one of the mounds near Sterling, Illinois. The foreign growth of bone in this specimen was stratified—deposited on the surface of the bone, in thin layers, like the layers in stalagmite. Bones exhumed from a mound on the west bank of Rock River, near Como, were very brittle, of a light and beautiful purplish color, when recently broken, and contained no animal matter. They resemble, in every respect, the bones exhumed from the church-yard of Ste. Genevieve, Paris, after a burial of over seven hundred years.—(Orfila Exhumations Juridiques, Vol. I., p. 350.)

WHITE CORPUSCLES OF THE BLOOD.

The London *Lancet* draws attention to an interesting memoir on the White Corpuscles of the Blood, which appears in the part just issued of the *Archives de Physiologie*, in which M. Renaut describes the different forms presented by the white corpuscles in different animals. In the river crayfish, for example, besides the ordinary lymph-corpuscles, there are many larger bodies with well defined nuclei, the protoplasm of which contains large highly refracting granules, resembling in many respects the vitelline granules of the frog and other batrachia. These corpuscles have a sharply limited but thin exoplastic pellicle; and if a drop of such lymph be allowed to fall into a drop of a one per cent. solution of osmic acid, the white corpuscles are instantly fixed, with their pseudopodia or protoplasmic processes extended; and these processes can then be seen to perforate the thin membrane, now blackened with the acid. There are thus two kinds of white corpuscles in the decapod crustacea—the lymphoid corpuscles and the amœboid corpuscles. Do similar differences exist in the blood of vertebrata? In reply to this, M. Renaut states that in the blood of all the vertebrata, from the cyclostome to the saurians, the white corpuscles are of two kinds; one, the ordinary white corpuscle, composed of hyaline protoplasm, presenting many short projecting points, with a nucleus undergoing gemmation and sending forth branched pseudopodia when placed under favorable conditions; the other containing numerous brilliant granules embedded in the protoplasm and surrounding the nucleus. These resemble the second form of corpucle described above as existing in the lymph of the river crayfish, but differ from them in having no outer limiting layer of condensed protoplasm, or exoplasm, as Haeckel has named it. The application of osmic acid shows that they may be subdivided into two other forms: one closely analogous to cells undergoing transformation into fat-cells, which present numerous granules, and stain black with osmic acid, and another set which contains granules that are not fatty, but which stain red with eosine. The best mode of demonstrating the existence of these three forms is to fix the blood in the rete mirabile of the capillary of the choroid in the posterior segment of the eye of a frog, by removing the anterior segment and exposing it to the vapor of osmic acid. At the expiration of twelve hours the eye is removed from the vapor, washed, the chorio-capillaris detached from the retina, and spread on glass; it is afterwards colored with, and mounted in, hæmatoxylate of eosine. The corpuscles may then be studied, and the three forms of ordinary, granular, and fatty corpuscles can be easily distinguished. M. Renaut finds that the white corpuscles of mammals generally, and of man in a state of health, all closely resemble each other, and are of the ordinary kind; but in disease, as in leucocythæmia, the white corpuscles are not only greatly increased in number, but vary considerably in size. Moreover, they are round, and present no pseudopodia. They are hyaline, and have a smooth, well defined limiting membrane, and some of them have nuclei which have undergone fission, just as in a cell that is about to segment. Hence, he is of the opinion that the white corpuscles multiply and increase in number whilst floating in the blood; other corpuscles may be observed, which are charged with granules of some proteid substance, resembling vitelline granules, or small masses of hæmoglobin; and, lastly, there are still other cells, which are charged with fat. M. Renaut has made some observations on the development of the red corpuscles of the lamprey, and gives the following succession of forms:—White corpuscle with nucleus proliferating, and protoplasm, not limited by an exoplasmic layer; corpuscle with nucleus proliferating, the protoplasm forming an uncolored disc, limited by an exoplasm; corpuscle with proliferating nucleus, protoplasm limited by an exoplasm, and forming a disc, more or less charged with hæmoglobin; red corpuscle with proliferating nucleus; and, finally, circular red corpuscle, with rounded nucleus.

MICROSCOPY.

It has been decided by the Executive Committee of the American Society of Microscopists to convene the next annual meeting of the Society at Elmira, N. Y., August 17, 1882, at 10 A. M. It is thought that there will be papers and discussions enough at Elmira to occupy us four days; thus, by adjourning Friday evening, August 20, or Saturday noon, August 21, there will be ample time—for those who wish to do so—to reach Montreal in time for the meeting of the A. A. A. of Science on Tuesday, August 24.

At the Columbus meeting Mr. E. H. Griffith, of Fairport, N. Y., a member of Executive Committee of this Society, renewed his generous offer of a prize of a Bausch & Lomb half-inch objection of 98° air angle (about 0.76 numerical aperture), to be awarded as follows:

"The prize shall be assigned to the author of the best paper on the adulteration of some important article of food or medicine. The paper shall be accompanied by permanently mounted slides, illustrating the various points under discussion; all papers and slides to become the property of the Society. The papers and accompanying studies to be in the possession of the President on the first day of the next annual meeting. He shall appoint a committee of three to examine the same, and report the name of the successful candidate before the close of the meeting. The names of the competitors shall not be made known to any member of the committee until after the award is made. The award shall not be made unless there shall be more than one competitor."

In order to carry out Mr. Griffith's instructions the following rules are established:

1. The papers and slides for the competition should be forwarded to Elmira in time to reach there before the day of the beginning of the next annual meeting, and should be addressed:

To the President of
THE AMERICAN SOCIETY OF MICROSCOPISTS,
Care of the Elmira Microscopical Society, Elmira, N. Y.

2. The envelopes should bear in their upper left-hand corner one of the enclosed labels, with some appropriate name or device other than the name of the author. The slides should bear the same label similarly marked (ten labels are sent with each circular).

3. Each paper should be accompanied by a sealed envelope bearing the same label and device, containing a slip with the name of the author.

4. The committee will be appointed on the first day of the Elmira meeting, and the papers and slides put into their hands. When they reach a decision, they will make a public report, stating the name or device of the successful paper. The sealed envelope bearing the same will then be opened by the President, who will announce the name of the successful author.

Persons not now members, but who shall become so at the Elmira meeting, are eligible as competitors for this prize, and can obtain the necessary labels by making application to the Secretary.

It is hoped that several papers will be received in competition for this prize which shall be found worthy of publication in the Transactions, though only one, of course, can receive the prize. The envelopes containing the names of unsuccessful competitors will not be opened except by permission of the authors, but will be destroyed by a committee appointed for that purpose.

Dr. George E. Blackham, the present President of the Society, has issued a stirring address to the members, and makes some excellent suggestions to those who would by their personal acting promote the success of the society.

Professor D. S. Kellicott of 119 Fourteenth Street, Buffalo, N. Y., is the Secretary of the Society.

FOSSIL POLYZOA—NOMENCLATURE.

In the second report of the committee consisting of Prof. P. M. Duncan and Mr. G. R. Vine, appointed for the purpose of reporting on Fossil Polyzoa, for the British Association, the order is divided into three subdivisions.—

1. *Cheilostoma*, Bark. = *Celleporina*, Ehrenberg.
2. *Cyclostomata*, „ = *Tabuliporina*, Milne-Ed., Hagenow, Johnston.
3. *Ctenostomata*, „

The following terms are used in this Report in describing the genera:—

ZOARIUM.—"The composite structure formed by repeated gemmation" = Polyzoarium and Polypidom of authors.

ZOŒCIUM or cell.—"The chamber in which the Polypide is lodged.

CŒNŒCIUM.—"The common dermal system of a colony." Applicable alike to the "Frond," or "Polyzoary," of Fenestella, Polypora, Phyllopora, or Synocladia: or to the associated Zoœcia and their connecting "interstitial tubuli," of Ceriopora, Hyphasmapora, and Archæopora, or species allied to these.

FENESTRULES.—The square, oblong, or partially rounded openings in the zoarium—*connected by non-cellular dissepiments*—of Fenestella, Polypora, and species allied to these.

FENESTRÆ applied to similar openings, whenever connected by the general substance of the zoarium—as in Phyllopora, Clathropora, and the Permian Synocladia.

BRANCHES.—The CELL-bearing portions of the zoarium of Glauconome, Fenestella, Polypora, or Synocladia; or the offshoots from the main stem of any species.

GONÆCIUM,—"A modified zoœcium or cell, set apart for the purposes of reproduction."

GONOCYST.—"An inflation of the surface of the zoarium in which the embryos are developed." Modern terms from the Rev. Thos. Hincks.

"PRESERVED VEGETABLES."

By OTTO HEHNER, F. I. C., F. C. S.

When some time ago public attention was forcibly drawn to the occasional injurious effects of preserved "canned" goods, I undertook a lengthy series of chemical and physiological experiments to ascertain the cause of such poisonous action. The results having so far only been communicated to professional chemists (*The Analyst*., vol. v., No. 57), I hope you will allow me, by way of affirmation of the paragraph in *The Lancet* of September 24, to give a short summary of them, as I think they may be of interest, and of some degree of importance, to medical readers.

Very frequently the gastric disturbances traceable to the consumption of preserved articles of food have been assigned to traces of lead dissolved from the solder with which the tins are closed, or present as impurity in the metal with which the can is lined. Now, although the occasional though very rare presence of lead in such articles cannot be denied, the effects should be attributed to the *tin* itself. Tin, even perfectly pure, is far more readily attacked by food matters than is commonly supposed; it is to be found in comparatively large amounts in an overwhelming majority of canned goods, irrespective of the nature of the same. Acid fruits, such as peaches or cherries, corrode the tins to an appalling extent; but even meats, nay, condensed milk, dissolve and become contaminated with serious quantities of the metal.

I base my observations upon the examination of the following foods:—Vegetable: French asparagus, American asparagus, peas, tomatoes, peaches (three different brands), pine apple (two kinds), white and red cherries, and marmalade. Animal: Corned beef (five brands), ox cheek, ox tongue (three kinds), collared head, tripe, oysters, sardines in oil, salmon, salmon cutlets, lobster, shrimps, curried fowl (two kinds), boiled rabbit, boiled mutton, roast chicken, roast turkey, ox cheek soup, gravy soup, sausages, condensed milk (three brands).

With the exception of the sausages, the whole of the samples contained more or less tin, many to such an extent that abundant reactions could be obtained from two or three grammes of the vegetable substances; whilst of the animal foods one of the soups contained thirty-five milligrammes, one of the condensed milks eight milligrammes, and oysters forty-five milligrammes of tin to the pound.

Pure tin is readily attacked even by carbonic acid in solution, all samples of soda-water or of other aerated beverages which I have tested giving distinct *tin* reactions. Aerated beverages are generally stated to be liable to lead contamination, but seeing that lead does not enter into the composition of any of the pipes or vessels of the machines made by modern manufacturers, I do not doubt but that the black coloration produced by sulphuretted hydrogen in the beverage in question has usually been erroneously attributed to lead, and is in reality due to tin. Tin, in fact, prevents the lead passing into solution; it completely precipitates the metal from lead solutions, an equivalent quantity of tin being taken up.

The question arises, is tin, when taken into the system, injurious to health or not? Forensic literature does not furnish a positive or satisfactory reply, but the following experiments appear to me completely to settle the point.

A half-grown guinea-pig took with its ordinary food seventy-five milligrammes of pure *stannous* hydrate in

two doses of twenty-five and fifty milligrammes each. Death resulted under symptoms of irritant poisoning. Tin was detected in large amount in the fæces and in the viscera, notably the liver.

Another similar animal took within three days, in six doses 450 milligrammes of *stannic* hydrate, *without* serious effect, tin appearing abundantly in the excrements. Accustomed in a manner to stannic salts, it quickly succumbed to fifty milligrammes of stannous hydrate.

It plainly follows that while stannic compounds are not injurious in the doses given, tin in the stannous condition is a virulent irritant poison.

These experiments lead me most strongly to support your demand for a better method of packing preserved food matters than in tin canisters. Tin invariably dissolves in the stannous condition in such solvents as occur in vegetable or animal substances, and the amount of oxygen in the sealed canisters being very minute, oxidation cannot render the metal comparatively unobjectionable.

I trust that the medical profession will object, unmistakably and strongly, to the administration of tin by grocers and oilmen to young and old alike, and, whilst acknowledging the enormous benefits conferred upon the masses by the introduction of preserved foods, will insist that the present system of packing be speedily abandoned.—*Lancet.*

CORRESPONDENCE.

To the Editor of " SCIENCE."

DEAR SIR: I have carefully read your article on " The Warner Astronomical Prizes," published in SCIENCE, of Sept. 24, wherein myself and Mr. Warner, are severely and unjustly criticised. In a former number you had criticised one of the conditions of the prize: viz, that " the comet must be telescopic and unexpected,' saying that a person might discover a comet by the aid of an opera glass. But what, I ask, is an opera glass but a telescope. In order to defend myself from even the semblance of crookedness, allow me to state a few facts, familiarity with which would, doubtless, have kept you from error. When the great comet (known as comet B) made its appearance so suddenly, all familiar with the conditions of the award, conceded that no just demand on Mr. Warner could be made, as it was neither telescopic nor unexpected, but very many people, not conversant with the conditions, and supposing that it applied to all comets, began to send in claims for discovery. Then Mr. Warner said, inasmuch as the comet was such a large and brilliant one, and that so many seemed not to have understood the conditions imposed, he would offer a *special* prize of $200 to the one whom I, after an examination of claims, should decide had first seen it. It is a point of no little significance, to remember that this in no sense was to be considered as the Warner-prize proper to be adjudicated upon by Profs. Hall and Young, *in the event of a controversy*, but was distinctly stated to be a *special* prize. The conditions of the original prize were neither in this, nor any other instance, to be deviated from. From a misconception of this vital point, which, under the circumstances, was, perhaps, natural, you have endeavored to make your readers believe that Mr. Warner took—wrongfully and unjustly—the matter out of the hands of Profs. Hall and Young, and placed it in my own, but you are grievously in error. I do not purpose to burden your columns with the reasons for not awarding the prize for comet B. Not an astronomer in the world, with all those letters before him, would have awarded it.

You make the task of deciding the question a very easy one, and so might I have found it by placing myself in the position of a judge, who must decide according to the evidence, true or false. Instead of condensing the letters to a half dozen, as you suggest, I could have reduced them to a single one, for one of the claimants solemnly declared that he saw it a year ago last August, and that he had watched it ever since, while another averred that he discovered it last January, and several claimed it before its discovery in South Africa, and some of these statements were sworn to at that.

Every astronomer knows that the comet (which was discovered in South Africa on May 21), in its northward journey, passed the sun, 8° west of it, at noon on the 19th of June, and, therefore, after its disappearance in the southern hemisphere, could not have been seen by any person, in any part part of the world, before the morning of the 22d of June, and yet not less than 1000 persons claimed (the statements of many being substantiated by affidavits), that they saw the comet at dates ranging all the way from May 1 to June 20. Was I to accept such statements as those, and accord to them the dignity of evidence, and award the prize for an invisible comet? The comet first became visible to us near the time of the summer solstice, when twilight commenced at about half past two A. M., which rendered even a bright and expected comet very difficult to see until its declination north became at least 15° greater than the sun's. Your assertion that I have awarded myself the prize for the discovery of one comet, is erroneous to the last degree. Where there is but one claimant, as was the case with Swift's, with Schaeberle's, and with Barnard's comets, Mr. Warner, without consultation with any one, pays the prize. Should any dispute arise as to priority of discovery, &c., then, according to the conditions, the matter was to be left to Profs. Hall and Young for a decision.

Again, you do me great injustice in saying that the essays ought not to be filed with me, because I am both a competitor and a judge. I am not a competitor for that prize, nor am I to be a judge. The essays are placed in my hands for safe keeping, and when the first of November arrives, will three astronomers (if as many can be found who are not competitors) be appointed as judges, to whom I shall send the essays for a decision agreeably to condition. 3d. As to who will appoint the judges, I am as ignorant as are you.

Trusting you will give this letter in its entirety, to the public, through the columns of your journal, I remain,

Yours truly, LEWIS SWIFT.

ROCHESTER, *October* 10, 1881.

RELATIONS BETWEEN THE CRANIUM AND THE REST OF THE SKELETON.—These relations form the subject of a paper by M. Manouvier, read at the last meeting of the French Association. The following are the author's conclusions:— 1. The weight of the cranium varies, in a general way, with the weight of the skeleton, but not proportionally, like the weight of the brain. 2. The weight of the skeleton, less the cranium, in a given race, varies nearly in proportion to the weight of the femur. 3. The weight of the cranium is greater relatively to that of the femur, the lighter the latter is. 4. The weight of the cranium is much more considerable relatively to that of the femur in woman than in man. 5. This sexual difference is so pronounced that it constitutes one of the best secondary sexual characters. About 82 women in 100 have the cranium heavier than the two femurs, while 82 men in 100 have it lighter. 6. The lower jaw is heavier relatively to the cranium in the anthropoids than in man, is inferior than in civilized races, in man than in woman, and in the adult than in the child. 7. The weight of the cranium is smaller relatively to that of the lower jaw, the heavier the latter is, etc.

NOTES AND QUERIES.

ELECTRICITY.—I wish to inquire if it has been determined whether upon the union of two currents of electricity of different electromotive forces, they form one current of an intermediate intensity, as two streams of water of different temperatures would form one of an intermediate temperature. Or, whether they each retain its own E. F. M., and follow the terms of its own intensity. And, if the problem has been determined, where I can find the particulars.

And, further, if the two retain their separate identities, whether any instrument has been made to measure the different quantities and intensities which pass in a single conductor.

This is a very important question in view of the great practical problems which we have now to solve in regard to the production and use of electricity.

SAML. J. WALLACE.

THE COLOR CHANGES OF AXOLOTL.—Prof. Semper has lately examined axolotl with regard to the influence of light on its color (*Würzburg Phys. med. Ges*). When young axoloti are reared in darkness they become quite dark; nearly as dark in red light; in yellow, on the other hand, pretty bright; and brightest in bright daylight. The difference is connected not only with the chromatic function found in various degrees in all amphibia, but on pronounced formation of a peculiar diffuse yellowish green coloring matter, increase of white, and diminution of dark chromatophores. Further, when axolotl are exposed to daylight in white dishes covered with white paper, much less dark pigment forms in them than when they are kept in white dishes without a paper cover (other things equal); though in the latter case they are apparently exposed to the most intense light; these darker axolotl are, however, still much brighter than those reared in red light or in darkness. Since (as experiment showed) the white covering paper let through much light, but very little of the chemical rays, it appears that chemical rays play no part in the formation of pigment. But the causes of the whitening in bright daylight and the darkening in absence of light remain unknown as before.

THE BLOOD OF INSECTS.—Operating with the larva of *Oryctes nasicornis*, M. Fredericq has observed (*Bull. Belj. Acad.*) that the blood of the animal, drawn off in a small glass cannula, is a colorless liquid, but on exposure to the air presently takes a decided brown color, and coagulates. The coloration he regards as a purely cadaveric phenomenon. The substance which becomes brown is probably formed in the moment of coagulation, and does not serve in the body as a vehicle between the external air and the tissues, like *hæmoglobin* in Vertebrates and many Annelids, *hæmocyanin* in Crustaceans, &c. When the larva is kept a quarter of an hour in hot water (50° to 55°), the blood extracted does not coagulate or become brown. Once the substance which browns is produced, even a boiling temperature does not prevent its browning. The brown substance once formed is very stable, not being decomposed either by acids or alkalies, and not made colorless by being submitted to vacuum or kept in a closed vessel. The existence of an intermediary in insects corresponding to hæmoglobin M. Fredericq thinks very problematical in view of the anatomical system, letting air penetrate into the heart of the tissues.

METEOROLOGICAL REPORT FOR NEW YORK CITY FOR THE WEEK ENDING OCT. 15, 1881.

Latitude 40° 45′ 58″ N.; Longitude 73° 57′ 58″ W.; height of instruments above the ground, 53 feet; above the sea, 97 feet; by self-recording instruments.

3 "	ONE "
SINGLE COPIES,	TEN CENTS.

PUBLISHED AT

TRIBUNE BUILDING, NEW YORK.

P. O. Box 3838.

LONDON, ENGLAND, - - - - 150 LEADENHALL ST.

SATURDAY, OCTOBER 29, 1881.

TO OUR ENGLISH READERS.

We have received from Messrs. Deacon & Co., of 150 Leadenhall street, London, England, a standing order for a large supply of "SCIENCE," which will be forwarded weekly. We shall be obliged if our English readers will make this fact known to their friends.

THE WARNER PRIZES.

WE afforded to Professor Swift ample space in our last week's issue, to reply to our strictures on his disposition of Mr. Warner's prize for Comet *b*, 1881. Our readers have now the facts before them and can judge for themselves on the merits of this matter. For ourselves we would say that, realizing the benefits that may accrue from Mr. Warner's gifts, we are not disposed to be too critical in regard to the benefactor nor to the dispenser, and we are far from supposing that either are knowingly walking in the paths of what Professor Swift calls "crookedness." But reading Professor Swift's reply, we cannot interpret it otherwise than as a confirmation of our objections to the course he has taken.

We admitted that, in this instance, under the conditions of the Warner prizes, no claimant could justly claim the prize. We followed by asserting, that as Mr. Warner waived the special conditions and told Mr. Swift to give the $200 to the man who first saw the Comet, it was his duty to have carried out his instructions to the letter.

Professor Swift confirms the position we took on this subject; in his letter he says: "all conceded that no just demands could be made on Mr. Warner" in regard to Comet *b*. Then Mr. Warner said, "inasmuch as the Comet was such a large and brilliant one, and as so many people seemed not to have understood the conditions imposed, *he would offer a special prize of* $200 TO THE ONE WHO I, after an examination of claims, should decide HAD FIRST SEEN IT."

Now comes the *muddle*. Mr. Warner admits that *under his conditions no one can claim the prize;* and therefore offers a special prize for THE ONE WHO FIRST SAW THE COMET. And yet Professor Swift in his letter of explanation says: "*the conditions of the original prize* were, neither in this nor in any other, *to be deviated from;*" and on this account concludes that "not an astronomer in the world would have awarded it."

What can be said or done with men who are so thoroughly and flagrantly inconsistent? Mr. Warner's course throughout appears to have been thoroughly practical; he saw the difficulty in awarding this particular prize, and met it in a most liberal spirit, and had his intentions been carried out, the thanks of the community would have been the unanimous response.

Passing over Professor Swift's apparent misinterpretation of Mr. Warner's instructions, the question may be asked: could "the one who had first seen it" be named? Waiving the claim of the "1000 persons with affidavits" who claimed to have seen the Comet in the United States before its possible appearance, and the 2000 other clod-hoppers and rustics whose claims appeared to have clouded the judgment of Professor Swift, we offer a few simple facts in regard to the first discoverer of Comet *b*, which would have influenced our judgment if called upon to decide on this matter:—

We believe that the first person in the United States who saw the Comet in question, noted its position, and duly reported the fact to Professor Swift was Mr. Edgar L. Larkin, of New Windsor, Ill. If Mr. Warner, however, prefers to award the prize to the *first person* who saw the Comet, irrespective of locality, then we are advised that the following facts bear on the subject:—

Dr. Gould's name was mentioned prominently in connection with its discovery, but according to his own statement, his attention was directed to it by his assistant, Mr. Wilson. But prior to this date it had been observed by Cruls, in Brazil, and also by several English astronomers at Melbourne. It now appears that Mr. John Tebbutt, of Windsor, New South Wales, is credited as the first astronomer to get an observation of this Comet; so that if the prize is to be awarded to the first discoverer, Tebbutt appears to be the man.

The assertion in Professor Swift's letter that Mr. Warner, without consultation with any, pays the prize in certain cases, causes us some surprise, as we thought that his previous experiences hardly warranted him to decide on matters astronomical, and that he delegated the task to others.

In regard to the prize essay, we would advise Mr. Warner to postpone the time of entry until January the 1st next, which will give a reasonable time for some creditable work to be done. We would also propose that the judges be named immediately. Professor Swift says in his letter, "as to who will appoint the judges I am as ignorant as are you." Who does know? Surely Mr. Warner will not propose to decide this matter.

In making these remarks we are far from desiring to disparage the value of such prizes as those offered by Mr. Warner. We understand that Mr. E. E. Barnard, who secured the last prize, is a young man under twenty-five years of age, and a self-taught astronomer. Under very discouraging financial circumstances he provided himself with a good five-inch telescope, with which he has done excellent work. His Warner prize will be turned to good account, as he writes to inform us that the $200 will enable him to purchase a plot of ground on which to build a house for his family; we need not add that an observatory will be a leading feature in Mr. Barnard's new house.

We feel a pleasure in showing the practical good Mr. Warner is doing by providing these scientific prizes, and we trust he may continue them during the following year. Our criticism is of a perfectly friendly character and made with some regret. We have received letters from subscribers confirming our view of the case, which will remain unpublished, as we desire to close the discussion.

ON THE DISCOVERIES OF THE PAST HALF-CENTURY RELATING TO ANIMAL MOTION.

By J. BURDON-SANDERSON, M. D., L.L.D., F.R.S.

[*Concluded from Page* 486.]

The living muscle of a frog is placed in a closed chamber, which is vacuous—*i. e.* contains only aqueous vapor. The chamber is so arranged that the muscle can be made to contract as often as necessary. At the end of a certain period it is found that the chamber now contains carbonic acid gas in quantity corresponding to the number of contractions the muscle has performed. The water which it has also given off cannot of course be estimated. Where do these two products come from? The answer is plain. The muscle has been living all the time, for it has been doing work, and (as we shall see immediately) producing heat. What has it been living on? Evidently on stored material. If so, of what nature? If we look for the answer to the muscle, we shall find that it contains both proteid and sugar-producing material, but which is expended in contraction we are not informed. There is, however, a way out of the difficulty. We have seen that the only chemical products which are given off during contraction are carbonic acid gas and water. It is clear, therefore, that the material on which it feeds must be something which yields, when oxidized, these products, and these only. The materials which are stored in muscle are oxygen and sugar, or something resembling it in chemical composition.

[1] Ludwig's first important research on this subject was published in 1881.

And now we come to the last point I have to bring before you in connection with this part of my subject. I have assumed up to this moment that heat is always produced when a muscle does work. Most people will be ready to admit as evidence of this, the familiar fact that we warm ourselves by exertion. This is in reality no proof at all.

The proof is obtained when, a muscle being set to contract, it is observed that at each contraction it becomes warmer. In such an experiment, if the heat capacity of muscle is known, the weight of the particular muscle, and the increase of temperature, we have the quantity of heat produced.

If you determine these data in respect of a series of contractions, arranging the experiments so that the work done in each contraction is measured, and immediately thereupon reconverted into heat, the result gives you the total product of the oxidation process of heat.

If you repeat the same experiment in such a way that the work done in each contraction is not so reconverted, the result is *less* by the quantity of heat corresponding to the work done. The results of these two experiments have been found by Prof. Fick to cover each other very exactly. I have stated them in a table[1] in which we have the realization as regards a single muscle of the following forecast of Mayer's as regards the whole animal organism. "Convert into heat," he said, "by friction or otherwise, the mechanical product yielded by an animal in a given time, add thereto the heat produced in the body directly during the same period, and you will have the total quantity of heat which corresponds to the chemical processes." We have seen that this is realizable as regards muscle, but it is not even yet within reach of experimental verification as regards the whole animal.

I now proceed abruptly (for the time at our disposal does not admit of our spending it on transitions) to the consideration of the other great question concerning vital motion, namely, the question how the actions of the muscles of an animal are so regulated and coordinated as to determine the combined movements, whether rhythmical or voluntary, of the whole body.

As every one knows who has read the "Lay Sermons," the nature and meaning of these often unintentional but always adapted motions, which constitute so large a part of our bodily activity, were understood by Descartes early in the seventeenth century. Without saying anything as to his direct influence on his contemporaries and successors, there can be no doubt that the appearance of Descartes was coincident with a great epoch—an epoch of great men and great achievements in the acquirement of man's intellectual mastery over nature. When he interpreted the unconscious closing of the eyelids on the approach of external objects, the acts of coughing, sneezing, and the like as mechanical and reflected processes, he neither knew in what part of the nervous system the mechanisms concerned were situated, nor how they acted.[2] It was not until a hundred

[2] Descartes' scheme of the central nervous mechanism comprised all the parts which we now regard as essential to "reflex-action." Sensory nerves were represented by threads (filets) which connected all parts of the body to the brain ("Œuvres," par V. Cousin, vol. iv., p. 359); motor nerves by tubes which extended from the brain to the muscles; "motor centres" by "pores" which were arranged on the internal surface of the ventricular cavity of the brain, and guarded the entrances to the motor tubes. This cavity was supposed to be kept constantly charged with "animal spirits" furnished to it from the heart by arteries especially destined for the purpose. Any "incitation" of the surface of the body by an external object which affects the organs of sense does so, according to Descartes, by producing a *motion* at the incited part. This is communicated to the pore by the thread and causes it to open, the consequence of which is that the "animal spirit" contained in the ventricular cavity enters the tube and is conveyed by it to the various muscles with which it is connected, so as to produce the appropriate motions. The whole system,

years after that Whytt and Hales made the fundamental experiments on beheaded frogs, by which they showed that the involuntary motions which such preparations execute cease when the whole of the spinal cord is destroyed—that if the back part of the cord is destroyed, the motions of the hind limbs, if the fore part, those of the fore limbs cease. It was in 1751 that Dr. Whytt published in Edinburgh his work on the involuntary motions of animals. After this the next great step was made within the recollection of living physiologists: a period to which, as it coincided with the event which we are now commemorating—the origin of the British Association—I will now ask your special attention.

Exactly forty-nine years ago, Dr. Marshall Hall communicated to the Zoological Society of London, the first account of his experiments on the reflux function of the spinal cord. The facts which he had observed, and the conclusions he drew from them, were entirely new to him, and entirely new to physiologists to whom his communication was addressed. Nor can there be any reason why the anticipation of his fundamental discovery by Dr. Whytt should be held to diminish his merit as an original investigator. In the face of this historical fact it is impossible to regard him as the discoverer of the "reflex-function of the spinal cord," but we do not the less owe him gratitude for the application he made of the knowledge he had gained by experiments on animals to the study of disease. For no one who is acquainted with the development of the branch of practical medicine which relates to the disease of the central nervous system will hesitate in attributing the rapid progress which has been made in the diagnosis and treatment of these diseases, to the impulse given by Dr. Marshall Hall to the study of nervous pathology.

In the mind of Dr. Marshall Hall the word reflex had a very restricted meaning. The term "excito-motary function," which he also used, stood in his mind for a group of phenomena of which it was the sole characteristic that a sensory impression produced a motor response. During the thirty years which have elapsed since his death, the development of meaning of the word reflex has been comparable to that of a plant from a seed. The original conception of reflex action has undergone, not only expansion, but also modification, so that in its wider sense it may be regarded as the empirical development of the philosophical views of the animal mechanism promulgated by Descartes. Not that the work of the past thirty years by which the physiology of the nervous system has been constituted can be attributed for a moment to the direct influence of Descartes. The real epoch-maker here was Johannes Müller. There can be no doubt that Descartes' physiological speculations were well known to him, and that his large acquaintance with the thought and work of his predecessors conduced, with his own powers of observation, to make him the great man that he was; but to imagine that his ideas of mechanism of the nervous system were inspired, or the investigations by which, contemporaneously with Dr. Marshall Hall, he demonstrated the fundamental facts of reflex action, were suggested by the animal automatism of Descartes, seems to me wholly improbable.

I propose, by way of conclusion, to attempt to illustrate the nature of reflex action in the larger sense, or, as I should prefer so call it, the Automatic Action of Centres, by a single example—that of the nervous mechanism by which the circulation is regulated.

although it was placed under the supervision of the "*âme raisonable*" which had its office in the pineal gland, was capable of working independently. As instances of this mechanism Descartes gives the withdrawal of the foot on the approach of hot objects, the actions of swallowing, yawning, coughing, etc. As it is necessary that, in the performance of these complicated motions, the muscles concerned should contract in succession, provision is made for this in the construction of the system of tubes, which represent the motor nerves. The weakness of the scheme lies in the absence of fact basis. Neither threads nor pores nor tubes have any existence.

The same year that J. R. Mayer published his memorable essay, it was discovered by E. H. Weber that, in in the vagus nerve, which springs from the medulla oblongata and proceeds therefrom to the heart, there exists channels of influence by which the medulla acts on that wonderful muscular mechanism. Almost at the same time with this, a series of discoveries[1] were made relating to the circulation, which, taken together, must be regarded as of equal importance with the original discovery of Harvey. First, it was found by Henle that the arterial blood-vessels by which blood is distributed to brain, nerve, muscle, gland, and other organs, are provided with muscular walls like those of the heart itself, by the contraction or dilation of which the supply is increased or diminished according to the requirements of the particular organ. Secondly, it was discovered simultaneously, but independently, by Brown-Séquard and Augustus Waller, that these arteries are connected by nervous channels of influence with the brain and spinal cord, just as the heart is. Thirdly, it was demonstrated by Bernard that what may be called the heart-managing channels spring from a small spot of gray substance in the medulla oblongata, which we now call the "heart-centre;" and a little later by Schiff, that the artery-regulating channels spring from a similar head central office, also situated in the medulla oblongata, but higher up, and from subordinate centres in the spinal cord.

If I had the whole day at my disposal, and your patience were inexhaustible, I might attempt to give an outline of the issues to which these five discoveries have led. As it is, I must limit myself to a brief discussion of their relations to each other, in order that we may learn something from them as to the nature of automatic action.

Sir Isaac Newton, who, although he knew nothing about the structure of nerves, made some shrewd forecasts about their action, attributed to those which are connected with muscles an alternative function. He thought that by means of motor nerves the brain could determine either relaxation or contraction of muscles. Now as regards ordinary muscles, we know that this is not the case. We can will only the shortening of a muscle, not its lengthening. When Brown-Séquard discovered the function of the motor nerves of the blood-vessels, he assumed that the same limitation was applicable to it as to that of muscular nerves in general. It was soon found, however, that this assumption was not true in all cases—that there were certain instances in which, when the vascular nerves were interfered with, dilatation of the blood-vessels, consequent on relaxation of their muscles, took place; and that, in fact, the nervous mechanism by which the circulation is regulated is a highly-complicated one, of which the best that we can say is that it is perfectly adapted to its purpose. For while every organ is supplied with muscular arteries, and every artery with vascular nerves, the influence which these transmit is here relaxing, there constricting, according (1) to the function which the organ is called upon to discharge; and (2) the degree of its activity at the time. At the same time the whole mechanism is controlled by one and the same central office, the locality of which we can determine with exactitude by experiment on the living animal, notwithstanding that its structure affords no indication whatever of its fitness for the function it is destined to fulfill. To judge of the complicated nature of this function we need only consider that in no single organ of the body is the supply of blood required always the same. The brain is during one hour hard at work, during the next hour

[1] The dates of the discoveries relating to this subject here referred to are as follows:—Muscular Structure of Arteries, Henle, 1841; Function of Cardaic Vagus, E. H. Weber, 1845; Constricting Nerves of Arteries, B. Séquard, 1858; Aug. Waller, 1853; Cardiac Centre, Bernard, 1858; Vascular Centre, Schiff, 1858; Dilating Nerves, Schiff, 1854; Eckhard, 1864; Lovén, 1866. Of the more recent researches by which the further elucidation of the mechanism by which the distribution of blood is adapted to the requirements of each organ, the most important are those of Ludwig and his pupils and of Heidenhain.

asleep; the muscles are at one moment in severe exercise, the next in complete repose; the liver, which before a meal is inactive, during the process of digestion is turgid with blood, and busily engaged in the chemical work which belongs to it. For all these vicissitudes the tract of grey substances which we call the *vascular centre* has to provide. Like a skilful steward of the animal household, it has, so to speak, to exercise perfect and unfailing foresight, in order that the nutritive material which serves as the oil of life for the maintenance of each vital process, may not be wanting. The fact that this wonderful function is localized in a particular bit of grey substance is what is meant by the expression "automatic action of a centre."

But up to this point we have looked at the subject from one side only.

No state ever existed of which the administration was exclusively executive—no government which was, if I may be excused the expression, absolutely absolute. If in the animal organism we impose on a centre the responsibility of governing a particular mechanism or process, independently of direction from above, we must give that centre the means of being influenced by what is going on in all parts of its area of government. In other words, it is essential that there should be channels of information passing inwards, as there should be channels of influence passing outwards. Now what is the nature of these channels of information? Experiment has taught us not merely with reference to the regulation of the circulation, but with reference to all other automatic mechanisms, that they are as various in their adaptation as the outgoing channels of influence. Thus the vascular centre in the medulla oblongata is so cognizant of the chemical condition of the blood which flows through it, that if too much carbonic acid gas is contained in it, the centre acts on information of the fact, so as to increase the velocity of the blood-stream, and so promote the arterialization of the blood. Still more strikingly is this adaptation seen in the arrangement by which the balance of pressure and resistance in the blood-vessels is regulated. The heart, that wonderful muscular machine by which the circulation is maintained, is connected with the centre, as if by two telegraph wires—one of which is a channel of influence, the other of information. By the latter the engineer who has charge of that machine sends information to headquarters whenever the strain on his machine is excessive, the certain response to which is relaxation of the arteries and diminution of pressure. By the former he is enabled to adapt its rate of working to the work it has to do.

If Dr. Whytt, instead of cutting off the head of his frog, had removed its brain—*i. e.*, the organ of thought and consciousness—he would have been more astonished than he actually was at the result; for a frog so conditioned exhibits, as regards its bodily movements, as perfect adaptiveness as a normal frog. But very little careful observation is sufficient to show the difference. Being incapable of the simplest mental acts, this true animal automaton has no notion of requiring food or of seeking it, has no motive for moving from the place it happens to occupy, emits no utterance of pleasure or distress. Its life processes continue so long as material remains, and are regulated mechanically.

To understand this all that is necessary is to extend the considerations which have been suggested to us in our very cursory study of the nervous mechanism by which the working of the heart and of arteries is governed, to those of locomotion and voice. Both of these we know, on experimental evidence similar to that which enables us to localize the vascular centre, to be regulated by a centre of the same kind. If the behavior of the brainless frog is so natural that even the careful and intelligent observer finds it difficult to attribute it to anything less than intelligence, let us ask ourselves whether the chief reason of the difficulty does not lie in this, that the motions in question are habitually performed intelligently and consciously. Regarded as mere mechanisms, those of locomotion are no doubt more complicated than those of respiration or circulation, but the difference is one of degree, not of kind. And if the respiratory movements are so controlled and regulated by the automatic centre which governs them, that they adapt themselves perfectly to the varying requirements of the organism, there is no reason why we should hesitate in attributing to the centres which preside over locomotion powers which are somewhat more extended.

But perhaps the question has already presented itself to your minds. What does all this come to? Admitting that we are able to prove (1) that in the animal body, Product is always proportional to Process, and (2) as I have endeavoured to show you in the second part of my discourse, that Descartes' dream of animal automatism has been realized, what have we learnt thereby? Is it true that the work of the last generation is worth more than that of preceding ones?

JURASSIC BIRDS AND THEIR ALLIES.*

By Professor O. C. Marsh.

About twenty years ago, two fossil animals of great interest were found in the lithographic slates of Bavaria. One was the skeleton of *Archæopteryx*, now in the British Museum, and the other was the *Compsognathus* preserved in the Royal Museum at Munich. A single feather, to which the name *Archæopteryx* was first applied by Von Meyer, had previously been discovered at the same locality. More recently, another skeleton has been brought to light in the same beds, and is now in the Museum of Berlin. These three specimens of *Archæopteryx* are the only remains of this genus known, while of *Compsognathus* the original skeleton is, up to the present time, the only representative.

When these two animals were first discovered, they were both considered to be reptiles by Wagner, who described *Compsognathus*, and this view has been held by various authors down to the present time. The best authorities, however, now agree with Owen that *Archæopteryx* is a bird, and that *Compsognathus*, as Gegenbaur and Huxley have shown, is a Dinosaurian reptile.

Having been engaged for several years in the investigation of American Mesozoic birds, it became important for me to study the European forms, and I have recently examined with some care the three known specimens of *Archæopteryx*. I have also studied in the Continental Museums various fossil reptiles, including *Compsognathus*, which promised to throw light on the early forms of birds.

During my investigation of *Archæopteryx*, I observed several characters of importance not previously determined, and I have thought it might be appropriate to present them here. The more important of these characters are as follows:—

1. The presence of true teeth, in position, in the skull.
2. Vertebræ biconcave.
3. A well-ossified, broad sternum.
4. Three digits only in the manus, all with claws.
5. Pelvic bones separate.
6. The distal end of fibula in front of tibia.
7. Metatarsals separate, or imperfectly united.

These characters, taken in connexion with the free metacarpals, and long tail, previously described, show clearly that we have in *Archæopteryx* a most remarkable form, which, if a bird, as I believe, is certainly the most reptilian of birds.

If now we examine these various characters in detail, their importance will be apparent.

The teeth actually in position in the skull appear to be

*Read before Section D., British Association for the Advancement of Science, at York, Sept. 2, 1881.

in the premaxillary, as they are below or in front of the nasal aperture. The form of the teeth, both crown and root, is very similar to the teeth of *Hesperornis*. The fact that some teeth are scattered about near the jaw would suggest that they were implanted in a groove. No teeth are known from the lower jaw, but they were probably present.

The presacral vertebræ are all, or nearly all, biconcave, resembling those of *Ichthyornis* in general form, but without the large lateral foramina. There appear to be twenty-one presacral vertebræ, and the same, or nearly the same, number of caudals. The sacral vertebræ are fewer in number than in any known bird, those united together not exceeding five, and probably less.

The scapular arch strongly resembles that of modern birds. The articulation of the scapula and coracoid, and the latter with the sternum is characteristic; and the furculum is distinctly avian. The sternum is a single broad plate, well ossified. It probably supported a keel, but this is not exposed in the known specimens.

In the wing itself the main interest centres in the manus and its free metacarpals. In form and position these three bones are just what may be seen in some young birds of to-day. This is an important point, as it has been claimed that the hand of *Archæopteryx* is not at all avian, but reptilian. The bones of the reptile are indeed there, but they have already received the stamp of the bird.

One of the most interesting points determined during my investigation of *Archæopteryx* was the separate condition of the pelvic bones. In all other known adult birds, recent and extinct, the three pelvic elements, ilium, ischium and pubis, are firmly anchylosed. In young birds these bones are separate, and in all known Dinosaurian reptiles they are also distinct. This point may perhaps be made clearer by referring to the two diagrams before you, which I owe to the kindness of my friend Dr. Woodward, of the Britism Museum, who also gave me excellent facilities for examining the *Archæopteryx* under his care. In the first diagram we have represented the pelvis of an American Jurassic Dinosaur allied to *Iguanodon*, and here the pelvic bones are distinct. The second diagram is an enlarged view of the pelvis of the *Archæopteryx* in the British Museum, and here too the ilium is seen separate from the ischium and pubis.

In birds the fibula is usually incomplete below, but it may be coossified with the side of the tibia. In the typical Dinosaurs, *Iguanodon*, for example, the fibula at its distal end stands in front of the tibia, and this is exactly its position in *Archæopteryx*, an interesting point not before seen in birds.

The metatarsal bones of *Archæopteryx* show, on the outer face at least, deep grooves between the three elements, which imply that the latter are distinct, or unite late together. The free metacarpal and separate pelvic bones would also suggest distinct metatarsals, although they naturally would be placed closely together, so as to appear connate.

Among other points of interest in *Archæopteryx* may be mentioned the brain-cast, which shows that the brain, although comparatively small, was like that of a bird, and not that of a Dinosaurian reptile. It resembles in form the brain-cast of *Laopteryx*, an American Jurassic bird, which I have recently described. The brain of both these birds appears to have been of a somewhat higher grade than that of *Hesperornis*, but this may have been due to the fact that the latter was an aquatic form, while the Jurassic species were land birds.

As the *Dinosauria* are now generally considered the nearest allies to Birds, it was interesting to find in those investigated many points of resemblance to the latter class. *Compsognathus*, for example, shows in its extremities a striking similarity to *Archæopteryx*. The three clawed digits of the manus correspond closely with those of that genus; although the bones are of different proportions. The hind feet also have essentially the same structure in both. The vertebræ, however, and the pelvic bones of *Compsognathus* differ materially from those of *Archæopteryx*, and the two forms are in reality widely separated. While examining the *Compsognathus* skeleton, I detected in the abdominal cavity the remains of a small reptile which had not been previously observed. The size and position of this inclosed skeleton would imply that it was a fœtus; but it may possibly have been the young of the same species, or an allied form, that had been swallowed. No similar instance is known among the Dinosaurs.

A point of resemblance of some importance between Birds and Dinosaurs is the clavicle. All birds have these bones, but they have been considered wanting in Dinosaurs. Two specimens of *Iguanodon*, in the British Museum, however, show that these elements of the pectoral arch were present in that genus, and in a diagram before you one of these bones is represented. Some other *Dinosauria* possess clavicles, but in several families of this subclass, as I regard it, they appear to be wanting.

The nearest approach to Birds now known would seem to be in the very small Dinosaurs from the American Jurassic. In some of these the separate bones of the skeleton cannot be distinguished with certainty from those of Jurassic Birds, if the skull is wanting, and even in this part the resemblance is striking. Some of these diminutive Dinosaurs were perhaps arboreal in habit, and the difference between them and the Birds that lived with them may have been at first mainly one of feathers, as I have shown in my Memoir on the *Odontornithes*, published during the past year.

It is an interesting fact that all the Jurassic birds known, both from Europe and America, are land birds, while all from the Cretaceous are aquatic forms. The four oldest known birds, moreover, differ more widely from each other than do any two recent birds. These facts show that we may hope for most important discoveries in the future, especially from the Triassic, which has as yet furnished no authentic trace of birds. For the primitive forms of this class we must evidently look to the Palæozoic.

THE LIMITED BIOLOGICAL IMPORTANCE OF SYNTHETIC ACHIEVEMENTS IN ORGANIC CHEMISTRY.*

By Professor Albert B. Prescott.

The solicitude shown for half a century as to the biological import of chemical synthesis arises from a misapprehension of the scope of chemical action. From all we know of chemism, it must be accepted, (1) that all the matter of protoplasm and cell is carried strictly in a state of chemical combination, but (2) it cannot therefore be accepted that chemical composition supplies the essential conditions or impulses for organization or other vital functions. The synthesis of all the chemical compounds of the living body may or may not be attainable in the laboratory, but its success would give no whit of promise for the development of organization. Chemical action is distinct from cell organization as it is from heat, cohesion, etc., and its corelations with all these forces have to await demonstration by experiment. Cell growth appears to be a necessary factor in the simple splitting of sugar into alcohol and carbon dioxide, and it may or may not be an essential factor in the chemical synthesis of proteids or of cellulose.

A gentleman of Milan, Signor Lorin, deserves high credit, for the public spirit of philanthropy he has shown in offering 20,000 francs to the municipal authorities to maintain a mortuary and post mortem room wherein the bodies of all persons dying of unexplained causes shall be rigidly examined before they are cremated.

THE TERRA DEL FUEGIANS AT THE GARDEN OF ACCLIMATION.

The whole world has heard of the savages, who are at present exhibited at the Zoological Garden of Acclimation of Bois de Boulogne; many have gone to see them, and have been well repaid, for they present an interesting spectacle to the observer. They are seen lying or squatting about the fire kindled under the trees of the large lawn, motionless for whole hours at a time, gazing with vacant eye at the astonished crowd which presses against the railings as though they contained remarkable animals. Do they think? We cannot tell this. Do they speak? Yes, they do speak, if we can call the gutteral sounds, the cluckings which at long intervals, they exchange with each other, a language. They remain there, indifferent, having no longer in operation the only cause which can agitate them, hunger; for they are fed. It is a curious sight, but also a sad one. A man at this stage of brutishness is not wholly an animal; but he is no longer a man. The Fuegians, for that is the name which Captain Weddel gave them in 1822, and which has been applied to them since that time, inhabit Terra del Fuego. When we read in the works of travelers the description of their country, we are no longer astonished at their profound degradation.

Terra del Fuego is a mountainous archipelago, separated from Patagonia by the straits of Magellan, and formed of enormous masses of steep rocks, which leave only the coast bordering upon the straits, upon which man can settle. In the parts where the rock is not absolutely bare, a thick and impenetrable forest of beeches covers the side of the mountain, and descends as far as the sea. No animal, with the exception of some foxes and birds, inhabits this country. The climate here is horrible. The mean temperature of summer, according to King and Darwin, is 10°C., and that of winter o.°6C. Mist is perpetual here, and tempests unceasing. Scarcely a day passes without the fall of rain, and even of snow. The habitable portion is only on the rocks of the shore. In the whole country, but a few acres of plain can be found.

For a long time these Fuegians have been known, and many descriptions of them have been given. Sebold, of Weert, who accompanied Simon, of Cord, made giants of them, eleven to twelve feet high. We see from the samples which we have under our eyes, that there is a certain exaggeration in that statement. We borrow from Orbigny the description which he gives of them; in our opinion, there is nothing to be changed in it, it is absolutely applicable to our savages.

Their head, says Orbigny, is tolerably large, their face is rounded; they have a short nose, a little broadened, open nostrils, small eyes, black and horizontal; a large mouth, thick lips, white teeth, well arranged; small ears, and the cheek bones a little prominent. They have but little beard, and this they pluck out. Their hair, like that of all the Americans, is black, long, and dull. Their body is massive, their chest large, and their bow-legs are relatively rather short. The women present the same characteristics as the men, and they will return with difficulty to the proportions exacted by European æsthetics. Their mean height is from 1.56 m., to 1.68 m.

Their language, as we have before stated, is guttural, and it has been compared by Cook to the utterance of a man who is gargling. This comparison expresses well the impression that is felt on hearing them.

The great naturalist, Charles Darwin, was able, during the many months which he passed in the country which they inhabit, to observe their habits, and he has given us a picture which, in order to be just, is not very attractive: it is from him that we borrow the particulars which follow. "Forced continually to move from one region to another, according as the resources of their settlement are exhausted, the Fuegians have no fixed abode. They construct a sort of hut by planting several branches in the ground and covering them with other branches intertwined on the side where the wind blows. Their dress consists of a piece of skin, which they carry over their shoulders, and which they pass from one shoulder to the other, according to the direction of the wind. It was necessary for ceremony to persuade the Fuegians at the Garden of Acclimation to put on a pair of drawers. Often they are completely nude. Their nourishment consists chiefly of shell-fish, and now and then of the rotten flesh of a seal or of a whale. At low tide, which may be in winter or in summer, in the night or in the day, they must get up to seek the shell-fish on the rocks; the women dive to obtain the eggs from the sea or remain patiently seated in their boats for several hours until they have caught several small fish with lines without hooks. If they happen to kill a seal, or if they happen to discover the half-rotten carcass of a whale, it is the signal for an immense feast. They then gorge themselves with the horrible food, and, to complete the feast, they eat several berries or several mushrooms which have no taste."

When the different tribes go to war they become cannibals. Besides, when in winter they are strongly pressed by hunger, they eat the old women before they do the dogs, because, they say, the latter capture otters, and the old women cannot. In this regard, it is to be regretted that they did not bring some of their dogs with them. The only domestic animals of these savages ought certainly to present a precious subject of observation.

Do these savages believe in another life, have they any rudimentary religion whatever? We are not able to pronounce on this, for it is impossible to draw any explanation from the savages themselves; they are incapable of comprehending an alternative, and we can never surely know if we understand them ourselves. All that we can say is, that each tribe or family possesses a magician whose functions have not yet been exactly defined by travelers, and that the Fuegians generally bury their dead.

It has been pretended that the family tie does not exist among them. Yet, we see in the account of Darwin that York Minster, one of the Fuegians brought back by Captain Fitz-Roy to his country, took as his wife the young girl who had accompanied him to Europe, and that the other returned Fuegian also had his wife when the expedition returned to the place inhabited by the tribe with which he had been left. Is not this a proof of the existence of a family relation, rudimentary if you wish, yet a real home among these savages.

As regards property, it is an unknown thing among them. Apart from arms and utensils, no Fuegian possesses anything of his own. If he kills a seal, it is shared among all the members of the tribe. If a present is made to one of them, he breaks it and divides the pieces. It is communism in all its beauty.

The different tribes have neither government nor chief. Each of them is, however, surrounded by other hostile tribes speaking different dialects. They are separated, the one from the other, by a neutral territory which remains absolutely deserted. The perpetual wars which these tribes have, seem to have for a cause the difficulty of obtaining food. The land is so steep that they cannot change their abode except by water; and necessity has forced them to become navigators and to build boats. Those who inhabit the shores of the Straits of Magellan pass, from time to time, into Patagonia to chase the guanacos in order to renew their clothes and their provisions. But even there they encounter enemies. The Patagonians, from whom they are distinguished by race and language, as well as by habits, pursue them with ardor, and seek to reduce them to slavery. A Fuegian slave is very highly estimated by the Patagonians, who value him among themselves, according to the quality, up to $200.

When we consider the few resources which the archi

Inhabitants of Terra del Fuego at the Garden of Acclimation in Paris (After a Photograph by Pierre Petit).

pelago of Terra del Fuego offers for the existence of man, even compared to the neighboring regions on the American continent, we ask what cause has persuaded the Fuegians to establish themselves there. To-day it is beyond doubt that these people are not negroes, as Bory Saint-Vincent believed, but that they belong to an Ando-Peruvian race which inhabits the Andes and a part of the pampas of Chili. They probably occupied, in olden times, the northern banks of the straits of Magellan, and are but a remnant of the Aucas and the Araucanos of Chili. Attacked by the Patagonians of the pampian race, not as strong and more poorly armed than their adversaries, they were obliged, at a time more or less remote, to yield the place to their redoubtable enemies and to take refuge in the inhospitable regions on the other side of the strait, where the Patagonians, detestable navigators, left them in quiet.

Then little by little have acted the forces of adaptation, which all-powerful habit, in returning their hereditary effects, have adapted the Fuegians to the climate and productions of their miserable country.

Their industry is modified in the same way, and today it is reduced to the construction of miserable boats, and to the manufacture of several weapons and utensils necessary to their sad existence. The boat built of a mass of shapeless pieces of wood, covered with canvas in the shape of the skins which they customarily employ, the boat which can be seen on the basin in the neighborhood of their enclosure, makes us shudder when we think that these savages venture in this frail machine on the agitated waters which wash their country. In regard to the collection of arms and utensils which can be seen in a neighboring shed, it indicates a certain ingenuity, but shows well to what a miserable condition these poor creatures are reduced.

These Fuegians, eleven in number, four men, four women, and three children, have been brought to Europe by M. Waalen, established for many years at Punta-Arenas, capital of Patagonia.

M. Waalen, who goes to fish for seals in the waters of Terra del Fuego, finds himself in connection with these savages. He was able, by gorging them with food, by treating them with prudence, for they are not always tractable and would be able to cause great obstructions, to induce them to remain on his ship, from which they were transshipped on a Hamburg steamer which makes the passage between Valparaiso and Europe. It was while the ship touched at Havre that M. Geoffroy Saint Hilaine, informed by a despatch, saw them and bronght them here. M. Waalen deposited in the hands of the Chilian Governor of Punta-Arenas, a sum of 12 to 15,000 francs, as security, binding himself to return these savages to their country after they had made a tour through the principal capitals of Europe.

What impression will they carry back of their sojourn among civilized people? If we are to judge of this by the Fuegians that Captain Fitz-Roy returned after a sojourn of three years in Europe, the impression will be a very fleeting one. These natives, three in number, two men, York Minster and Jemmy Button, and a young girl, Fuégia, seemed almost entirely civilized. Captain Fitz-Roy landed them in the middle of their tribes, furnished them with implements and tools of all sorts, built them a house, cleared up a corner of ground, and left them in the company of a missionary. When he returned, several months after, he found no trace of their installment, and had to take on board the poor missionary, who ran the greatest danger. Of his three pioneers, two, York Minster and Fuégia who became his wife, parted in plundering their comrade, and the latter, who had taken a wife in his tribe, became a filthy and disgusting savage, delighted with his condition, scarcely knowing how to speak English, and who showed with pride to the officers of the expedition the implements of bone and of flint which he had manufactured.

It seems, after this experience, that it is impossible to draw these savages from their debasement, and yet they have an intellectual capacity, latent, it is true, which appears superior to that of Australians. They learn languages with remarkable facility, and have a spirit of imitation carried to extremes, which ought to be utilized in order to teach them things well. The future will tell us if those who are at present in the Garden of Acclimation, will derive any profit from their sojourn among us. Our opinion is that they will be delighted at finding themselves in their own homes, and the remembrance of all that they will have seen will remain in their minds as a dream which will not perhaps be wholly agreeable.—(*Translated from La Nature.*)

ON A NEW SYSTEM OF BLOWPIPE ANALYSIS.*

By Lieut.-Colonel W. A. Ross (late R. A.)

(1) THE USE OF ALUMINIUM PLATE FOR VOLATILIZING SUBSTANCES.

Volatile metals and sulphur compounds, &c., are, in the old system, treated before the blowpipe, as is well known, upon the support of a parallelopiped of charcoal held horizontally in the direction of the blast from the blowpipe, the disadvantages of which are: (*a*) that *black* sublimates as those now known to be obtainable from arsenic, antimony, lead, &c., are undistinguishable on the black charcoal. (*b*) The greater part of the sublimate from most volatile metals is blown away by the blast—a serious objection when, as is often the case, there is only a trifling proportion of such metals present in a mineral or compound. (*c*) When the charcoal becomes incandescent, the most interesting portion of the sublimate (that next the assay) is often thus resublimed and lost. (*d*) The white charcoal ash is so mixed up with sublimates as often to conceal them, and, in cases of minute quantities, to mislead the operator into supposing there is a sublimate at all. (*e*) In the treatment of a compound containing two or more volatile metals, sulphides, or oxides, the sublimates obtained therefrom are mechanically, and perhaps sometimes chemically, combined, and then cannot be separated, so as to be distinguished from each other, by means of the blowpipe, or in any other way at the time, on the spot. (*f*) It is impossible to obtain a blowpipe sublimate from charcoal free from the silica, &c., of the ash, by scraping it off for supplementary examination. (*g*) Most charcoals, after blowpipe treatment for any length of time, split up into cracks and deep fissures, into which the sublimate or the assay falls and is lost.

Here are several objections to the use of charcoal as a blowpipe support; most of them serious, some fatal to a thorough pyrological examination of volatile substances; and yet it has obtained ever since Von Swab invented the chemical employment of the blowpipe in 1738 (in which year he thus treated an ore of zinc at Delarne in Sweden), and is still used at Freiberg.

In 1869 Napoleon III had offered, or I understood him to have offered, a premium of £1000 to any one who could discover an efficient solder for aluminium, and being then on sick-leave in India, I thought of employing my leisure in attempting this discovery.†

After investigation, I imagined (from burning my fingers so often), that the reason an aluminium solder could not be made, was the enormous heat-conducting powers of the metal, which transferred the heat from a blowpipe-flame so quickly away over the entire substance of a fragment of given bulk, that no one part of it could

*British Association, York, 1881.

† In reply to a question, Col. Ross answered that he had not discovered a new solder, but that on one occasion last year (1880) he actually did succeed in soldering two small pieces of aluminium together, and that he has a description of the process in his notes.

be raised to the fusing-point, so that, although small portions of almost every other metal or alloy could be readily fused upon it, even the most fusible, such as antimony, bismuth, &c., could not be made to combine with the aluminium.

As I had then studied blowpipe analysis on the Freiberg system for ten years, it was obvious to me that, although I had no chance of otaining the £1000, the facts thus ascertained might be utilized so as to make aluminnum plate or foil remedy in part, at all events, the disadvantages above described of charcoal as a blowpipe support.

I found that arsenic, antimony, bismuth, &c., the fusion of the smallest particle of which upon platinum is so fatal to it, could be treated without the slightest danger before the blowpipe upon aluminium, which metal also, probably from the reason above given, withstood heat concentrated upon any point, in direct proportion to the bulk of the fragment used as a support.

I found that some volatile metals, as *e. g.*, antimony, would not yield a sublimate when treated before the blowpipe upon the bare aluminium plate, but readily did so when a small slip or lozenge of charcoal was placed between the assay and the aluminium. Here, then, was a rapid and effectual means of *separating* the pyroxides or sublimates obtainable from a compound, for instance, of antimony and arsenic; the latter subliming readily upon the bare aluminium plate; the former only after treatment upon a charcoal slip.

The horizontal charcoal support was, of course, changed into a perpendicular one, in direct opposition to the blast from the blowpipe, so as to catch all sublimates of every kind; the grey-colored, shining aluminium betrayed at once the faintest sublimates, whether black or white; these, again, could be readily treated by the oxidizing or redueing flame of the blowpipe on the aluminium, where they thus afforded, in most cases, new and characteristic reactions; the perpendicular aluminium could be graduated by a scale showing the different specific gravities of sublimates by their mean ascension on the plate, unacted upon by the blast as in the case of charcoal; and finally, any portion of a sublimate could be easily and cleanly scraped off with a penknife, so as to be afterwards examined in any way desired.

Another advantage I found, referrable, I presume, to the same cause (of superior heat-conduction in the support) is that the alkaline carbonates, so often used in blowpipe analysis, as in the detection of manganese, for instance, assume, when treated before the blowpipe on aluminium, a globular shape, and that the resulting bead or ball of sodium or potassium carbonate, can be readily picked, when cool, off the plate with forceps, instead of lying in a kind of pool and sticking to the metal as they do in the case of platinum foil.

To other uses of aluminium plates, as in flattening blowpipe beads and their contents for microscopical purposes, I have not time to allude.

(2) A NEW AIR-RESERVOIR MOUTH BLOWPIPE (CALLED BY ME A "PYROGENE.")

A member of the Royal Geological Survey of England told me in Jermyn street, that he believed many geologists and mineralogists were deterred from using this important little instrument by the trouble if not difficulty of blowing, and for a long time I tried to discover some means of obviating this difficulty in vain. At last, one day, in the Zoological Gardens of London, looking reflectively at the antics of some anthropoid types of our ancestors there, I could not help feeling a kind of regret that the process of "Natural Selection" should have eventually deprived my race of the pouch under the jaw, no doubt at one time possessed by them, which would have served so admirably as an air-reservoir in using the blowpipe, and it suddenly struck me that I could partially remedy the defects of specific development in this matter, by applying an elastic air-reservoir of indiarubber to the ordinary mouth-blowpipe.

Here is the result. I have made it of a simple tube-like form, instead of the usual tapering one, as seen in Black's blowpipe, because I had to adapt it to be packed in a cigar-case like this, the only way of effecting which was to have it in a telescopic arrangement, opening and shutting thus: and this arrangement had another advantage, that, namely, of adapting the length of the instrument to the differing optical focus of differing vision.

For the jet I took Wollaston's ingenious idea of passing the stem of the blowpipe through the arm of the jet; only instead of doing that, it suited my purpose better to pass the jet through the stem of the blowpipe thus. Of course, in either case, the inserted tube must fit air-tight —an easy matter to effect. Over the throat of the mouthpiece is tied a piece of oiled silk, which acts as a valve, preventing the return of the breath into the cheeks. In this manner all difficulty in blowing is entirely removed, and even a child can use this blowpipe, because all he has to do is to blow through the valve till the air-bag is filled; then he can stop until the pressure of the blast begins to slacken, when a few more breathings will refill the bag. The blast pressure from the bag may also be increased by the operator placing it between himself and the table, and gently pressing the bag with his body, which he can easily do while using this apparatus.

I have only to add that, as you observe, the jet and air-bag fit for packing into the tube of the blowpipe itself, for which purpose there is no necessity, as in the one I have here, to make the end screw off, as all one has to do is to draw the telescopic arrangement out altogether, and, slipping in the jet and bag, to shut it up again; this, of course, would make the article cheaper. Griffin makes them (with the screw end) for, I believe, half a crown, but, of course, any ordinary mechanic could make such a blowpipe for himself for a few pence.

(3) THE PYROLOGICAL CANDLE.

I begin a brief description of this fuel with the remark that it is practically impossible for the traveller to use gas of any kind—not even petroleum gas—as fuel, on account of the difficulties of carriage. The same remark applies, but in another way, to oil of any description. A bottle of this is no doubt, easily carried, but is very apt to leak at the cork, and so to spoil any or most articles near it in a box.

Considerations of this kind led me, in 1871, to look to the modern composite candle as a substitute for the Berzelius blowpipe lamp, supplied with Plattner's Freiberg apparatus, which I had used for twelve years. The candles then used for blow-pipe operations were, indeed, in no respect different from those used for illuminating purposes. How Von Engeström, Bergmann, and the more modern pyrologists who are said to still use common candles for blowpipe work, contrived to do anything useful with them, I fail to understand. With even a small wick in the *centre* of the candle, which, of course, must be turned on one side to prevent it from stopping the blast, the heat radiation from the blowpipe-pyrocone melts the tallow or wax from that side more rapidly than the remainder of the circumference melts, so that a deep channel is soon formed, down which the fluid fuel runs, leaving the wick "high and dry." The consequence is that the pyrocone becomes "thready," from the burning of dry carbonaceous particles eliminated from the wick, and when it is cut down a mass of unconsumed tallow almost covers it at one side.

I therefore adopted the plan of having the candle made with a thick, and even double, wick, placed at one side instead of in the middle of the fuel, and in order to supply more of the latter, I had my candles made a prismatic instead of a round shape. I placed a thick collar of a good conducting metal, such as zinc, round the

edge of the candle, just under the wick, in order to conduct away and diffuse through itself the vibrations of heat. At first I had a series of these metallic collars, and proposed to remove them as the candle burned down; but I afterwards found that one or two good thick zinc collars would be sufficient.

Here is a candle from my cigar blow-pipe case which I am at present using, and another unused one, as made for me by Price & Co. of Battersea.

(4) CANDLE SCISSORS.

In Plattner's apparatus scissors are supplied for cutting the lamp-wick, which of course can also be used for other purposes, *and also* a pair of pliers for squeezing the wick together, and pressing it in any direction; these latter cannot be used, from the dirty state into which they get, for anything else. I use these two articles combined into one—*i. e.*, a pair of ordinary scissors with knobs at the end. This also goes into my cigar blowpipe-case.

(5) ORDINARY WATCHMAKER'S PLIERS,

with a piece of wire-strapping round them, to enable them to act as holders of platinum wire supports, and they also act as the best cleaners of the wire by drawing the latter from between the pressed flat sides.

(6) TWO AGATE SLABS FOR GRINDING POWDERS.

I have here got instead, a small Freiberg agate mortar, with a pestle made from an agate pen, as I had no slabs small enough to pack away in this cigar-case.

(7) REAGENTS. BORIC ACID.

It has always seemed to me as though blow-pipe workers, or, as I call them, "Pyrologists," could no more profess to begin analytical operations by using a *salt* as reagent, than the analytical chemist could say he intended to begin his solution-work by using sodium nitrate instead of nitric acid. By employing boric acid instead of borax, therefore, in 1869, I at once obtained a series of new, very pretty, and important reactions, especially in the case of the alkaline earths, which formerly used to be the weakest part of blowpipe analysis; now, they are one of the easiest. Space and time do not allow me to describe these reactions here; and, unfortunately, I have brought no boric acid with me here in order to illustrate them; but here is a little German-silver cigar-light box in which the acid is kept, as it does not thus deteriorate. This also goes into the cigar-case.

Phosphoric acid is another of my new reagents (when I say "new," I mean that they are now 12 years old, but new in the sense that they have not been as yet generally adopted.) I use it instead of the old reagent "microcosmic salt." It affords, with several oxides before the blowpipe, new and interesting colors, as in the case of cobalt oxide, which imparts to it a very fine and pure violet instead of the ordinary blue. Of course, when a sufficient quantity of soda to form metaphosphate of sodium, or microcosmic salt after the ammonia has been driven off, has been added, the bead becomes blue, and this fact enables it to be used as an alkalimeter. It is the only reagent which requires to be kept in a stoppered bottle; and is such a powerful acid before the blowpipe that gold leaf is rapidly dissolved in it, yielding a brilliant purple bead. It affords, with iron oxide, a bead the color of watery blood. This ends the list of things packed in the cigar-case.

(8) A COMPASS IN WHICH THE NEEDLE POINTS E. AND W.

This is made by bending an ordinary magnetized needle in the centre until the points are opposite, like a lady's hairpin. It is, in fact, an ordinary horseshoe-magnet suspended, and such a magnet suspended swings E. and W. for a very obvious reason. It might prove useful in Arctic voyages, as such a needle would probably possess little or no "dip." If you bend an ordinarily magnetized needle at a right or any other angle, and suspend it from or on its centre of gravity, a line bisecting the angle will point E. and W., and it was such a needle I first made in order to find a very delicate test for traces of iron in ores. The more open or obtuse the angle, the more delicate this test is. I call it the "Equatorial Needle.' With a right-angled equatorial needle you can detect the mere trace of iron in the ore *Molybdenite*.

(9) AN ALLOY-BUTTON OF GOLD AND SILVER IN WHICH THESE METALS HAVE BEEN PARTLY SEPARATED BY THE BLOWPIPE ALONE.

Many years ago I found that, if you heat an alloy of two or more metals very gently with the blowpipe, so as not to promote fusion, in which case the ball spins round, and all the component metals are mixed again—that one nearly pure metal invariably leaves the others, and approaches the source of heat. This is a case of gold and silver alloy, in which the silver has approached the source of heat, but the process can be admirably illustrated in the case of a common bronze pin, in which the tin approaches the source of heat, while the copper remains in the background. Such a process might obviously be found useful in metallurgy on the large scale.

ASTRONOMY.

To the Editor of "SCIENCE."

On the early morning of June 30, 1881, the definition was very good. On no other occasion was *Comet B*, 1881, seen so clearly. As it appeared in our 8¼-inch refractor, it presented some peculiarities which I have not noticed in any published drawings, and therefore mail you the enclosed.

The prominent features were an unsymmetrical pear shaped coma surrounding the nucleus, two streams on either side, and one directly opposite the tail, which blended with the envelope. Around the whole was a very faint secondary envelope.

Very respectfully,

ISAAC SHARPLESS.

HAVERFORD COLLEGE OBSERVATORY, *September* 1, 1881.

CORRESPONDENCE.

The Editor does not hold himself responsible for opinions expressed by his correspondents. No notice is taken of anonymous communications.]

To the Editor of SCIENCE.

The "Ononid" meteors were watched this morning from 12.20 to 3.05 by four observers. The shower seemed quite abundant, 190 meteors being mapped during the time of observation. About one-half of these undoubtedly belonged to a common system. The radiant point as deduced from these, and which, considering their number cannot be greatly in error, was R. A.—86°, Dec. + 16° which brings it just outside the limits of the constellation Onon. No stationary meteors were observed and but very few with short paths near the radiant point. This may be due to the fact that they were so faint (mostly about equal in brightness to a fourth magnitude star) that the short paths were not sufficiently conspicuous to call our attention to them. An auroral light was visible in the north and east during the early part of the watch. Chambers gives 85°, + 16 as the radiant point, and adds that Tupman makes it 90°, + 11.

Respectfully,

ISAAC SHARPLESS.

HAVERFORD COLLEGE OBSERVATORY, PA., 10*mo*, 19*th*, 1881.

DR. H. RAYMOND ROGERS AND HIS CRITICS.

To the Editor of "SCIENCE."

Prof. Merriam, in your journal, page 495, writes as follows: "I do not like to see so great an authority as Faraday misunderstood, as he evidently is by your correspondent on page 459 of your journal, and that, too, in a way which he took particular care to caution against—as to the law of gravitating action. That it acts inversely as the square of the distance he fully believed and admitted; or, to use his own words, 'I know it is so.'"

The quotation objected to was made verbatim from Faraday's writings, and the sentiments contained therein were frequently expressed by him, and with emphasis. In the work entitled "Correlation and Conservation of Force," page 363, is an essay by Faraday entitled "The Conservation of Force," in which we read the following, viz.: "I believe I represent the received idea of the gravitating force aright in saying that it is a simple attractive force exerted between any two or all the particles or masses of matter, at every sensible distance, but with a strength varying inversely as the square of the distance. The usual idea of the force implies *direct* action at a distance: and such a view appears to present little difficulty except to Newton, and a few, including myself, who in that respect, may be of like mind with him. This idea of gravity appears to me to ignore entirely the principle of the conservation of force; and by the terms of its definition, if taken in an absolute sense, '*varying* inversely as the square of the distance,' to be in direct opposition to it." Again, in the same essay, page 366, "the assumption which we make for the time with regard to the nature of a power (as gravity, heat, etc.,) and the form of words in which we express it, that is, its definition, should be consistent with the fundamental principles of force generally. The conservation of force is a fundamental principle; hence the assumption with regard to a particular form of force ought to imply what becomes of the force when its action is *increased* or *diminished*, or its *direction changed;* or else the assumption should admit that it is deficient on that point, being only half competent to represent the force; and, in any case, should not be opposed to the principle of conservation. The usual definition of gravity as ***an attractive force between the particles of matter varying inversely as the square of the distance***, whilst it stands as a full ***definition*** of the power, is inconsistent with the principle of the conservation of force."

Faraday is here laboring to show the incompetency of that definition *alone*. He thinks the natural philosopher ought to look for effects and conditions as yet unknown; and so virtually calls aloud for some one to fill up what to him appears a serious deficiency. He called the old definition only a *half*-assumption, and felt the necessity of some enlargement of it, that it might stand secure. He says: "the half-assumption is, in my view of the matter, more dogmatic and irrational than the whole, because it leaves it to be understood that power can be created and destroyed almost at pleasure."

Faraday called for, what we believe, the electric theory amply supplies. Not only so, but he also indicated this very source of supply. For example, a "grain of water" having a given force of gravity has also "electric relations equivalent to a very powerful flash of lightning." He says, "It may, therefore, be supposed that a very large apparent amount of the force causing the phenomena of gravitation, may be the equivalent of a very small change in some unknown condition of the bodies, whose attraction is varying by change of distance. For my own part, many considerations urge my mind toward the idea of a cause of gravity, which is not resident in the particles of matter merely, but constantly in them, and all space."

We have been led to think that it was not impossible to *find* such "cause of gravity, not resident in the particles of matter merely," but which by means of a "very small change in some [formerly] unknown condition of the bodies," shall bring the whole subject of gravitation out from the shadowy realms of darkness into abiding sunlight.

In brief, Faraday insists that the totality of the force of gravity is not expressed by the definition that "gravity acts directly as the mass and inversely as the square of the distance." Indeed, he says as pithily as when he uttered your correspondent's quotation, "I know it is so." "That the *totality* of a force can be employed according to that law *I do not believe!*"

It might, by the way, be of interest to learn a little more definitely as regards what it was that Faraday knew was so. The following are his words: "That the result of one exercise of a power may be inversely as the square of the distance I believe and admit; and I know it is so in case of gravity." The same sentence, however, continues: "but that the *totality* of a force can be employed according to that law I do not believe either in relation to gravitation or electricity or magnetism, etc."

It may be asked what can be correctly known of the action of electricity or magnetism where the item *polarity* is left out? "What I object to," says Faraday, "is the pretence of knowledge which the definition sets np when it assumes to describe, not the partial effects of the force, but the nature of the force as a whole."

Satisfied with the old definition as your correspondent may be, Faraday looked for a "missing link." We may say that he pointed it out in saying:—"when we remember that the earth itself is a magnet, pervaded in every part by this mighty power, universal and strong as gravity itself, we cannot doubt that it is exerting an appointed and essential influence over every particle of matter, and in every place where it is present. What its great purpose is seems to be looming up in the distance before us:—the clouds which obscure our mental sight are daily thinning, and I cannot doubt that a glorious discovery in natural knowledge and in the wisdom and power of God in the creation is awaiting our age."

I would conclude this part of my reply to your correspondent, with the recommendation that he study Faraday, for "I do not like to see so great an authority as Faraday misunderstood."

Again, as regards the earth's return from aphelion to perihelion:—

It is admitted that my reply (p. 459) to Mr. Hendricks

was left open to objection. This may be accounted for by the fact that there was shown to me his article *minus two paragraphs*—the last paragraph on page 458 and first on 459. Therein *inertia* alone was represented as *bringing back* the planet from aphelion to perihelion. That the planet, traveling its orbit from perihelion to aphelion, as it were *diagonally against* the central attraction of the sun, would find its velocity and momentum diminished sufficiently to be made to return, I do not doubt; but that on the *second* round, it would reach the farthest limits of its first round, I do not think there is any reason to believe. The tendency would be to bring the orbit into a perfect circle very speedily. In the polarity, which is a factor of magnetism, we find a needed *regulative* agency. Do we say that this agent is too insignificant? Nevertheless may it not be, in the words of Faraday, the "*very small change* in some unknown condition of the bodies" involved in the operation, which is all-sufficient for what is required of it? We recognize the force of Faraday's objection to the popular definition of gravity, viz.: that *alone* it is incompetent, and contradicts the law of conservation—except as we add to it *something more*. That something more we fully believe to be that electrical or magnetic constituent which Faraday says "exerts an appointed and essential influence over every particle of matter."

QUERY.—Is it wise or philosophical to recognize a cosmical force of incalculable energy, and yet in our theory of the cosmas make no practical account of it whatsoever?

H. RAYMOND ROGERS.

DUNKIRK, N. Y.

The death of Mr. Charles A. Spencer, of Geneva, N. Y., has caused universal regret, and in many respects it may be considered a national loss, for as a representative of America's skilled opticians his position was unique. As a pioneer he was the first to manufacture Microscope objectives in the United States, and at once developed a skill in the manufacture of these minute and delicate glasses, which he maintained to the last. Spencer was no copyist, his inventive genius and thorough knowledge of the optical principles involved in the making of objectives enabled him to keep in the van of all those who devoted themselves to the same art.

The greatest triumph of Spencer was in the enlargement of the angle of aperture of his objectives, in which respect he was always in advance of the best European makers, but he will always be remembered as a conscientious worker, who never permitted an objective to leave his hands which was not worthy of the maker.

METEOROLOGICAL REPORT FOR NEW YORK CITY FOR THE WEEK ENDING OCT. 22, 1881.

Latitude 40° 45′ 58″ N.; Longitude 73° 57′ 58″ W.; height of instruments above the ground, 53 feet; above the sea, 97 feet; by self-recording instruments.

SCIENCE AND MEDICINE.

A few words on the relation of the natural sciences to medicine, as one of the greatest aids for the achievement of success, should be welcome reading to all members of the medical profession whose aspirations are above the dead level of mediocrity.

The physician may at first sight desire to stifle all discussion on this point by saying, that the requirements of study involved in acquiring a knowledge of medical practice *per se* occupy too much of his time to admit of his taking up outside issues, which he considers mere refinements of practice. There are others who take the absurd view that, to add a knowledge of the natural sciences is to become in the highest sense of the word a Chemist, a Physicist, or a Biologist. Seeing that the attainment of a complete knowledge of either of these sciences, is a work of a life time, it is argued, that they are to be shunned as impossibilities.

The path of the would-be scientific medical man is made clear by the encouraging words of one of his own profession, Dr. G. Vivian Poore, M.R.C.P., who says, there is a minimum of knowledge in this respect which is sufficient to endow the physician with a *scientific grasp of his art.* What is really wanted, is sufficient knowledge to enable a medical man to read these various sciences with intelligible results for himself, *when he needs* and as often as he desires to consult them, to show him as objectively as possible, those great principles which have already found application in his healing art. This will lead him to think and enable him to act with precision in any great emergency.

Let it be understood that there is no necessity for cramming the head with a mass of details, and that our object is to enrich and not encumber the mind of the medical practitioner.

To those who are ignorant of the advantages of some knowledge of the natural sciences in medical practices, the following observations of Dr. Poore may be read with interest.

"There are those who hold that the student of medicine has but little need of special training in the natural sciences, but such a position I believe to be untenable, and if I have to say one thing more emphatically than another to the first year's students, it is to advise them, not on any account to neglect their purely scientific studies. They are the very foundation of your professional knowledge, and without a solid foundation, no firm or worthy superstructure can be raised.

How can a man hope to rightly comprehend that most complicated of all machines, the human body, with its levers, pumps, and elastic canals, unless he be first furnished with the principles of mechanics and hydraulics? Who will say that a proper knowledge of the eye, or of the many optical instruments used in medicine, is attainable without some acquaintance with the laws of light; or that the intricacies of the ear, and the art of auscultation can at all be understood by him, who knows nothing of the laws of sound. The laws of heat must be studied in order to appreciate the difficult problems afforded by the animal temperature, its variations in health and disease, and the means of influencing it by therapeutic agents. Without the principles of chemistry we should be intellectually lost in the human laboratory, and unable to employ chemical agencies in the treatment of disease; and electricity is so correlated with the other physical sciences, and of so much service both in diagnosis and treatment, that its separate study has also become essential. Neither can we altogether neglect geology and meteorology, since conditions of soil and atmosphere are now recognized as important factors in the causation and relief of suffering.

It is scarcely necessary to insist on a knowledge of those sciences which are called "biological." *Anatomy* and *Histology*, formerly the mere handmaids of medicine, but now recognized as sciences worthy of independent study, are as necessary to us as is a chart to the navigator; while *Physiology*, which teaches us the use and mode of action of the anatomical and histological elements, is the medical practitioner.

Zoology and botany are not so absolutely necessary for us as are the other sciences, but it is evident that they are very necessary as preliminary studies for the biologist, to whom we look for instruction, for without a study of the simple forms and conditions of life a proper understanding of human anatomy and physiology is not attainable, and in so far as they teach us the conditions of existence of the various vegetable and animal parasites which affect the human body, from micrococci upwards, they are necessary for us as *surgeons and physicians.* This list of sciences is truly formidable, but I nevertheless assert that there can be no true study of medicine without a knowledge of the principles of all of them; and, for my own part, I have never had any difficulty, as a teacher of clinical medicine, in discriminating easily, by a perusal of their clinical reports, between those students who have, and those who have not, had an insight into the principles of pure science.

Scientific principles are to the physician and surgeon what the sextant and compass are to the navigator. Without them he cannot rise above the rank of a lighterman or a ferryman, but must be content to remain a mere "pill-monger," or a chirurgeon of a base mechanic sort. With them he may fearlessly launch his bark upon unknown seas, and may have the good fortune to extend the frontiers of science, or discover, as it were, new continents, to give a wider scope to the art which he professes."

To the medical man who would reap the advantages held out by Dr. Poore, *we confidently suggest the value of this journal* as a means of accomplishing the ends desired, at the least cost, and most convenient form. The impecunious can thus avoid the purchase of the mass of scientific literature with which the market is flooded, and the overworked practitioner receiving the journal weekly is not embarrassed by redundancy, and yet can safely rely on passing nothing of importance, while articles of special interest to the profession will be constantly brought before his notice.

In the previous numbers of "SCIENCE" may be found valuable articles by Professors Burt G. Wilder and Sage, of Cornell; Drs. Hammond and Spitzka, of New York; Dr. Clemenger, of Chicago; Dr. J. A. Mason, of Newport, and many other specialists of equal merit.

Now the value of a knowledge of science, as a means of "getting on" as Huxley terms it, is indubitable, and while there are few trades in which some knowledge of *science* may not be profitably applied to the pursuer of his occupation, we think that the words of Dr. Poore must carry conviction, that the *student* or Physician who would attain the higher stages of development of his art, must be kept "*au courant*" with such facts and principles, which are weekly published in "SCIENCE," for they will probably find their application in every intelligible diagnosis and discussion on medical practice.

"SCIENCE," November 5th, 1881.

WE learn with regret that Dr. Ed. C. Spitzka, who has been requested to appear in the Guiteau case, by both the Government prosecutor and counsel for the defence, has declined to attend.

The question of mal-practice is not likely to be seriously entertained at the trial, and the whole issue will probably rest upon the evidence touching the insanity of the prisoner.

We should judge from the published papers of Dr. Spitzka that his evidence would be in favor of the prisoner's insanity; it becomes, therefore, the more important that he should attend, as it would avoid the suspicion, in case of conviction, that the assassin had not received a fair trial.

NEW YORK ACADEMY OF SCIENCES.*

October 3, 1881.

REGULAR BUSINESS MEETING.

Vice-president Dr. B. N. Martin in the Chair.

Twenty-five members present.

After the transaction of business, the members were invited, in accordance with the usual custom at the first meeting of the season, to present notes and observations gathered during the summer, and responses were made by Mrs. E. A. Smith, Prof. C. A. Seeley, and others.

Mr. W. L. Chamberlain referred to the gold deposits recently opened in Fulton and Saratoga counties, N. Y. The ore consists of auriferous pyrites and is contained in the gneiss of the foothills of the Adirondacks.

Remarks were made, by a member, on a visit to the sandstone quarries at Portland, Conn.: by Mr. Todd, on a peculiar atmospheric phenomenon, a vaporous band stretching across the sky, apparently not auroral, observed in the Adirondacks: and by Dr. Martin, on a remarkable atmospheric coloration, luminous brilliance of the clouds, etc. observed last month at Saratoga, in the early morning, attributing it to an abundance of a smoky fog produced by the recent forest fires, and calling attention to the fact that this phenomenon has been noticed only in the territory east of the meridian of Saratoga.

Mrs. P. Hanaford described the same appearances as seen during the "Yellow Day" Sept. 6, near Boston, and also on Nantucket: another member, as seen in the Genesee valley, explaining that the strong West and Northwest winds prevailing at the time had wafted high in the air vast volumes of smoke derived from the abundant forest fires throughout Western N. Y.: Messrs. Todd, Chamberlain, and others, describing the electric brilliance of the gas-lights, the strange modification of the green color of foliage, the absence of smoky odor, etc., as observed at Great Barrington, Mass., and in less degree in New York city: Mr. N. L. Britton, on the same facts as observed out at sea, off Fire Island and Montauk Point, Long Island, N. Y.: Prof. D. S. Martin, as observed between Saratoga and Catskill, N. Y., and Prof C. A. Seeley, calling attention to the extremely attenuated character of the carbon particles, produced by their long transportation from distant localities.

Mr. Geo. F. Kunz mentioned that Mt. Mica, at Paris, Maine, the locality so famous for colored Tourmalines for the last fifty years, had been purchased by a Mining Company and was being worked for Cassitterite, Mica and Tourmaline, principally through the efforts of Dr. A. C. Hamlin of Bangor, Maine.

Dr. Hamlin has the finest known collection of American Tourmaline, and he recently reported the finding of a crystal three inches long and one-half inch thick, a transparent gem, of a beautiful blue-green color. This was taken from the new mine, and many more remarkable specimens may be expected as the work advances.

Mr. Kunz said that during the last year a German Agate-hunter returned to his native country after 20 years collecting in Brazil, taking with him a large suite of fine colored Tourmalines, some five inches long and not more than one-eighth of an inch thick, transparent, and of a green color; also many fine green crystals with red, yellow, white, and other colored centres, many of these equalling for variety of color anything yet found, most of which will cut as gems. There is also in this lot one exceptionally fine green crystal over one inch square. This collector brought with him also at least 1000 kilos of transparent yellow Spodumene, the same as that described by A. Pisani of Paris some eighteen months ago, and is dissimilar only in color to the new variety of Spodumene found at Stony Point, North Carolina, described in the February number of the *American Journal of Science* for 1881, by Dr. J. Lawrence Smith, as Hiddenite. Some of the specimens which he brought will cut as fine yellow gems. All these were found in the Minas Geraes district. Recently a new locality for Chrysoberyl has been found in Ceylon, where they occur of gem value in an unusual variety of color. They vary in color from yellow to brown, and from brown to green. The latter color is the variety known as Alexandrite. This gem has heretofore been found but of very inferior size and color, but here it occurs of remarkable size, having in one case afforded a gem weighing 26 kts. They are a beautiful green color by day and a Columbine red, or brownish red, by night. The Chrysoberyl Cat's Eye is found here of the same color, and possessing the same dichroic property as the Alexandrite, viz., changing color, from green to red, and hence might very properly be called an Alexandrite Cat's Eye. Many of the Chrysoberyls are erroneously called and sold as a variety of sapphire.

* Official Report.

SECTION OF CHEMISTRY.

October 10, 1881.

Vice-president Dr. B. N. Martin in the Chair.
Nineteen members present.
A paper was read by Mr. James H. Stebbins, Jr., of which the following is an abstract:

ON SOME NEW SALTS OF THYMOLE SULPHO-ACID, AND SOME NEW FACTS CONCERNING THE SAME.

60 grms. thymole were dissolved in 50 grms. 66° sulphuric, at a temperature of 100 C. The pink crystalline mass so obtained was dissolved in water, and converted into the lime salt.

This salt crystallizes with two molecules of water, in rhombic plates, and shows under the polariscope a beautiful effect of circular polarized light.

FORMULA.

a $(C_6\ H_2\ (C\ H_3)\ (C_3\ H_7)\ (O\ H)\ (S\ O_3)_2\ Ca + 2\ H_2\ O$

a. Calcium salt of alpha thymole sulpho-acid.

AMMONIUM SALT.

This salt was obtained by decomposing the lime salt, with ammonic carbonate. It crystallizes in white rhombic plates, with 2 mols. of water.

FORMULA.

a $C_6\ H_2\ (C\ H_3)\ (C_3\ H_7)\ (N\ H_4\ S\ O_3)$ a $H + 2\ H_2\ O$.

The soda salt has likewise been obtained, and will be described in a subsequent paper.

Remarks were made by Mr. James D. Warner on the nature of the corona of the Sun, etc. Mr. Stebbins reported the yellow coloration of the atmosphere in September at the Thousand Islands in the St. Lawrence.

SECTION OF GEOLOGY AND MINERALOGY.

October 17, 1881.

The President, Dr. J. S. Newberry, in the Chair.
Fifty-one persons present.
Dr. Newberry exhibited specimens of Native Lead and Oxide of Lead from a mine in the Wood River country, Idaho, crystallized gray copper, and fine crystallized Rhodochrosite from the Ulay mines, Southwest Colorado.

Prof. T. Egleston pronounced the crystals of rhodochrosite to be the finest specimens ever yet found. He further called attention to the discovery of the presence of tellurium in merchant copper from Lake Superior. This curious specimen of native copper pig was found to contain about 0.5 per cent. of that element, which has never yet been detected in the copper. In the furnace the pig yields dense white fumes; it is useless for brass, etc., and only fit for the manufacture of cupric sulphate for batteries. With the tellurium are associated a little silver and gold, which are found not to be uniformly distributed, as hitherto supposed, but so variably that the proportion of silver varies widely in portions taken from the furnace within ten minutes of each other.

Dr. J. S. Newberry then remarked on "Geological Facts recently observed in Montana, Idaho, Utah and Colorado."

Idaho and Montana.—The famous placers at Helena and Virginia, which have yielded thirty millions of dollars, are now exhausted, but vein-mining is in successful progress and yielding rich results at Butte, at the Alice, Lexington, Copper Bell, and other mines. These are true fissure veins, traversing a granite formation, and the speaker predicted their abundant yield of silver and copper twenty years hence. These territories have been simply crossed by two government expeditions and their resources have not been at all studied. It is the coming mining region, more discoveries of promising mines having been recently made here than in any other portion of the country. On the east of the mountains in Montana and Wyoming lies a fine agricultural country and excellent stock range, the herds ranging freely throughout the winters, in spite of their severity, with little loss, and grazing upon a native bunch-grass (*Festuca scabrella*) and the buffalo grass (*Buchloe dactyloides*). The climate is salubrious, the country very beautiful in many parts and very promising for emigration. In the adjacent Rocky Mountain range there are also many mining opportunities.

The remarkable lava plain, 400 miles long by 75 miles wide, in Central Idaho, was then described.

Snake River, one of the chief tributaries of the Columbia, flows along its southern border for several hundred miles; its northern tributaries sinking under the lava sheet and flowing in subterranean channels 50 or 60 miles long. The rock is a basalt said to contain everywhere a small quantity of gold and silver. It is generally covered with an impalpable soil that produces a dust excessively annoying to the traveler, and sustains a general growth of sage brush. In places, however, the rock is bare and looks like a congealed stormy sea.

Three buttes are set on the surface of this lava plain, and each has probably been a local volcanic vent; but it is probable that most of this eruptive material has been an overflow from great fissures of which the position is not indicated on the surface.

Snake River crosses a portion of this plain in a cañon at the head of which are the great Shoshone Falls, 208 feet in vertical altitude.

An alluvial plain borders Snake River for 200 miles, abounding in black sand which contains much gold. This is, however, extremely fine, having been transported a long distance from its place or origin, and therefore difficult of separation. New and promising methods and machines are about to be tried in the exploitation of these extensive deposits. A wide mountain belt extends from the north side of the lava plain to and beyond the British line, and is apparently a good mining country throughout. Already a great number of productive and promising mines are opened in the southern portion of this belt. In the Wood River district the veins are not large, but numerous, regular and persistent, and the ore of high grade—mostly argentiferous galena, carrying $100 to $500 in silver to the ton. Near Challis, further north, is the celebrated Ram's Horn mine, located on a true fissure vein, generally not more than five feet wide, but continuous for more than five miles. The wall rocks are slate, the vein stone siderite (carbonate of iron), the ore gray and yellow copper, yielding $100 to $1200 in silver to the ton. A few miles west of Challis is the mining town of Bonanza, where are located the celebrated Charles Dickens and Custer mines, carrying both silver and gold.. Still further west in the Saw-Tooth range, a high and very picturesque mountain chain running north and south, recent discoveries of valuable mines have been made. From this district north to the Canadian line, a broad mountain belt extends over northern Idaho and northwestern Montana, a country which abounds in veins of silver, copper and gold. Among the mines now worked in this region the most celebrated is the Drum Lomond, in Montana. It is opened on a large vein of rich quartz and is owned by an old miner who cannot read, but who is said to have refused a million of dollars for the property. It is probably worth much more than this.

Most of the mountainous districts of Idaho and Montana are covered with coniferous forests, consisting of the Douglas spruce and the northern nut pine, *Pinus*

flexilis. The smaller plants form an Alpine flora of much interest, including many beautiful flowering species; perhaps the most striking being *Bryanthus*, which has a fine fir-like foliage and clusters of beautiful purple flowers. It belongs to the heath family and closely resembles the heather of Scotland.

The streams of this region are clear, cold, and rapid, and abound in fish, chiefly of the salmon family, and these have given the name to Salmon River, the principal water course.

Two species of salmon were running up the Salmon River, one the large Quinnat or Chinook salmon, comparatively rare, and the other the "red fish" (*Oncorhynchus nerka*). This is a small salmon, 15 to 18 inches in length, and weighing 3 to 5 pounds. As seen in their migration their bodies are brick red to purple in color, the heads dark or light green; they were then going up to their spawning ground, Redfish Lake, one of a half dozen of small lakes on the head waters of the Columbia, which are the special breeding places of this interesting fish. Coming all the way from their abode in the ocean, led by an infallible but inscrutable instinct, they push on night and day till they reach their remote birthplaces in these little lakes far up in the mountains and 1000 miles from their starting point. Here they accomplish apparently the great object of their lives, the reproduction of the species, by depositing the spawn in the shallows of the rivulets which fall into the lake.

The always attractive coloring of the fish, during this nuptial season becomes greatly heightened; the body assumes a brilliant, almost luminous red, as bright as that of the gold fish, and where numbers are dashing through the water literally in a blaze of excitement, they produce an exhibition that is strikingly novel and interesting.

When the spawning season is over they probably do not return, as none are seen descending the rivers. The young fish start on their migration to the ocean while yet very small, and within the first year of their lives, remaining away it is supposed some three or four years during which they acquire their full growth when they return to die where they were born.

An active industry has grown up in the capture of the red fish in their annual migrations, but it is pushed with so much energy and unsparing cupidity that their numbers are rapidly diminishing and the species will apparently be soon extirpated in these waters unless protected by legal enactment.

A branch of the Union Pacific Railroad is being constructed from Granger, Wyoming, to the mouth of the Columbia. On this a large amount of traffic is expected, as it will link together many settlements having a considerable resident population and traverse in different portions of the route rich agricultural and mining districts.

Dr. Newberry then briefly described a small but remarkably rich placer gold deposit he visited on the west flank of Mount Wheeler, the highest mountain in Nevada, and mentioned the discovery of an outcrop of lower silurian rocks full of fossils, including several new trilobites discovered by him in Southwestern Utah, but deferred all details till he should make them the subjects of special remark to the Academy.

Colorado.—Reference was made to the general character of Southwestern Colorado, the interesting topography of the region, especially the vast plateau which rises westward from the base of the Rocky Mountains on to the slopes of the Wasatch; the ascent of Marshall's Pass by the Denver and Rio Grande Railroad, the most remarkable feat of railroad engineering performed in the country, and the exceedingly picturesque region about the Pagosa the greatest hot spring on the continent. Where the San Juan river issues from the mountains a prairie occurs, surrounded by picturesque forest-clad hills, and with a beautiful view of snow-clad mountains in the distance. In the centre of the prairie lies a basin 40 by 60 feet across, boiling like a huge caldron, the ebullition being produced by the violent escape of carbonic acid gas. The banks are lined by the remains of beetles, snakes, etc., destroyed by too trustful reliance upon the hot waters, and by interesting mineral deposits. This is one of the most beautiful places in the country and likely to be a famous resort.

Along the route from Pueblo to Gunnison and Lake City, and thence eastward by Del Norte, there are some places of resort for invalids and pleasure-seekers, which are destined to be very well known, being far more beautiful and salubrious than the now celebrated localities at Manitou and Colorado Springs. One of these is Wagon Wheel Gap, on the Rio Grande. The river is a rapid, turbulent stream, and the Gap is seven to ten miles long, just wide enough to permit a wagon-road. Then a wide, open space is reached, the basin of an ancient lake, girdled by a wonderfully beautiful amphitheatre of mountains. Here 8500 feet above the sea, the hot springs, charming rides, fine hunting and fishing, an atmosphere as pure and clear as crystal, constitute the attractions of a resort, which far surpasses any other, and which will be reached by the railroad now being pushed through the Gap about January 1, 1882.

From Gunnison, specimens have been recently brought of magnetite and hematite, which probably represent inexhaustible masses, and at Crested Butte, within twenty-five miles of this locality, is found the best coking coal in the West. The region borders on a volcanic area, and the coking coal is from that portion of the basin, which has mostly escaped the alteration by volcanic heat. It is firm and not affected by the weather, with a small amount of ash and sulphur.

On Anthracite Creek are found many thousand acres of Anthracite of better quality than that of Pennsylvania. Recent analysis made at the School of Mines shows it to contain less than one per cent. of sulphur, and three per cent. of ash.

The forest vegetation of Colorado is very simple. The piñon or nut pine is very common, also the yellow pine (*P. ponderosa*), Douglas' spruce, Menzies' spruce, etc. In the mountains the general vegetation is picturesque but not so varied as in the lowlands. The following plants are among the most characteristic in the lowlands of Colorado and Utah.

The evening primrose (*Œnothera Cæspitosa*) with its large beautiful white flowers.

The wild tobacco (*Nicotiana attenuata.*)

The sun flower (*Helianthus.*)

The bee flower (*Cleome integrifolia*) presenting purple acres by the roadside, and the yellow species (*C. lutea*) less common.

The American primrose (*Primula Parryi.*)

The pasque flower (*Anemone patens, Var. Nuttalliana.*)

The *Eriogonums*, about twenty species, coloring whole mountain sides yellow.

The Oregon grape (*Berberis aquifolium.*)

Phacelia circinata in tufts of purple flowers on rocky slopes.

The lily (*Calochortus Gunnisoni* and *C. Nuttalli*) or "blackeyed Susan" (Indian—"Seego,") very plenty in the moister portion of the sage-plains.

The clematis (*Anemone alpina*) with its purple flowers.

The penstemons, of which 20 or 30 species are peculiar to that country, deep crimson, pink, and purple and blue in color, often very showy, and so abundant that whole acres of ground are colored by them.

The columbine (*Aquilegia canadensis,*) and also a much larger species (*A. cerulea,*) clothing the mountains of Colorado and Utah, with blue, cream-colored, and white flowers. A large number of dried plants were exhibited from a collection of several hundred species just brought on from Colorado, with collections procured from Prof. Marcus Jones of Salt Lake City, and others.

RETARDED DEVELOPMENT IN INSECTS.*

By C. V. Riley, Washington, D. C.

In this paper the author records several interesting cases of retarded development in insects, whether as summer coma or dormancy of a certain portion of a given brood of caterpillars, the belated issues of certain imagines from the pupa, or the deferred hatching of eggs. One of the most remarkable cases of this last to which he calls attention, is the hatching this year of the eggs of the Rocky Mountain Locust, or Western Grasshopper (*Caloptemus spretus*), that were laid in 1876, around the Agricultural College at Manhattan, Kansas. These eggs were buried some ten inches below the surface, in the Fall of 1876, in grading the ground around the chemical laboratory. The superincumbent material was clay, old mortar and bits of stone, and a plank sidewalk was laid above all. In removing and regrading the soil last spring Mr. J. D. Graham noticed that the eggs looked sound and fresh, and they readily hatched upon exposure to normal influences, the species being determined by Prof. Riley from specimens submitted by Mr. Graham. Remarkable as the facts are there can be no question as to their accuracy, so that the eggs actually remained unhatched during nearly four years and a half, or four years longer than is their wont, and this suggests the significant question: How much longer could the eggs of this species, under favoring conditions of dryness and reduced temperature, retain their vitality and power of hatching?

Putting all the facts together Mr. Riley concludes that we are as yet absolutely incapable of offering any satisfactory explanation, based on experiment, of the causes which induce exceptional retardation in development among insects. It is a very general rule that a rising temperature stimulates and accelerates growth, while a falling temperature retards and torpifies, and experiments recorded by the author* show that such is the case with regard to the eggs of *Caloptcnus spretus*. But there are many exceptions to the rule. The eggs of Crustaceans, as *Apus* and *Cypres*, are known to have the power of resisting drought for six, ten or more years without losing vitality, while in some cases they seem actually to require a certain amount of desiccation before they will hatch. Yet the fact remains that different act differently in this respect. In short, nothing is more patent to the observing naturalist than that species, and, even individuals of the same species, or the progeny of one and the same individual, act very differently under like external conditions of existence; or in other words, that temperature, moisture, food, etc., influence them differently. Hence—as has been shown by Semper to be the case with other animals, so it is with insects—changes in the external conditions of existence will not affect the fauna as a whole equally, but will act on individuals. We can understand how this great latitude in susceptibility to like conditions may and does, in the case of exceptional seasons, prove beneficial to the species by preserving the exceptional individuals that display the power to resist the unusual change; but we shall find ourselves baffled when we come to seek a demonstrable explanation of the cause or causes of such retardation, while the principles of evolution afford us the only hypothetical one at all satisfactory. In the innate property of organism to vary, and in the complex phenomena of heredity, we get a glimpse at the cause—a partial explanation—of the facts of retarded development; for the exceptional tendency in the present may be looked upon as a manifestation through atavism of traits which in the past had been more commonly possessed and more essential to the species.

ON THE "LIFE DURATION OF THE HETEROCERA (MOTHS*)."

(Abstract.)

By J. A. Lintner, State Entomologist of New York.

The subject of life duration of our insects, not having been given special study, so little is known upon it, that the present contribution would not be warranted, were it not that the confession of our ignorance upon the point, may serve as an incentive to its examination.

It is a difficult field of study, for the observations should be made upon the insects in the natural conditions—not in confinement. Even of the latter state, our knowledge is quite limited. Entire broods of species have seldom been reared, except in the Bombycidæ and Sphingidæ, where the eggs are easily to be obtained. But in the large family of Noctuidæ, I do not know that an entire oviposition, or even a considerable part of one, has ever been carried through to the perfect stage, nor have I any personal knowledge of the time, place, manner or duration of copulation among them.

In the Attacinæ of the Bombycidæ, the lives of most are brief; that of the female seldom reaches fifteen days, while in the male it is still shorter. It is longer in the Sphingidæ.

We may best obtain an approximation to the life period of the moths, from reference to the dates when they are observed abroad. The lists published of collections "at sugar," furnish us with the best data. From a list prepared by myself, it appears that a large number of species of Noctuidæ were abroad for about one month. Deducting one-third of this time for their probable unequal emergence from the pupæ, there would remain a term of three weeks for their approximate life duration.

Mr. W. L. Devereaux, of Clyde, N. Y., from his observations, also infers, "that most of the species remain for about a month."

As would be expected from so heterogeneous a family as the Noctuidæ, the different groups present different life periods. The genera Xylina, Homoptera and Catocala, are found to have a considerably longer continuance than that above given. Three species of Xylina were observed by me for forty-one, forty-seven and fifty-one days; ten species of Catocala, for an average of forty-five days; and nine species of the same genus, as reported by Mr. Devereaux, for fifty-seven days.

In view of the benefits which would result to Entomology, it is suggested, that in future lists published of our insects, the different dates at which they are observed throughout the year, be included. It would aid us in determining life duration—would indicate the time when to guard against the commencement of insect attack—when to commit our crops to the ground—when to search for specimens for our cabinets—in short, it would furnish an essential part of the life histories of our species.

* Read before the A. A. A. S., Cincinnati, 1881.

Mr. G. Fasoldt says, in a letter to the *American Journal of Microscopy*:—

I have ruled plates up to 1,000,000 lines to the inch, one of which was purchased by the United States Government at Washington.

These plates show lines truly and fairly ruled, as far as lenses are able to resolve, and above this point the *spectral* appearance of the bands in regular succeeding colors (when examined as an opaque object) shows, beyond doubt, that each band contains fairly ruled lines up to the 1,000,000 band.

I do not believe that I will ever attempt to rule higher than 1,000,000 lines per inch, as from my practical experience and judgment, I have concluded that that is the limit of ruling.

ELECTRIC RAILROADS IN PARIS.

The visitors at the Electrical Exhibition can see a very fine model in bronze, surmounted by very beautiful designs, which represents an electric elevated railroad. This model is placed in the large aisle very near the pavilion of the City of Paris. It is in miniature a part of the new system of railroads which should be constructed over all the great streets of the capital in order to lessen the nnmber of encumbrances and to supply the want of locomotive means of which the whole city justly complains. M. J. Chrétien, the inventor of the new system, proposes its immediate application to all the great boulevards.

Electricity has indisputable advantages over other methods of locomotion. It is an economic method which can produce very slow as well as very rapid motion, which causes no noise or smoke, and which only allows the use of light vehicles and, consequently, the laying of unobstructive tracks. The building of electric railroads in places where business is most active, will have the double result of freeing the public roads of obstructions and of giving to the public sufficient means of transportation.

The following details we borrow from a pamphlet published by M. J. Chrétien entitled "Chemin de fer electrique des boulevards." The electric road is a double-railed viaduct supported by a row of columns spaced about forty or fifty metres from each other, and placed in the middle of the road. A central hollow beam rests on the columns and carries all the load; it runs the whole length of the boulevard, at a height varying from five to seven metres above the earth in order to compensate for the irregularities of the ground. On each side of the beam the rails are placed, resting on a metallic platform, so that there is one on the right and another on the left.

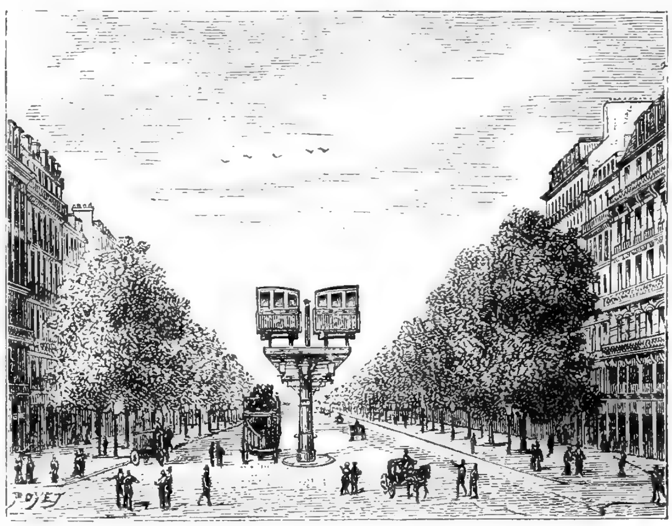

Fig. 3.—SECTION OF THE PROPOSED ROAD.

The stations, twelve in number, are placed about 500 metres from each other, and we can ascend by a very convenient staircase, placed either over the sidewalk or over the pavement. For the station most elevated above the ground, electric elevators are provided for the use of those who wish to ascend. It can even be said that it is easier to take the electric road than to ride in an omnibus.

Two works for the supply of the motive force are placed under the ground. Each of these works consists of steam engines to furnish the motive force and Gramme dynamo-electric machines to produce the electric currents, when they are set in motion by the steam engines.

The electricity thus produced is transmitted through the whole length of the road by conducting wires, and distributed to the various carriages. These are put in motion by means of electric machines, which each of them carries, and which receive, through the conducting wires, the electricity necessary to attain the speed required.

Thanks to very simple means, applications of electricity, there can be no collisions, no accidents of any kind; the motions are easier than in the ordinary railroad, and the carriages can regulate their speed with remarkable precision.

The speed is about 350 to 400 metres a minute, that is to say, the speed of a good trotting horse; with this speed, and reckoning a half minute for the mean time of stoppage at station, the whole length of the road, which is 4500 metres, can be traversed in about 17 or 18 minutes. This is half the time of an ordinary omnibus.

According to the ideas which we draw from the pamphlet spoken of, the capacity for transportation of the electric road is so great, that we with some difficulty accept the given figures, while it is easy to try the exactness of them. Thus, every minute a carriage, with places for 50, passes each station; so that, if the carriages are always full, there will be 100 persons carried each minute in the two directions, and if we take account of the additions during the journey, we will have about twice as much; that is about 200 persons every minute, or 12000 per hour. But it is possible to still increase the carrying capacity, and to reach the maximum corresponding to the trip of two carriages joined together, at intervals of a minute. We will arrive, in this case, to the colossal figure of 24000 persons an hour. Although these figures appear more than sufficient, it is certain, for those who know the activity at certain times upon the boulevards, that there are times when everybody cannot find room without waiting.

From the given estimate, the total expense necessary for the construction of the road, will only be from eight to ten millions, according to the greater or less magnificence necessary to construct a work of this importance in the centre of such a city as Paris.

Assuming an expense of eight millions, it is calculated that the price of a seat can be fixed at ten centimes, to realize profits large enough to pay the city an annual revenue of a million or a million and a half, without asking any subsidy whatever. The electric road has then as its several results, the furnishing the means of an agreeable, easy and economic locomotion, the satisfying the demands of a great traffic, which is growing day by day, and the supplying of an important revenue to the city, while still the price of a seat is kept at ten centimes.

In regard to the appearance of the road, which has a great importance in such a city as Paris, where art has never been too much sacrificed, it will certainly be seen, after a careful examination of the given designs and the engravings, that it is possible to give an artistic character to this work. Such as it is represented, the elevated road lacks neither strength nor magnificence; it is in the modern style, which alone is becoming to a work which our ancestors never dreamed of. It has been suggested besides, that, in order to fully satisfy the artistic demands, a competition should be opened to all architects and artists; and this would certainly lead to excellent results.

The utility and advantage of the electric road cannot be disputed; that it should exist is obvious, and the proposed work leaves nothing to be desired. This splendid work will certainly be accomplished, but perseverance and labor are necessary in order to vanquish all resistance, routine, and inertia, against which it would otherwise be fatally injured.—*Translated from La Nature.*

CHLORAL HYDRATE IN TOOTHACHE.—Dr. Spörer recommends that three to four lumps of hydrate of chloral (0.03–0.06 gram), should be inserted into the hollow and painful tooth, the chloral being allowed to dissolve.—*St. Petersburg, Med. Wochenschrift.*

MECHANICAL SCIENCE*

By Sir W. Armstrong, C.B., D.C.L., LL. D., F.R.S.

The astonishing progress which has been made in the construction and application of machinery during the half century which has elapsed since the nativity of the British Association for the Advancement of Science, is a theme which I might with much complacency adopt in this address, but instead of reviewing the past and exulting in our successes, it will be more profitable to look to the future and to dwell on our failures. It is but justice to say that by growing experience, by increasing facilities of manufacture, and by the exercise of much skill and ingenuity, we have succeeded in multiplying and expanding the applications of our chief motor, the steam-engine, to an extent that would have appeared incredible fifty years ago; but the gratulation inspired by this success is clouded by the reflection that the steam-engine, even in its best form, remains to this day a most wasteful apparatus for converting the energy of heat into motive power. Our predecessors of that period had not the advantage of the knowledge which we possess of the true nature of heat, and the conditions and limits affecting its utilization. In their time heat was almost universally regarded as a fluid which, under the name of caloric, was supposed to lie dormant in the interstices of matter until forced out by chemical or mechanical means. Although Bacon, Newton, Cavendish, and Boyle all maintained that heat was only internal motion, and although Davy and Rumford not only held that view, but proved its accuracy by experiment, yet the old notion of caloric continued to hold its ground, until in more recent times Joule, Meyer, Codling, and others, put an end to all doubt on the subject, and established the all-important fact that heat is a mode of motion having, like any other kind of motion, its exact equivalent in terms of work. By their reasonings and experiments it has been definitely proved that the quantity of heat which raises the temperature of a pound of water 1° Fahrenheit, has a mechanical value equal to lifting 772 lbs. one foot high, and that conversely the descent of that weight from that height is capable of exactly reproducing the heat expended.

The mechanical theory of heat is now universally accepted, although a remnant of the old doctrine is displayed in the continued use of the misleading term "latent heat." According to the new theory, heat is an internal motion of molecules capable of being communicated from the molecules of one body to those of another, the result of the imparted motion being either an increase of temperature, or the performance of work. The work may be either external, as where heat, in expanding a gas, pushes away a resisting body, or it may be internal, as where heat pulls asunder the cohering particles of ice in the process of liquefaction, or it may be partly internal and partly external, as it is in the steam engine, where the first effect of the heat is to separate the particles of water into vapor, and the second to give motion to the piston. Internal as well as external work may be reconverted into heat, but until the reconversion takes place, the heat which did the work does not exist as heat, and it is delusive to call it "latent heat." All heat problems are comprised under the three leading ideas of internal work, external work, and temperature, and no phraseology should be used that conflicts with those ideas.

The modern theory of heat has thrown new light upon the theory of the steam-engine. We now know what is the mechanical value in foot pounds of the heat evolved in the combustion of one pound of coal. In practice we can determine how much of that heat is transmitted to the water in the boiler, and we are taught how to calculate the quantity which in the process of vaporisation takes the form of internal work. We can determine how much disappears in the engine in the shape of external work, including friction, and the remainder, with the exception of the trifling quantity saved in the feed-water, we know to be lost. Taking a good condensing engine as an example, we may roughly say that, dividing the whole heat energy into ten equal parts, two escape by the chimney, one is lost by radiation and friction, six remain unused when the steam is discharged, and only one is realized in useful work. It may be fully admitted that the greater part of the aggregate loss is inevitable; but are we to suppose that the resources of science, ingenuity, and skill have been exhausted in the attainment of so miserable a result? Nothing but radical changes can be expected to produce any great mitigation of the present monstrous waste, and without presuming to say what measures are practicable and what are not, I will briefly point out the directions in which amelioration is theoretically possible, and shall afterwards advert to the question whether we may hope to evade the difficulties of the steam-engine by resorting to electrical methods of obtaining power.

To begin with the loss which takes place in the application of heat to the boiler; why is it that we have to throw away, at the very outset of our operations, twice as much heat as we succeed in utilizing in the engine? The answer is, that in order to force a transmission of heat from the fire to the water in the boiler, a certain excess of temperature over that of the water must exist in the furnace and flues, and the whole of the heat below the required excess must pass away unused, except the trifling portion of it which disappears in the production of draught. Further, that since we cannot avoid admitting the nitrogen of the air along with the oxygen, we have to heat a large volume of neutral gas which has no other effect than to rob the fire. Considering what efforts have been made to facilitate the transmission of the heat by augmenting the evaporative surface, and using thin tubes as flues, it is vain to expect any great result from further perseverance in that direction, and unless a method can be devised of burning the fuel inside instead of outside the apparatus, so as to use the heated gases conjointly with the steam as a working medium in the engine, a remedy appears to be hopeless. We already practice internal combustion in the gas-engine, and it is clear that with gaseous fuel, at all events, we could associate such a mode of combustion with the vaporization of water. We may even regard a gun as an engine with internally-burnt fuel, and here I may remark that the action of heat in a gun is strictly analogous to that of heat in a steam-engine. In both cases the heat is evolved from chemical combination, and the resulting pressures differ only in degree. The gun is the equivalent of the cylinder, and the shot of the piston, and the diagrams representing the pressure exerted in the two cases bears a close resemblance to each other. While the powder is burning in the gun we have a nearly uniform pressure, just as we have in the cylinder while the steam is entering, and in both cases the uniform pressure is followed by a diminishing pressure, represented by the usual curve of expansion. If in the steam-engine we allowed the piston to be blown out it would act as a projectile, and if in the gun we oppose mechanical resistance to the shot, we might utilize the effect in a quieter form of motive power. But it is a remarkable fact that such is the richness of coal as a store of mechanical energy that a pound of coal, even as used in the steam-engine, produces a dynamic effect about five times greater than a pound of gunpowder burnt in a gun. I cannot, however, on this account encourage the idea that steam may be advantageously substituted for gunpowder in the practice of gunnery.

And now to turn from the fire which is the birthplace of the motive energy, let us follow it in the steam, to the condenser, where most of it finds a premature tomb. From the point at which expansion commences in the cylinder the temperature and pressure of the steam begin to run down, and if we could continue to expand indefi-

*British Association, 1881.

nitely, the entire heat would be exhausted, and the energy previously expended in separating the water into steam would be wholly given up in external effect; but this exhaustion would not be complete until the absolute zero of temperature was reached (viz., 461° below the zero of Fahrenheit). I do not mean to say that an ideally perfect engine necessarily involves unlimited expansion, seeing that if instead of discharging the steam at the end of a given expansion, we made the engine itself do work in compressing it, we might, under the conditions of Carnot's reversible cycle so justly celebrated as the foundation of the theory of the steam-engine, recommence the action with all the unutilized heat in an available form. But an engine upon this principle could only give an amount of useful effect corresponding to the difference between the whole work done by the engine, and that very large portion of it expended in the operation of compression, and this difference viewed in relation to the necessary size of the engine, would be quite insignificant, and would in fact be wholly swallowed up in friction. Carnot did not intend to suggest a real engine, and his hypothesis therefore takes no cognizance of losses incident to the application of an actual fire to an actual boiler. His ideal engine is also supposed to be frictionless, and impervious to heat except at the point where heat has to be transmitted to the water, and there the condition of perfect conduction is assumed. In short an engine which would even approximately conform to the conditions of Carnot's cycle is an impossibility, and a perfect steam-engine is alike a phantom whether it be sought for in the cyclical process of Carnot, or under the condition of indefinite expansion. Practically we have to deal with a machine which, like all other machines, is subject to friction, and in expanding the steam we quickly arrive at a point at which the reduced pressure on the piston is so little in excess of the friction of the machine as to render the steam not worth retaining, and at this point we reject it. In figurative language we take the cream off the bowl and throw away the milk. We do save a little by heating the feed water, but this gain is very small in comparison with the whole loss. What happens in the condenser is, that all the remaining energy which has taken the form of internal work is reconverted into heat, but it is heat of so low a grade that we cannot apply it to the vaporization of water. But although the heat is too low to vaporize water it is not too low to vaporize ether. If instead of condensing by the external application of water we did so by the similar application of ether, as proposed and practised by M. du Trembley twenty-five years ago, the ether would be vaporized, and we should be able to start afresh with high tension vapor, which in its turn would be expanded until the frictional limit was again reached. At that point the ether would have to be condensed by the outward application of cold water and pumped back, in the liquid state, to act over again in a similar manner. This method of working was extensively tried in France when introduced by M. du Trembley, and the results were sufficiently encouraging to justify a resumption of the trials at the present time, when they could be made under much more favorable conditions. There was no question as to the economy effected, but in the discussions which took place on the subject it was contended that equally good results might be attained by improved applications of the steam, without resorting to an additional medium. The compound engine of the present day does in fact equal the efficiency of Du Trembley's combined steam and ether-engine, but there is no reason why the ether apparatus should not confer the same advantage on the modern engine that attended its application to the older form. The objections to its use are purely of a practical nature, and might very possibly yield to persevering efforts at removal.

I need scarcely notice the advantage to be derived from increasing the initial pressure of the steam so as to widen the range of expansion by raising the upper limit of temperature instead of reducing the lower one. It must be remembered, however, that an increase of temperature is attended with the serious drawback of increasing the quantity of heat carried off by the gases from the fire, and also the loss by radiation, so that we have not so much to gain by increase of pressure as is commonly imagined.

But even supposing the steam-engine to be improved to the utmost extent that practical considerations give us reasons to hope for, we should still have to adjudge it a wasteful though a valuable servant. Nor does there appear to be any prospect of substituting with advantage any other form of thermodynamic engine, and thus we are led to inquire whether any other kind of energy is likely to serve us better than heat, for motive power.

Most people, especially those who are least competent to judge, look to electricity as the coming panacea for all mechanical deficiency, and certainly the astonishing progress of electricity as applied to telegraphy, and to those marvellous instruments of recent invention which the British Post Office claims to include in its monopoly of the electric telegraph, as well as the wonderful advance which electricity has made as an illuminating agent, does tend to impress us with faith in its future greatness in the realm of motive power as well.

The difference between heat and electricity in their modes of mechanical action is very wide. Heat acts by expansion of volume which we know to be a necessarily wasteful principle, while electricity operates by attraction and repulsion, and thus produces motion in a manner which is subject to no greater loss of effect than attends the motive action of gravity as exemplified in the ponderable application of falling water in hydraulic machines. If then we could produce electricity with the same facility and enconomy as heat, the gain would be enormous, but this, as yet at least, we cannot do. At present by far the cheapest method of generating electricity is by the dynamic process. Instead of beginning with electricity to produce power, we begin with power to produce electricity. As a secondary motor an electric engine may, and assuredly will, play an important part in future applications of power, but our present inquiry relates to a primary, and not a secondary, employment of electricity. Thus we are brought to the question, from what source, other than mechanical action, can we hope to obtain a supply of electricity sufficiently cheap and abundant to enable it to take the place of heat as a motive energy? It is commonly said that we know so little of the nature ot electricity that it is impossible to set bounds to the means of obtaining it; but ignorance is at least as liable to mislead in the direction of exaggerated expectation as in that of incredulity. It may be freely admitted that the nature of electricity is much less understood than that of heat, but we know that the two are very nearly allied. The doctrine that heat consists of internal motion of molecules may be accepted with almost absolute certainty of its truth. The old idea of heat being a separate entity is no longer held except by those who prefer the fallacious evidence of their senses to the demonstrations of science. So also the old idea of electricity having a separate existence from tangible matter must be discarded, and we are justified in concluding that it is merely a strained or tensional condition of the molecules of matter. Although electricity is more prone to pass into heat than heat into electricity, yet we know that they are mutually convertible. In short I need scarcely remind you, that according to that magnificent generalization of modern times, so pregnant with great consequences, and for which we are indebted to many illustrious investigators, we now know that heat, electricity, and mechanical action, are all equivalent and transposable forms of energy, of which motion is the essence.

To take a cursory view of our available sources of energy, we have, firstly, the direct heating powers of the

sun's rays, which as yet we have not succeeded in applying to motive purposes. Secondly we have water power, wind power, and tidal power, all depending upon influences lying outside of our planet, And thirdly we have chemical attraction or affinity. Beyond these there is nothing worth naming. Of the radiant heat of the sun I shall have to speak hereafter, and bearing in mind that we are in search of electricity as a cause, and not an effect, of motive power we may pass over the dynamical agencies comprised under the second head, and direct our attention to chemical affinity as the sole remaining source of energy available for our purpose. At present we derive motive power, from chemical attraction through the medium of heat only, and the question is, can we with advantage draw upon the same source through the medium of electricity. The process by which we obtain our supply of heat from the exercise of affinity is that of combustion, in which the substances used consist, on the one hand, of those we call fuel, of which coal is the most important, and on the other, of oxygen, which we derive from the atmosphere. The oxygen has an immense advantage over every other available substance in being omnipresent and costless. The only money value involved is that of the fuel, and in using coal we employ the cheapest oxidizable substance to be found in nature. Moreover the weight of coal used in the combination is only about one-third of the weight of oxygen, so that we only pay upon one-fourth of the whole material consumed. Thus we have conditions of the most favorable description for the production of energy, in the form of heat, and if we could only use the affinities of the same substances with equal facility to evolve electric energy instead of heat energy, there would be nothing more to desire; but as yet there is no appearance of our being able to do this. According to our present practice we consume zinc, instead of coal, in the voltaic production of electricity, and not only is zinc thirty or forty times dearer than coal, but it requires to be used in about six-fold larger quantity in order to develop an equal amount of energy. Some people are bold enough to say that with our present imperfect knowledge of electricity we have no right to condemn all plentiful substances, other than coal, as impracticable substitutes for metallic zinc, but it is manifest that we cannot get energy from affinity, where affinity has already been satisfied. The numerous bodies which constitute the mass of our globe, and which we call earths, are bodies in this inert condition. They have already, by the union of the two elements composing them, evolved the energy due to combination, and that energy has ages ago been dissipated in space in the form of heat, never again to be available to us. As well might we try to make fire with ashes, as to use such bodies over again as sources of either heat or electricity. To make them fit for our purpose, we should first have to annul their state of combination, and this would require the expenditure of more energy upon them than we could derive from their recombination. Water, being oxidized hydrogen, must be placed in the same category as the earths. In short, the only abundant substances in nature possessing strong unsatisfied affinities are those of organic origin, and in the absence of coal, which is the accumulated product of a past vegetation, our supply of such substances would be insignificant. This being the case, until a means be found of making the combination of coal with oxygen directly available for the development of electric energy, as it now is of heat energy, there seems to be no probability of our obtaining electricity from chemical action at such a cost as to supplant heat as a motive agent.

But while still looking to heat as the fountain-head of our power, we may very possibly learn to transmute it, economically, into the more available form of electricity. One method of transformation we already possess, and we have every reason to believe there are others yet to be discovered. We know that when dissimilar metals are joined at opposite ends, and heated at one set of junctions while they are cooled at the other, part of the heat applied disappears in the process, and assumes the form of an electric current. Each couple of metals may be treated as the cell of a voltaic battery, and we may multiply them to any extent, and group them in series or in parallels, with the same results as are obtained by similar combinations of voltaic cells. The electricity so produced we term Thermo-electricity, and the apparatus by which the current is evolved is the thermo-electric battery. At present this apparatus is even more wasteful of heat than the steam-engine, but considering the very recent origin of this branch of electrical science, and our extremely imperfect knowledge of the actions involved, we may reasonably regard the present thermo-electric battery as the infant condition of a discovery, which, if it follow the rule of all previous discoveries in electricity, only requires time to develop into great practical importance. Now if we possessed an efficient apparatus of this description we could at once apply it to the steam-engine for the purpose of converting into electric energy the heat which now escapes with the rejected steam, and the gases from the fire. The vice of the steam-engine lies in its inability to utilize heat of comparatively low grade, but if we could use up the leavings of the steam-engine by a supplemental machine acting on thermo-electric principles, the present excessive waste would be avoided. We may even anticipate that in the distant future a thermo-electric engine may not only be used as an auxiliary, but in complete substitution of the steam-engine. Such an expectation certainly seems to be countenanced by what we may observe in animated nature. An animal is a living machine dependent upon food both for its formation and its action. That portion of the food which is not used for growth or structural repair, acts strictly as fuel in the production of heat. Part of that heat goes to the maintenance of the animal temperature, and the remainder gives rise to mechanical action. The only analogy between the steam engine and this living engine is that both are dependent upon the combustion of fuel, the combustion in the one case being extremely slow, and in the other very rapid. In the steam-engine the motion is produced by pressure, but in the animal machine it is effected by muscular contraction. The energy which causes that contraction, if not purely electrical, is so much of that nature that we can produce the same effect by electricity. The conductive system of the nerves is also in harmony with our conception of an electrical arrangement. In fact a description of the animal machine so closely coincides with that of an electro-dynamic machine actuated by thermo-electricity, that we may conceive them to be substantially the same thing. At all events, the animal process begins with combustion and ends with electrical action, or something so nearly allied to it as to differ only in kind. And now observe how superior the result is in nature's engine to what it is in ours. Nature only uses heat of low grade, such as we find wholly unavailable. We reject our steam as useless at a temperature that would cook the animal substance, while nature works with a heat so mild as not to hurt the most delicate tissue. And yet, notwithstanding the greater availability of high-grade temperature the quantity of work performed by the living engine relatively to the fuel consumed, puts the steam-engine to shame. How all this is done in the animal organization we do not yet understand, but the result points to the attainability of an efficient means of converting low-grade heat into electricity, and in striving after a method of accomplishing that object we shall do well to study nature, and profit by the excellence which is there displayed.

But it is not alone in connection with a better utilization of the heat of combustion that thermo-electricity bears so important an aspect, for it is only the want of an efficient apparatus for converting heat into electricity that prevents our using the direct heating action of the

sun's rays for motive power. In our climate, it is true, we shall never be able to depend upon sunshine for power, nor need we repine on that account so long as we have the preserved sunbeams which we possess in the condensed and portable form of coal, but in regions more favored with sun and less provided with coal the case would be different, The actual power of the sun's rays is enormous, being computed to be equal to melting a crust of ice 103 feet thick over the whole earth in a year. Within the tropics it would be a great deal more, but a large deduction would everywhere have to be made for absorption of heat by the atmosphere. Taking all things into account, however, we shall not be far from the truth in assuming the solar heat, in that part of the world, to be capable of melting annually, at the surface of the ground, a layer of ice 85 feet thick. Now let us see what this means in mechanical effect. To melt 1 lb. of ice requires 142.4 English units of heat, which, multiplied by 772, gives us 109,932 foot pounds as the mechanical equivalent of the heat consumed in melting a pound of ice. Hence we find that the solar heat, operating upon an area of one acre, in the tropics, and competent to melt a layer of ice 85 feet thick in a year, would, if fully utilized, exert the amazing power of 4000 horses acting for nearly nine hours every day. In dealing with the sun's energy we could afford to be wasteful. Waste of coal means waste of money and premature exhaustion of coal beds. But the sun's heat is poured upon the earth in endless profusion—endless at all events in a practical sense, for whatever anxiety we may feel as to the duration of coal, we need have none as to the duration of the sun. We have therefore only to consider whether we can divert to our use so much of the sun's motive energy as will repay the cost of the necessary apparatus, and whenever such an apparatus is forthcoming we may expect to bring into subjection a very considerable proportion of the 4000 invisible horses which science tells us are to be found within every acre of tropical ground.

But whatever may be the future of electricity as a prime mover, either in a dominant or subordinate relation to heat, it is certain to be largely used for mechanical purposes in a secondary capacity, that is to say, as the offspring instead of the parent of motive power. The most distinctive characteristic of electricity is that which we express by the word "current," and this gives it great value in cases where power is required in a transmissible form. The term may be objected to as implying a motion of translation analogous to the flow of a liquid through a pipe, whereas the passage of electricity through a conductor must be regarded as a wave-like action communicated from particle to particle. In the case of a fluid current through a pipe, the resistance to the flow increases as the square of the velocity, while in the case of an electric current the resistance through a given conductor is a constant proportion of the energy transmitted. So far therefore as resistance is concerned electricity has a great advantage over water for the transmission of power. The cost of the conductor will however be a grave consideration where the length is great, because its section must be increased in proportion to the length to keep the resistance the same. It must also be large enough in section to prevent heating, which not only represents loss but impairs conductivity. To work advantageously on this system, a high electromotive force must be used, and this will involve loss by imperfect insulation, increasing in amount with the length of the line. For these reasons there will be a limit to the distance to which electricity may be profitably conveyed, but within that limit there will be wide scope for its employment transmissively. Whenever the time arrives for utilizing the power of great waterfalls the transmission of power by electricity will become a system of vast importance. Even now small streams of water inconveniently situated for direct application may, by the adoption of this principle, be brought into useful operation.

For locomotive purposes also we find the dynamo-electric principle to be available, as instanced in the very interesting example presented in Siemens' electric railway, which has already attained that degree of success which generally foreshadows an important future. It forms a combined fixed engine and locomotive system of traction, the fixed engine being the generator of the power and the electric engine representing the locomotive.

Steam power may both be transmitted and distributed, by the intervention of electricity, but it will labor under great disadvantage when thus applied, until a thoroughly effective electric accumulator be provided, capable of giving out electric energy with almost unlimited rapidity. How far the secondary battery of M. Faure will fulfill the necessary conditions remains to be seen, and it is to be hoped that the discussions which may be expected to take place at this meeting of the British Association will enable a just estimate of its capabilities to be formed. The introduction of the Faure battery is at any rate a very important step in electrical progress. It will enable motors of small power, whatever their nature may be, to accomplish, by uninterrupted action, the effect of much larger machines acting for short periods, and by this means the value of very small streams of water will be greatly enhanced. This will be especially the case where the power of the stream is required for electric lighting, which, in summer, when the springs are low, will only be required during the brief hours of darkness, while in winter the longer nights will be met by a more abundant supply of water. Even the fitful power of wind, now so little used, will probably acquire new life when aided by a system which will not only collect, but equalize, the variable and uncertain power exerted by the air.

It would greatly add to the utility of the Faure battery if its weight and size could be considerably reduced, for in that case it might be applicable to many purposes of locomotion. We may easily conceive its becoming available in a lighter form for all sorts of carriages on common roads, thereby saving to a vast extent the labor of horses. Even the nobler animal that strides a bicycle, or the one of fainter courage that prefers the safer seat of a tricycle, may ere long be spared the labor of propulsion, and the time may not be distant when an electric horse, far more amenable to discipline than the living one, may be added to the bounteous gifts which science has bestowed on civilized man.

In conclusion I may observe that we can scarcely sufficiently admire the profound investigations which have revealed to us the strict dynamical relation of heat and electricity to outward mechanical motion. It would be a delicate task to apportion praise amongst those whose labors have contributed, in various degrees, to our present knowledge; but I shall do no injustice in saying that of those who have expounded the modern doctrine of energy, in special relation to mechanical practice, the names of Joule, Clausius, Rankine, and William Thomson, will always be conspicuous. But up to this time our knowledge of energy is almost confined to its inorganic aspect. Of its physiological action we remain in deep ignorance, and as we may expect to derive much valuable guidance from a knowledge of Nature's methods of dealing with energy in her wondrous mechanisms, it is to be hoped that future research will be directed to the elucidation of that branch of science which as yet has not even a name, but which I may provisionally term "Animal Energetics."

The dark violet fluor-spar of Wölsendorf contains some strongly odorous substance, the nature of which has not hitherto been satisfactorily explained. From recent experiments (described to the Berlin Chemical Society,) Herr Low concludes that the smell is due to presence of *free fluorine*, arising on elevation of temperature through dissociation of a small quantity of flouride, (probably ceric fluoride).

CORRESPONDENCE.

To the Editor of "SCIENCE."

It seems to me that Pres. Gaines' objection to the accepted theory of vision (see SCIENCE of Aug. 6, p. 370) may easily be answered.

It is universally agreed that vision is a sensation produced by ethereal undulations, and that these undulations are induced by molecular motion in a luminous body. Each point of a luminous body is a radiant point, that is, emits rays of light in every direction, and it is by some of these rays of ethereal undulations, either directly from the luminous point or refracted by, or reflected from, some non-luminous body, that all impressions of vision are made. Hence, all non-luminous objects are manifested to vision by reflected light, but reflected light is also *radiant* light; that is, reflected ethereal waves radiate from every point of non-luminous objects manifested to vision. These waves have fallen upon the reflecting surface (not necessarily a minimum surface or front) from various directions, many of them reflected from other non-luminous objects, and, the angle of reflexion being the same as the angle of incidence, they necessarily *radiate* from the object; and by their difference of intensity, that is, by the different capacities of contiguous surfaces to reflect rays in a particular direction, we receive different impressions from the different parts of the object, and hence assign to the object peculiarities corresponding to the peculiarities of the sensations produced. Hence, though I admit that we become cognizant of objects by radiant light, I contend that in all cases where the object is not self-luminous, the rays that impress us are reflected rays produced by some luminous body of which we learn nothing from these reflected rays.

DES MOINES.

ANOTHER CONFIRMATION OF PREDICTION.

By PLINY EARLE CHASE, LL.D.

On the 4th of October, 1878, I presented a communication to the American Philosophical Society,* in which I showed that the position of Watson's first intra-Mercurial planet, as computed by Gaillot and Monchez, represented the third intra-Mercurial term of my harmonic series. At the last meeting of the British Association, Professor Balfour Stewart read a paper in which he gave indications of sun spot disturbances by a planet, revolving in 24.011 days, and consequently having a semi-axis major of .163. This confirmation, both of my own prediction,† and of the calculations of the French astronomers, is the more interesting, because the first confirmation of my series was contained in a communication which was made to the Royal Society by Messrs. De la Rue, Stewart and Loewy, forty-one days after I had announced the series to the Philosophical Society, and published it in the New York Tribune.‡ The accordances are as follows:

London, England, - - - - 150 Leadenhall St.

SATURDAY, NOVEMBER 12, 1881.

The distribution of honors at the French Electrical Exhibition is very gratifying to the pride of the American people, as the American exhibitors have relatively carried off a large share of the prizes.

Edison has maintained the prestige of his country, and asserted the integrity and value of his wonderful series of electrical inventions, by *alone* receiving a "diploma of honor" for the electric light. This high mark of distinction he shared in other departments with the United States Signal Office, the Smithsonian Institution, the United States Patent Office, and Messrs. Graham & Bell.

Gold medals were awarded to the Anglo-American and Brush Electric Light Companies, the United States Electric Lighting Company, Elisha Gray and Taintor. Silver medals to Bailey & Puskas, Conolly Brothers & MacTighe, Dolbear, Eccard, Electric Purifier Company, Hubbard Pond Indicator Company, Western Electric Manufacturing Company, Western Electric Light Company and the Electro-Dynamic Company. Bronze medals to Messrs. Chavat, Cumming and Dion, the Hoosac Tunnel Company, the Trinitro Glycerine Works, Partz, Photo-Relievo Company, Whitehouse, Mills & Williams.

That Mr. Edison, with the whole world competing, and with every system represented, should receive from such a critical committee this special recognition and honor, as the inventor of the most perfect system of electrical illumination, appears to decide this point in a decisive manner. The practical application of this system on a scale which will astonish the world, is near at hand. The immense dynamo machines designed for use to illuminate a district in New York City with Mr. Edison's perfected lamps have been placed in position, and the mass of details connected with placing wires and fittings are nearing completion. Soon the word will be given that all is ready, and Mr. Edison will probably enjoy a triumph to which all his previous successes will be insignificant.

Mr. Edison must experience some regret that he was unable to be present at Paris, and in person receive the congratulations which would have been showered upon him, but we understand that he was most worthily represented by Mr. Charles Batcheler and Mr. Otto Moses, whose courtesy and indefatigable exertions have been fully recognized in some of our Parisian exchanges.

An instrument was lately described in a French journal, which was invented for the purpose of detecting oleomargarine as against pure butter.

This instrument discriminated between the specific gravities of the two substances. Shortly after the announcement of the making of this instrument, a report was spread in the daily papers, that the slight difference of density between oleomargarine and butter, was insufficient for this purpose.

A correspondent writes as follows on this subject: "The report that no difference of density is of any use in distinguishing oleomargarine from butter, is very easily disposed of, as the density of oleomargarine is 0.915 and the density of butter is 0.925. One will float at 15 C. in alcohol $53\frac{3}{4}$ per cent., and the other in alcohol $59\frac{1}{4}$ per cent. I mean by floating that the butter or oleomargarine will neither rise nor sink, when placed in the alcohol. If placed in the middle it will neither go to the top nor bottom, except very slowly. Of course there are persons who cannot distinguish between 0.915 and 0.925 specific gravities, and who cannot make an observation at a fixed temperature, but it is unreasonable to expect that any process can be satisfactory to such persons."

SCIENTIFIC ASSOCIATIONS IN WASHINGTON.

The three societies at the metropolis, the Philosophical, the Anthropological, and the Biological, all reorganized in October under very favorable auspices. A short account of their proceedings is given below:

Philosophical Society of Washington.—Three papers were read, one on Geology, by G. K. Gilbert, which our correspondent did not hear; a communication on Fog-signals, by Prof. Johnson, of the Light-house Board, and a paper on the Best Methods of Calculating the Solar Parallax, by Professor Harkness, of the National Observatory. Mr. Johnson's remarks were an account of investigations made the last summer upon the refractions of sound, in pursuance of the experiments set on foot by Professor Henry. The inquiries were prosecuted mainly in Newport harbor and its vicinity. The facts set forth were of great interest to scientific men and of great practical value to the mariner. Professor Harkness, who is a very ready speaker, gave the Society an explanation of the various methods employed in calculating the distance of the sun and the planets, inclining to prefer the transit observations as yielding the best

results. Professor Harkness has great hopes of photography as an auxiliary in this direction.

THE ANTHROPOLOGICAL SOCIETY.—Four papers were read in October, all of them mythological and all of permanent value, to wit: the Buffalo Woman: an Omaha Myth, by the Rev. Owen Dorsey; Myths of the Wintuns, by Major J. W. Powell; the Stone God of the Putepemni, by the Rev. S. D. Hurman; and the Dangers of Symbolic Interpretations, by Col. Gerrick Mallery. It is impossible to give an abstract of a myth. We can only say that Major Powell years ago conceived the idea of studying myths by the Baconian method. He told the writer of this sketch, "there are books and books on mythology, but very few myths. I will collect a volume of well authenticated myths, from which mythologic philosophy can be deduced." The Major has himself gathered a great number, and Messrs. Dorsey and Hurman were for many years missionaries among the Dakotas, speaking their language with the greatest freedom. Our readers will be pained to hear that Major Powell has been confined for several weeks by an acute attack of iritis. Colonel Mallery's paper was a thoughtful treatment of the subject of symbolism, neatly considered in its threefold aspect of signs, emblems, and symbols. The North American Indians north of Mexico had not arrived at that psychologic stage wherein true symbolism manifests itself.

THE BIOLOGICAL SOCIETY OF WASHINGTON.—The opening meeting of the Biological occurred on the evening when the city was all excitement over the reception of our French and German guests. The session of Friday, October 28th, however, was one of considerable interest. Professor Lester F. Ward exhibited an example from the petrified forests of Wyoming, mimicking the paw of an animal, which elicited a discussion as to the formation of agates and other minerals of that character.

Mr. Henry Elliot's communication on the biology of the Sea-Otter was very instructive. Little is known of the habit of this animal, the stuffed specimens in the museums conveying a very poor notion of its form. It is supposed to breed on the great beds of kelp which float in the northern seas, having one pup at a birth. Its fur is a hundred times more valuable than all other fur products combined. The hunting is especially dangerous and requires great skill.

Professor Thomas Taylor exhibited and described a freezing microtome, in which the cooling effect of a current of water from salt and ice is used to produce the hardening. The extreme cheapness, simplicity, and practicability of this apparatus will enable the microscopist to dispense with the more costly and difficult methods hitherto used for obtaining thin sections of tissues and for examining the brain and other soft parts of the body in a rigid condition.

THE EVOLUTION OF FLYING ANIMALS.

By CHARLES MORRIS.

There are some questions in Biological science which it will be difficult, if not impossible, to settle by an appeal to facts, and in the investigation of which we are obliged to employ a degree of speculation. Thus we have abundant reason to believe that birds are direct derivatives from reptiles. We know, in fact, that these animals resemble each other in such essential particulars as to justify the grouping of them together in a single vertebrate section, the Sauropsidæ of Huxley. We can even trace, by aid of the palæontological record, some of the steps by which birds arose from their reptilian progenitors. And yet no definite hypothesis has been advanced as to how the scales of the reptile became the feathers of the bird, how the quadrupedal habit of the one became the bipedal habit of the other, or how the walking changed to the flying method of locomotion.

These questions we cannot now, and perhaps may never be able to, answer with the argument of facts. But if some probable mode by which such variations may have arisen can be suggested, the speculation will hardly be an empty one. All the great theories of science have simply the force of highly probable speculations, based on known facts; and lesser theories, if given the same basis, may prove equally desirable.

One of the most striking features in animal life is its tendency to spread outwards, functionally, in every possible direction, so as to occupy each field of nature in every advantageous manner. One-half of the animal world seeks to feed on the other half, while this second half seeks to escape being fed upon. This is one of the main elements of natural selection. Every change in organization that proves an advantage to the carnivorous animal in assailing his prey, is apt to be retained. Every change that aids his prey in escaping is likewise retained. Through this cause there have been contifiual variations, since every favorable change in the one class would prove injurious to the other class, unless met by an equal counter change.

In this long continued process of adaptation to circumstances, every advantage offered by water and land to their animal inhabitants, in overcoming their prey, or in escaping from their enemies, has been long since adopted, and an immense variety of animal forms has arisen in consequence. But the air also presents favorable conditions both for escape and pursuit, and the adaptation of animals to aerial flight is so obviously advantageous, that it must have arisen as soon as the developing organization of animal life, and the occurrence of the necessary terrestrial conditions, rendered it possible.

In considering the problem of how flight originated, it will be desirable to take up successively the three questions above given. First, how did scales become feathers? The three higher classes of vertebrate animals have each its peculiar dermal covering. The Reptile has its bony plates, or its scales, the Mammal its hairs, and the Bird its feathers. Scales, hairs, and feathers are alike in origin, and are but specialized forms of a similar epithelial outgrowth. Yet these three classes of animals seldom invade each other's province. No reptile has a hairy or feathery coating. If mammals and birds were evolved from reptilian progenitors, the change of scales into hairs and feathers forms one of the processes of this evolution, and should be explicable under the natural selection hypothesis.

Certainly reptiles never became feathered through the Lamarckian process. No effort to fly, however vigorous, could have converted the scale of the reptile into the feather of the bird. It would be useless for flight until it had become almost a perfect feather, and therefore there could be no moulding influence upon its intermediate stages. The rudimentary feather must have arisen under the pressure of some other influence, and its adaptation to flight must have been a secondary resultant.

If we ask, what is the rudimentary feather, we seem to find it in the hair. In the larger land birds, as the Ostrich, the feathers on some parts of the body are indistinguishable from hairs; and in the tails of flying-squirrels the hairs spread out in a manner that seems preliminary to a development into the feathery condition. We may begin by asking, then, through what process of natural selection did the scale develop into the hair?

In seeking to solve this problem we first ask, what advantage has the hair over the scale as a dermal covering? The only positive answer we can make to this is, that it has greater warmth. It enables the haired animals to endure degrees of cold which would be fatal to the scaled animals. This difference in covering has a marked effect on the lives of the two classes of animals. Through the wide possibilities of increase in length and thickness of their hairy coat, mammals can endure the

greatest extremes of winter temperature, while reptiles are strictly summer animals, those inhabiting the colder zones being forced to hibernate during the winter. Existing reptiles, then, have no need of a warmer covering than they possess. Their local ties and life habits render this sufficient to protect them from all the changes of temperature to which they are exposed during their period of activity. But if the possession of a hairy covering would have enabled the reptiles of the past to remain active throughout the whole year in cold climates, why was it not developed? The answer is that it would have been of no special advantage to them. They are otherwise unfitted for activity during the season of low temperature, and to adapt them to this condition, not only their outer covering needed to be modified, but their internal organization as well. This change in organization has taken place in many cases, and with it the development of a warmer covering than the reptilian coat. But the reptile, thus modified, has lost its reptilian character. It has, in the one case, with other less important changes, become a bird; in the other case, with other more important changes, it has become a mammal.

The change in internal organization referred to is that in the circulating system. The imperfect heart, the sack-like lung, and the half-ærated blood of the reptile have developed into the perfect heart, the unlike but widely-extended lungs, and the fully ærated blood of the mammal and the bird. The varying temperature of the reptile is exchanged for the unvarying temperature of his successors. The so-called cold-blooded reptile, with its insufficient oxygenating organs, is at a disadvantage as compared with the bird and the mammal, with their fully oxygenated blood.

To bodily activity is necessary an internal temperature sufficiently high to render the organic chemistry of the body active. In the temperature of the tropics, and the summer temperature of the extra tropical zones, all animals possess this temperature, and none are at a disadvantage in this particular. But the reptile depends directly on the solar heat for its temperature, the bird and the mammal do not. Thus when the temperature falls the internal temperature of the reptile similarly decreases, its organic chemical change declines in activity, it becomes sluggish in movement, unable to obtain food, and would perish but for the hibernating habit which is customary with it. But the bird and the mammal preserve the temperature essential to organic chemical activity. They continue, therefore, awake and energetic, and in a condition to obtain the necessary food-supply.

The reptile is essentially a tropical animal. Its organization unfits it for the extremes of extra tropical temperature, and it is active in the temperate and frigid zones only during the tropic heat of their summers, but conceals itself and continues torpid during the cold of their winters.

Birds and mammals are essentially adapted to a life in the colder zones. They must have originated in regions in which wintry cold, for some part of the year, replaced the summer heat. The reptilian circulation sufficed for the needs of animals bathed in a fixed degree of external heat, high enough to promote their bodily activity. But animals exposed to severe cold during any portion of the year must either hibernate during that period, or must gain an improved circulation. The heat which fails them without must be produced within, or their activity must cease.

This is what we must understand from the systems of circulation of the bird and the mammal. Their reptilian progenitors slowly gained more complex lungs with an increased ærating surface; the blood became more fully oxygenated; the arterial and venous blood became more completely separated in the chambers of the heart; and as a natural result the internal temperature increased. Such slight changes could not have been preserved and augmented unless of advantage. They would have been of no special advantage to the tropical animal. To the animal of the temperate zones they were decidedly advantageous, in enabling it to remain active during a greater portion of the year, and finally during the whole year, the internal stores of heat replacing the lost external stores when winter replaced summer.

But these internal stores must not only be produced, but must be retained. A heat-retaining covering is necessary to hinder the chilling effect of the wintry air. The reptilian scale is obviously not sufficient for this purpose. As the internal heat of the animal increased, and it was able to prolong its period of active life more and more into the cold season, some modification of the scale became necessary, so as to make it more efficient in retaining this internal heat. The scales may, from their points of origin, have grown out longitudinally, covering each other in successive layers, and thus forming a warmer and closer covering. Such a process of elongation, if accompanied by a narrowing of the individual points of origin, would, in time, convert the the scale into a hair. It is well known that they are capable of becoming so converted, by such an elongating outgrowth.

Thus the haired and feathered animals could not have arisen until the possibly general summer of early times was replaced by a double season of summer and winter in the extra tropical regions. But though thus of temperate origin, there was nothing to hinder their spreading both into the frigid and the tropic zones. Their improved circulation gave them an activity superior to that of the preceding reptilian rulers of the tropics, and they thus had an advantage in the life battle, which soon showed its effects. The giant reptiles disappeared and giant mammals took their place. Gradually the reptiles retreated before the march of the mammals. They sank to the ground, hid in holes, learned to creep, to squirm, to swim, while their mammalian successors proudly stalked over their conquered realm, the lords of the earth.

If this, through the advantage gained by adaptation to wintry cold, animals were evolved possessed of a perfect circulation, a fixed internal temperature, and a poorly conducting external covering of hair; and if these animals, through their improved powers, banished their reptilian predecessors, or forced them to retreat to the waters, the holes, and the dark recesses of the earth; it remains to consider the subsequent variations of these hair covered animals; or, at least, of the flying sections of these creatures.

The next question to be considered is that of the change from a quadrupedal to a bipedal habit of motion. There is only one true biped among the whole great class of mammals, namely, man. He is approached in this bipedal habit by the higher apes, and it is not difficult to understand how the specialization of limbs took place in the latter. It undoubtedly arose from the climbing habits of monkeys. The fore limbs became used as grasping organs, the hind limbs as supporting organs. As climbing monkeys increased in size, they must in many cases have moved by grasping upper branches with their hands, and supporting their feet on lower branches. This was an imperfect bipedal movement. Eventually some of them became too heavy to render a continual arboreal residence desirable. These came to spend the most of their lives upon the earth, as we find in the larger apes of the present day. But these apes are neither quadrupeds nor bipeds. The specialization of their limbs during a long arboreal residence has unfitted them for either mode of motion upon the ground, and they move along in an awkward and inefficient compromise between the two modes of motion. Evidently the method of progression of these animals is not a desirable one for a land residence. Natural selection must tend to make them full quadrupeds or full bipeds. Those of them which have recently changed their arboreal for a ground habitat, have not had time to change. Those which earlier descended to the earth have

evolved improved methods of progression. The most of them have returned to the quadrupedal condition, if we may conceive the four-footed baboons to have arisen in this manner. As to whether any of them have gained the perfected bipedal condition, it is perhaps best to make no assertion. Those who hold that man had an ape-like progenitor, must accept this view.

There are other mammals with partially bipedal habits. These compromise the jumping animals, the kangaroos, jerboas, etc. But in these cases there has been no specialization of the fore-limbs. They have simply become partly aborted. The bear also, through its plantigrade feet, and perhaps its climbing habit, has gained imperfect bipedal powers, and a grasping habit with its fore limbs. But there has been no specialization of these limbs. They continue true walking organs.

In the reptilian world other instances of bipedal habits present themselves, developed in still another manner.

The animals thus organized are all creatures of a vanished age—the huge Deinosaurian reptiles presented to us in the geological record. These creatures may have gained their specialization of form through the same cause, though not in the same manner, as the giraffe gained its special formation. Many of them lived by browsing on the foliage of trees. And these, instead of developing an elongated neck, like the giraffe, probably obtained their food by a partially climbing process. Their fore limbs clasped the tree trunk, while their weight rested on the hind limbs and the tail. In this manner they were able to reach the desired food.

A long continuance of such habits would produce, through selection, a specialization of the fore limbs. To become efficient organs for grasping tree trunks, they must have become inefficient walking organs. Through this specialization the fore limbs seem to have become small and comparatively weak, the hind limbs large and powerful. To look at the remains of these creatures now, as preserved for us in the rock strata, it seems as if a quadrupedal motion must have been very awkward and inefficient; while their habit of erecting themselves on their hind legs, may have rendered a bipedal motion easy and natural. Professor E. D. Cope says of them: "some have chiefly squatted, some leaped on their hind legs like the kangaroo, some stalked on erect legs like the great birds, with their small arms hanging uselessly by their sides." Yet when we consider the great size of these reptiles, which comprise the huge Iguanodon and Megalosaurus, the Hadrosaurus of our New Jersey marl, and other such gigantic creatures, we may well imagine that they presented an appearance widely different from that of any existing creatures. To see animals thirty feet in height and huge in proportion, to whom our elephant would be a mere pigmy, stalking about erect on their hind legs, would certainly be an astonishing spectacle. Yet such a view was very probably presented by that bizarre world of the past which time has swept away.

These Deinosaurian reptiles, with their peculiarities of structure, their hollow bones, and their three-toed feet, presented certain strong affinities to the great land birds of modern times. So close, indeed, that some have conjectured that these large wingless birds, such as the Ostrich, are direct descendants of the Deinosaurs. In this claim there are no powers of flight to be explained, yet the possession of feathers by the ostrich seems a fatal obstacle to the hypothesis. Feathers are a highly specialized form of dermal covering. They are specially adapted to purposes of flight, and we can imagine for them no other use which the less specialized hairs or scales would not have subserved. We are therefore disposed to conclude that any animals possessed of feathers must have gained them through powers of flight in themselves or their ancestors; and that the resemblances in organization above mentioned arose from similarity in modes of progression, and not from hereditary connection.

How, then, was the further step in the process taken? The primitive hairy covering being gained, how did hairs develop into feathers, how were the imperfect bipeds among land animals succeeded by the perfect bipeds among flying animals, and how did motion upon the earth develop into motion through the air? It certainly did not arise as a result of leaping habits. We cannot imagine the spring of a kangaroo as so advantageously aided by an accidental conformation of the fore limbs, as to produce a natural selection of this conformation. If these leaping animals habitually sought to assist their flight by a motion of the fore limbs, then any membraneous expansion or special thickness of hairy covering would be advantageous. But none of those now existing have such a habit, and without it their leap could never become a flight.

(*To be continued.*)

THE NEW COMPRESSED AIR LOCOMOTIVE.

On the 13th ultimo a trial of a new engine built by the Baldwin Works, Philadelphia, took place on the Second Avenue Railroad, the result of the trial being on the whole satisfactory. Compressed air as a motive power for railway engines has been repeatedly tried already in this country and in Europe. At Paris and Nantes the Mekarski Air Engine has at different times been used with more or less success, at Glasgow. Mr. Scott Moncrieff has labored perseveringly to demonstrate the superiority of compressed air over steam for locomotive purposes, while in June last year Col. Beaumont produced (in London) an engine which was thought at the time to have eclipsed its predecessors in point of efficiency and small working cost. The "success," however, of these engines has been so very undecided, and the advantages they presented in point of cleanliness, and absence of smoke and noise, have been so counterbalanced by the cost of compressing and storing the air, that as yet we have heard of no line of railroad or tramway being *successfully* worked by compressed air.

Comparing the data obtainable from these engines with the result of the late trial, we find a decided superiority in the efficiency of the American engine which possesses several new and important features, and is the result of long experience and study of the subject by the inventor and patentee, Mr. Thos. Hardie, the Pneumatic Company's Chief Engineer.

A short description of the engine and its trial may not be uninteresting to our readers. In length and weight it is as nearly as possible the same as an average Elevated Railroad engine, the part usually reserved for the boiler being in this case occupied by the receivers for containing the air, four in number and of unequal lengths, having an aggregate capacity of 460 cubic feet, in which air is stored at a pressure of 600 lbs. per square inch. Inside the cab is a small boiler (the consumption of coal in which is nominal) through which air from the receivers is passed before being allowed to enter the cylinders. An automatic throttle valve on the supply pipe of this boiler regulates the pressure at which the cold air enters the boiling water. The air being thus heated expands and the pressure is of course considerably augmented, and in this hot, moist condition it passes into the cylinders, having a far larger percentage of efficiency than if it were allowed to do so in a cold, dry condition. There is thus by this means a great saving in the quantity of air consumed. The system of drawing air from the reservoir at a low pressure and expanding it by heat until it attains a working pressure of from 100 to 130 lbs. per square inch is, we believe, entirely novel, and in this respect the engine differs altogether from Col. Beaumont's machine, in which air was admitted to the cylinders at its initial reservoir pressure—1000 lbs., and then quickly cut off.

In a former engine built by the Pneumatic Company

the air, instead of being heated by a small boiler, was made to pass through a tank which was supplied at intervals with boiling water and recharged as soon as the water cooled. The present arrangement is the result of experience derived from its predecessor.

The valve gear is simple and is fitted with a variable expansion valve under the control of the engineer, by which the cut-off can be varied from 1-10th to 5-8ths of the stroke. The link is worked by "crossed" eccentric rods, the effect of this being to prevent *any* opening of the parts when the reversing lever stands in the middle notch. By this arrangement the cylinders are, when necessary, converted into vacuum pumps and are utilized to operate the vacuum brakes attached to the cars. It has been found that when using the air expansively while running, *i. e.*, with a quick "cut-off," the expension is sometimes so rapid that towards the end of the stroke the pressure in the cylinders is less than the external atmosphere; to obviate the loss of power which would be caused by the vacuum thus created, valves are placed in the exhaust passages, which prevent any vacuum being formed. Another feature in the engine is the existence of a suction and delivery valve at each end of both cylinders, which render it possible when going down hill, or approaching a station, to convert the cylinders themselves into "compressors," by which the pressure in the reservoirs can be increased, thus utilizing the waste energy which is usually given off in friction against the brakes. This arrangement is so successful that no other brakes are required on the engine. There are several minor points in the construction of the machine which it is not necessary to mention here; we may, however, say in conclusion that the engine has been carefully studied in every detail.

At the trial, the engine started from 128th street with a pressure in the reservoirs of 580 lbs. per inch, and travelled as far as 42nd street, a distance of 4½ miles or thereabouts, stopping at every station, and loaded with three cars containing about 50 people. At 42nd street some switching was done, and the engine then returned to the starting place, reaching 128th street with a remaining pressure of 115 lbs.

These figures show that the train would have run from Harlem to South Ferry, the entire route of the Elevated Road. But in making any practical calculation, it must be remembered that four cars are often used instead of three, and that these four cars would often be loaded with 600 persons. This probably implies an additional weight of about thirty tons to that placed behind the Pheumatic Engine during the recent experiment.

The company must be congratulated on building a most successful engine.

UNIVERSAL ENERGY OF LIGHT.*

By Pliny Earle Chase, LL. D.,

Professor of Philosophy in Haverford College.

Force is generally regarded as a function of mass and velocity. The greatest known velocities which can be produced by central forces are wave velocities. The greatest known wave-velocity which appears to be universally diffused is the velocity of light.

Let $v\lambda$ = velocity of light; v_0=circular-orbital velocity at sun's surface $=\sqrt{g_0 r_0}$; v_3=Earth's mean orbital velocity; v_r = velocity of Sun's equatorial rotation; u_3= potential velocity of water at 0°C. $=\sqrt{2g \times 100 \times 1389.6}$ ft.; u_4 = potential velocity of water at its maximum density; u_5=potential velocity of water-evaporation = $\sqrt{2g \times 536.37 \times 1389.6}$ ft.; m_0, m_3, m_5, m_6=masses of Sun, Earth, Jupiter, Saturn; h_0=Earth's semi-axis major; h_2=height of mean oscillatory projection due to the combining energy of H_2O; t_a=time of acquiring circular-orbital velocity at Laplace's limit of synchronous rotation and revolution = time of rotation $\div 2\pi$; t_n = time of acquiring "nascent" or dissociative velocity at nucleal surface = ½ time of rotation $= \pi t_a$; χ =Weber's electrochemical unit; μ=electromagnetic unit; ρ_0=total magnetic force; ρ_3=terrestrial magnetic force; t_0=present value of t_n at Sun's surface; g_0=gravitating acceleration at sun's surface.

The simplicity of the relations of the universal velocity $v\lambda$ to other physical velocities, is shown in the following equations:

$$1.\quad \frac{v\lambda}{u_3} = \frac{h_o}{h_2} = \frac{m_o}{m_3} = \frac{t_n^2}{t_a} \cdot \sqrt{\frac{\rho_0}{\rho_3}}$$

$$2.\quad \frac{v\lambda}{v_0} = \frac{v^o}{u_4} \cdot \sqrt{2} = \frac{t_n}{t_a} \cdot \frac{v_0}{v_r}$$

$$3.\quad \frac{v\lambda}{g_0} = t_0$$

$$4.\quad \frac{v\lambda}{v_3} = \sqrt{\frac{m_0 m_5}{m_3}} = \frac{m_o t_a}{m_3 t_n} \cdot \sqrt{\frac{\mu}{\chi}}$$

$$5.\quad \frac{v_5}{u_5} = \frac{3^4 m_0}{2 m_6} = \frac{5 \times 3^3 m_0}{m_5}$$

The velocity of solar atmospheric rotation, at the secular mean centre of gravity of the solar system, is also equivalent to u_5.

The law of conservation of areas, in an expanding or contracting nucleus, requires that g_0 should vary inversely as t_0. Equation 3 should, therefore, hold good for all stages of solar existence, past, present and future.

The values which satisfy the above equations are: m_0=328470 m_3; h_0=92476500 miles; $v\lambda$ = 185760 miles; v_3=18.412 miles; u_3=2986 ft.; u_5=6916.2 ft.

The following table shows the accordance between theoretical and observed values:

	Theoretical.	Observed.
Boiling point of water........	99°.18	100°
Combining heat of H_2O......	69319	67616 to 69584*
ρ_6........................	140.65	140 lb. pr. sq. in.
Maximum density of water....	4°.19	3°.33 to 4°.85
v_3........................	18.31	18.41
Latent heat of steam..........	536°.374	536°.385 †
$\chi \div \mu$........................	107.38	106.67

The velocity of light is also a factor of electromotive energy. Weber and Kohlrausch demonstrated this fact by measuring quantity of electricity; Thomson and Maxwell, by measuring electromotive force; Ayrton and Perry, by measuring electrostatic capacity.

Perhaps the most interesting of the above indications is the past, present and future equivalence of Sun's "nascent" velocity to the velocity of light; the sum of the cyclical reactions of solar superficial gravitation against the actions of external gravitation, during each half-rotation, being *equivalent to the velocity of light.*

* Read before the American Association for the Advancement of Science, August, 1881.

The Metal Actinium, by J. L. Phipson. — The author stated that he had been able to separate a new element from the pigment zinc-white. The oxide of the new element is said to be slightly soluble in caustic soda, and is soluble in ammonia and ammoniacal salts. Its color is uninfluenced by exposure to light. The sulphide of actinium is described as a pale yellow canary-colored substance; it is insoluble in ammonium sulphide, is soluble in acetic acid, and becomes darker on exposure to the air.—*British Association*, 1881.

* The mean of six estimates, cited by Naumann, is 68886.

† This is the mean of four estimates, viz.: Favre and Silbermann, 535°.77; Andrews, 535°.90; Regnault, 536°.67; Tyndall, 537°.20.

THE ELECTRIC EXPOSITION.

THE ELECTRIC LIGHT.

THE GENERATORS.

The Palace of Industry offers to the world a unique collection of apparatus for producing the electric light.

The problem seems to be solved, if we can judge by the multiplicity of the solutions proposed; we shall see in the sequel that it is not yet completely solved, but this same multiplicity sets out well in relief the incomparable elasticity of electricity applied to light, and shows that it is possible from this day to introduce the electric light in all applications; by giving to it, in each particular case, the special qualities which assure its superiority over other systems, under the limitation of two conditions which we shall treat separately: economy and the distribution of electricity.

We shall rapidly examine the processes of generating electricity for the special purpose of light; a following article will be devoted to lights, regulators, and incandescent lamps.

Three methods are known of generating electricity in quantity sufficient for the electric light: hydro-electric piles, thermo-electric piles, and electro-dynamic machines.

In this Exposition there is no thermo-electric pile applied to light. Some years ago we had hoped that M. Clamond would have continued his work in thermo-electricity, but he has, unfortunately, done nothing, and we can only express our regrets in this respect.

The piles intended for the electric light are represented at the Exposition but by two types: the pile of M. Cloris Baudet and that of M. Tommasi.

The pile of M. Cloris Baudet is a pile with bichromate of potash; with five elements, of which, according to the inventor, only one a day needs to be replaced, the pile can sustain a voltaic arc, with carbons of three millimetres, whose power is about 15 Carcel burners.

The pile of M. Tommasi is a Bunsen pile. The improvements which have been applied to it do not appear fortunate to us, and we do not yet know of an application where it serves in a practical manner for domestic usage, as the prospectus pompously announces it. It is only necessary to approach for a moment the exposition of M. Tommasi, on the ground floor, in order to *feel*—in the proper and in the figurative sense—that the vapor of liberated hypoazotic acid makes the pile absolutely inapplicable to the usage for which it was primitively intended.

The instalment of this extensive apparatus and the manipulation which it requires, are, on the other hand, out of proportion with the result obtained.

Leaving aside these two separate cases, and the electric accumulators, to which we shall return, we can say that the electric light of the Palace is exclusively obtained from mechanical generators of electricity.

The motors which drive the electric machines demand a special study. They are of two kinds: steam and gas. The Exposition contains several interesting types of motors especially intended to drive the electro-dynamic machines; we will cite among others the Brotherhood motor and the Dolgoronki rotative system motor. In these systems of motors of great rapidity, the driving shaft of the electric machine forms the prolongation of that of the motor; thus all intermediate transmission is done away with, but simplicity is purchased, it must be admitted, by a greater expenditure of steam.

The largest part of the motive force is produced by fixed, half-fixed, or movable machines varying from five to 150 horse-power. We do not say that the latter are most economic, because they consume, with equal power, much less of carbon, and because they have also a more regular motion—an essential condition for a good electric light.

We will notice more particularly two types of these powerful machines: one, exhibited by MM. Carels, is an expansion-engine, in a single cylinder; the other, exhibited by MM. Weyher and Richemond, belongs to the *compound* type, that is to say, with a compound cylinder; the expansion is made successively in the two cylinders. Figure 7 represents this motor driving the electric generators with alternate currents of Gramme and Lambotte-Lachaussée. The advantage of expansion-engines, either with one cylinder or with two conjugate cylinders, is great, for as soon as 100 horse-power is reached, less than a kilogramme of carbon is consumed each hour for every horse-power.

A large number of gas motors are also used to produce motive force. Most of them belong to the Otto type; they vary from 1 to 50 horse-power. The gas motors are practical enough, and also, up to a certain point, economical, when they serve to produce a light for a few hours each day, and in an intermittent manner.

For the same quantity of gas consumed, we can obtain 10 or 15 times more light by passing through the medium of the motor, the electric generator and the lamp, than by directly burning the gas in the ordinary burners, all in producing 100 or 150 times less heat in the light.

It is by an 8 horse-power gas motor that M. Jaspar drives the three Gramme machines which feed the three regulators placed in hall XV; a 50 horse-power gas motor also serves to light a part of the Palace.

We now come to the machines. We can first divide them, according to the generally admitted classification, into magneto-electric machines, of which the inductors are magnets, and into dynamo-electric machines, of which the inductors are electro-magnets.

The Exposition contains only two kinds of magneto-electric machines, the old type of Alliance and the machine of M. de Méritens. These machines are applied to beacon lights, and they also feed several Berjot regulators. Without wishing to condemn the electro-magnetic machines, it seems to be established, even by the Exposition, that their industrial reign has terminated. It must not be concluded by this that the electro-magnetic machines are worthless, but only that they are not industrial, in the practical sense of the word; that is to say, the power being equal, they are heavier, more expensive, and more encumbering than the electro-dynamic machines which are almost universally employed to-day.

In light-houses, where the question of capital engaged plays but a secondary role, the preference has been given to magneto-electric machines which, in consequence of the masses put in motion, give a greater relative regularity than electro-dynamic machines.

Magneto-electric machines, applied to light, are all with alternative currents.

Dynamo-electric machines are divided into two classes, according as they furnish alternative or continuous currents.

Machines with continuous currents.—The machines with continuous currents are suited to illumination by the voltaic arc and by incandescence. When they supply a single light they are mounted as represented in figure 1:

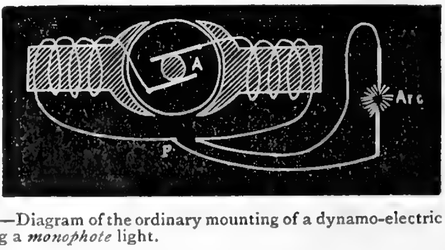

FIG. 1.—Diagram of the ordinary mounting of a dynamo-electric machine supplying a *monophote* light.

(A) an *inducted* Gramme ring, or Siemens bobbin turning between the two poles of an inductor II′, sustained

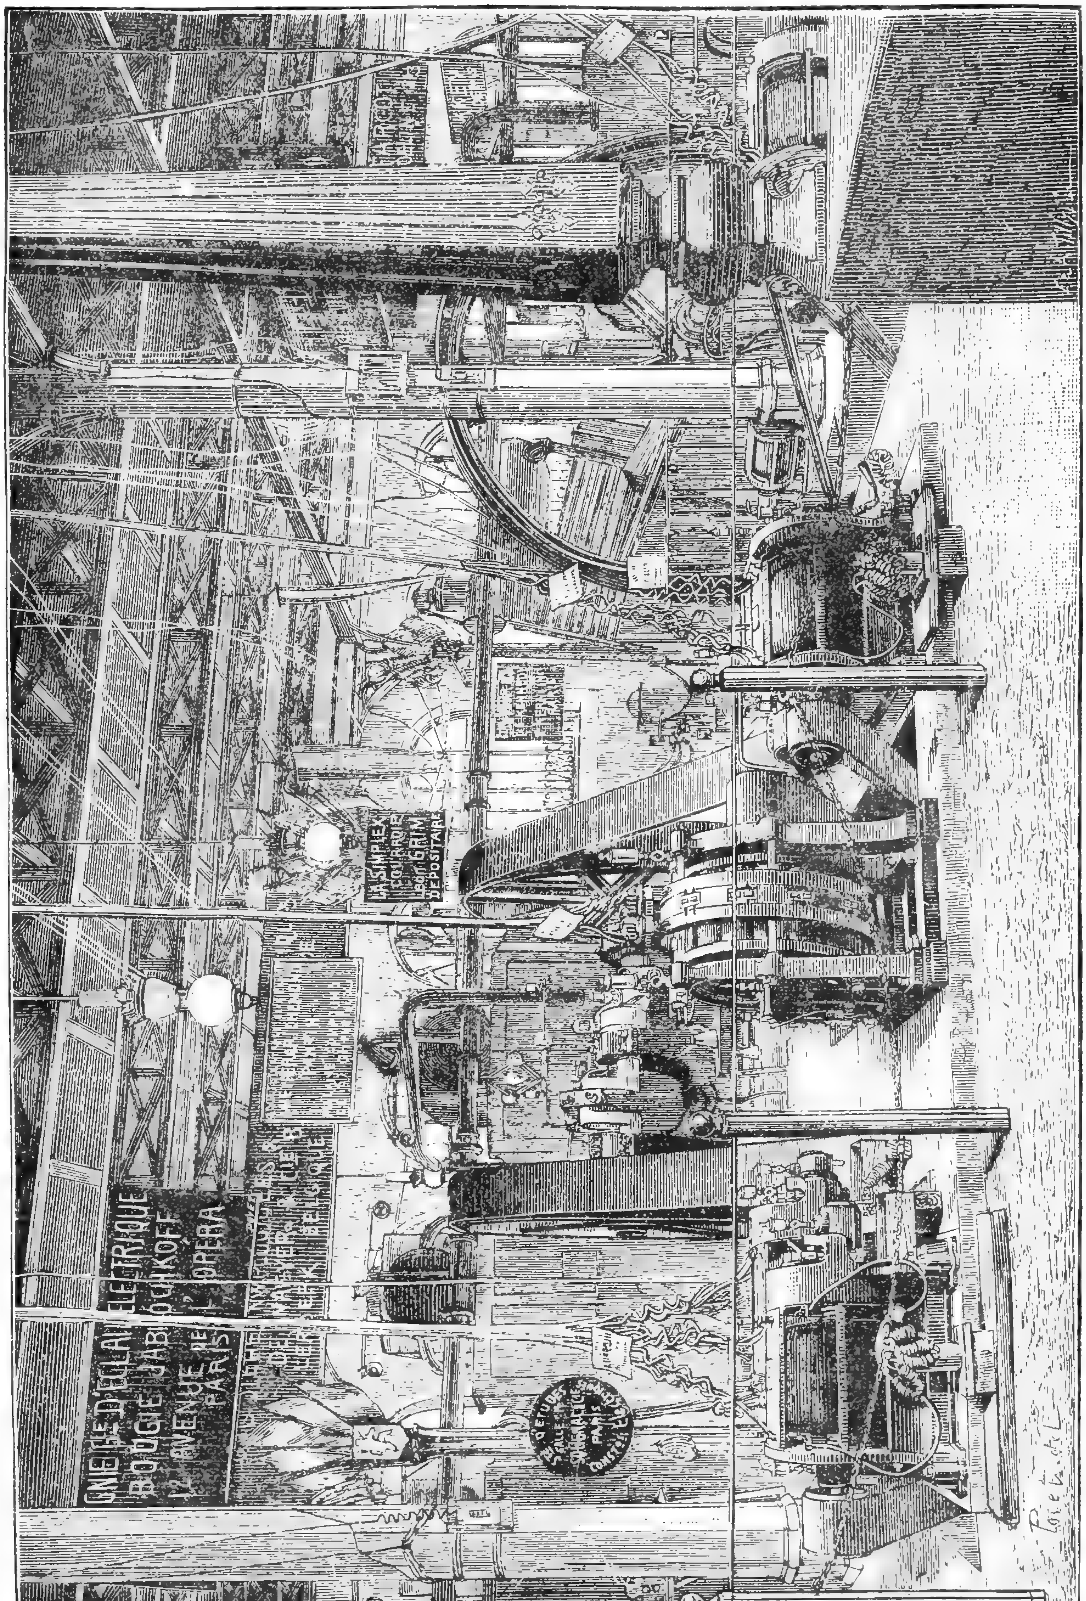

Fig. 7.—The Electric Generators of the Palace of Industry. International Exposition of Electricity. (After a photograph.)

by the current from the bobbin, which also traverses the voltaic arc.

This is the mounting adopted to-day in most of the *monophote* regulators.

On examining this system a little closer, we see that it presents a serious inconvenience. When the arc is lengthened, the intensity of the current diminishes, for two reasons, first, in consequence of the increase of resistance of the current; second, because this enfeeblement corresponds to an enfeeblement in the same way of the power of the inductors, and, as a result, of the electro-motive force of the machine, since this electro-motive force is itself a function of the power of the inductors. If the arc is made shorter, the reverse phenomenon results. This is a poor condition of regulation, since the increase of power of the machine corresponds to a shortening of the arc, and inversely, the diminution of the electro-motive force, corresponds to the lengthening of the arc. The production of the machine is, then in a contrary direction to the needs of the arc, and it is certainly one of the great reasons for which this mounting demands, in order to work well, sufficiently sensible regulators. They avoid this inconvenience by several methods.

The first consists of arranging the inductors *by derivation;* this arrangement, conceived by Wheatstone in 1866, has not yet received many practical applications. M. Siemens, of London, is studying it at the present time and we shall find, by and by, an application of it in Edison's machine.

The second method, universally employed in the machines with alternative currents and which is commencing to spread in somewhat important applications where the lights have continuous currents, consists of charging the inductors of a series of machines by a special machine. Diagram 2 represents this arrangement. The arcs 1, 2, 3, 4 are bound to the brooms of the inducted bobbins A_1, A_2, A_3, &c., of the respective machines.

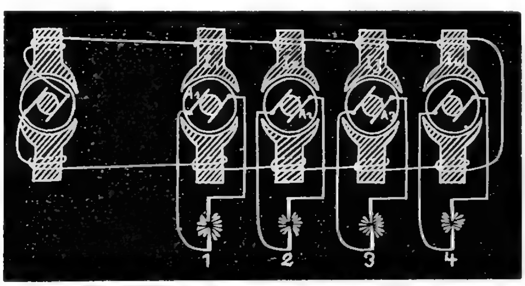

FIG. 2.—MACHINES charged by a special machine. Four machines with continuous currents supplying four regulators with a voltaic arc. The inductors are supplied by a separate generator.

By this means a constant magnetic field is assured, whose power depends only on the velocity of the generator; as a result, the electro-motive force is then absolutely independent of the variations of resistance of the voltaic arc which it sustains. Thus is found the advantage of the magneto-electric machines whose magnetic field is constant, but we gain the additional advantage of having the most powerful machines, and of being able to vary the production of these machines by regulating at will the rapidity of the generator. There is in the French section a series of machines, arranged according to this principle.

Such are the arrangements employed with the *monophote* apparatus.

When a single machine is to supply several lights the arrangements change, and the lamps can be grouped in different ways.

When they are all branched over two general conductors starting from the limits of the machine, the lights are said to be established in *derivation*, in *multiple* or in *quantity* (fig. 3). When the lights are arranged, one following the other, on one and the same conductor, they are said to be mounted in *tension*, in *series*, or in *circuit* (fig. 4).

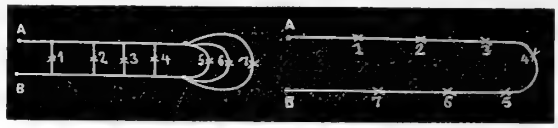

FIG. 3.—Mounting in derivation, in multiple arc, or in quantity.

The mounting in multiple arc requires volume, that in circuit requires especially pressure or tension. The one or the other is applied according to the case.

Sometimes even several *derivations* are established, each carrying two, three, ten, etc., lamps in *circuit*. It is the case, for example, of the lamps of the Swan system of incandescence, fed by Brush machines.

The reasons of these multiple combinations are easy to comprehend. If the electric source of the machine we are arranging has more electro-motive force than that exacted by a single light, it would be an advantage to group several lights on the same circuit; when, on the contrary, the volume of current which the machine can produce is greater than that which is necessitated by a single light, we arrange them in *quantity* or in *derivation*. The Edison and Maxim systems of incandescence are monted in quantity over the source. They differ only, leaving on one side for a moment the lamp itself, in the manner of regulating the current.

In the Maxim system, the mounting of which is represented in figure 5, a separate generator supplies a series of machines, whose brooms are set between them in quantity, that is to say, by poles of the same name. All the lamps are branched over the conductors in derivation. The regulating obtains, by charging *automatically* the setting of the brooms of the generator, which reacts on the power of the current of the generator, and, consequently, on that of the inductor.

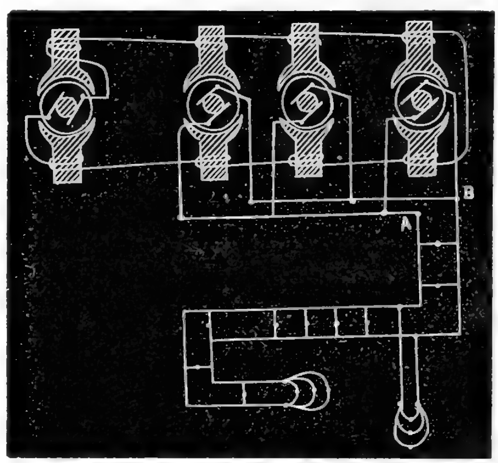

FIG. 5.—Mounting of the Maxim machines.

In the Edison system, the lamps are also mounted in derivation, but the inductors II[1] (fig. 6) are placed on a derived circuit led to the brooms of the machine in B and B[1]. The power of the inductors is regulated, and consequently that of the machine, by manœuvring by hand a rheostat which serves to increase or diminish the resistance of the generating current, and consequently the electro-motive force of the machine. It is the Wheatstone mounting.

Machines with Alternative Currents.—The employment of alternative currents steps in with electric candles, because the two carbons must be equally consumed. Certain regulators also act with the alternative currents. The equal consuming of the carbon limits the displacement of the luminous point, which is often an advantage. All

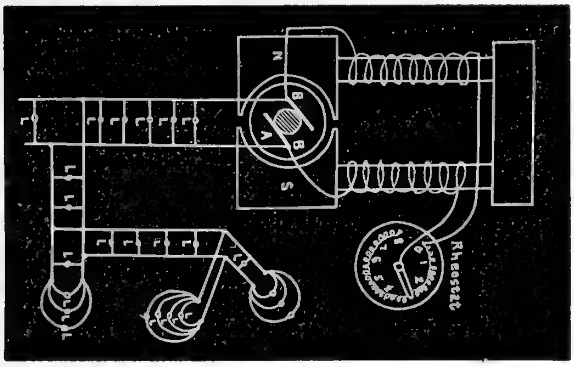

FIG. 6.—Mounting of the Edison machine.

the lights with alternate currents produce a peculiar humming owing to the nature of the currents which traverse them; this humming is often sufficient to forbid their use in places where it is necessary to have comparative silence.

The ensemble of a system of lighting by dynamo-electric machines, with alternative currents always includes two distinct machines: a machine with continuous currents or *generator*, and a machine with alternate currents, or *distributor*. This distributor consists of a variable number of circuits. Figure 8, simplified to show the

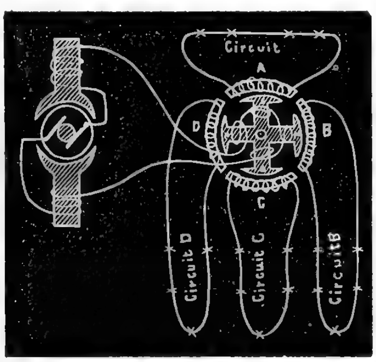

FIG. 8.—Mounting of a machine with alternate currents for candles.

principle, represents the mounting of a Gramme machine with alternative currents, supplying twenty Jablochkoff candles, arranged on four circuits of five candles each. The *movable* inductor bears eight poles, the successive ones with contrary names, in place of four. The generator can be of any system, whatever; it is only necessary to have a continuous current.

The power is regulated by the reciprocal velocities of the generator and the distributor. Sometimes the two machines mounted on the same axis turn with the same velocity, forming in reality but one. These machines are *self-generators*. In this case, we can no longer regulate the generator by its velocity, since this velocity is conjointly acting with the distributor; the regulating is then effected by the resistances introduced in the generating circuit. We have supposed the inducted bobbins *fixed* and the inductors *movable*. It is the case with the Lontin, Gramme, and Lambotte-Lachaussée machines. At other times, as in the Wilde and Siemens machines with alternate currents, the inducted bobbin is movable and the inductors fixed, but nothing is changed for this in the general principle. We see from these several examples that the art of the engineer allied with the science of the experimentalist, offers some resources to convert mechanical energy into electric energy and then to distribute it to the lights which utilize it.

MICROSCOPISTS.

The first meeting of the State Microscopical Society of Illinois, for the present season was held at the rooms of the Society, in the Academy of Sciences, Friday evening October 14, the President, Dr. Lester Curtis in the chair.

After the transaction of routine business, Mr. Stuart described the microscopical structure of some vegetable drugs. The subject is not suitable for abstraction, and requires illustrations to be useful.

His paper was followed by one by Dr. Curtis, describing a new stand made for him by Bulloch. This stand presented some novel features, among the most striking was a mechanical stage of extreme thinness, admitting light at an angle of 160°. The movements were effected by a double pinion above the stage, an arrangement pronounced by those familiar with the operation of the contrivance, as exceedingly useful and convenient.

The stand excited considerable interest, as did also a right angled camera lucida of German manufacture which was adapted to it, the superiority of which over the ordinary form was so marked as to be unmistakable on trying it, even under the disadvantages of a crowded room and constant jar. After a discussion of the papers, the meeting adjourned.

E. B. STUART.
Secretary pro tem.

PERMANGANATE OF POTASH USED AS AN ANTIDOTE TO THE POISON OF SERPENTS.

Very interesting experiments have been made in Brazil, by M. de Lacerda, which have established the fact that permanganate of potash is one of the most energetic antidotes to the venom of snakes. M. de Lacerda has addressed a memorial of his important works to the Academy of Sciences (meeting of the 12th of September, 1881).

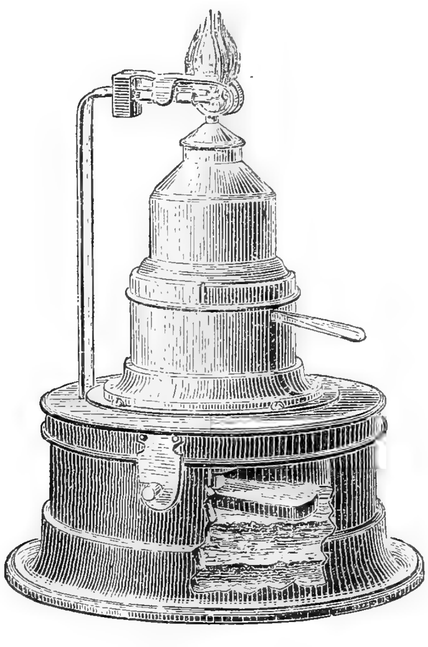
The result of these researches is really astonishing; thus in a series of experiments, frequently renewed, of injecting the active venom of *boshrops*, diluted with distilled water, in the cellular tissues, or the veins of dogs, M. de Lacerda found that the permanganate of potash was able *to stop completely the manifestation of local injuries from the venom*. Yet the same poison, which had served for these experiments, being injected without antidote into other dogs, always produced great local tumefactions, with loss of substance and destruction of tissue.

These very remarkable results have been stated on various occasions, not only by the Emperor of Brazil, who assisted at these experiments, but also by physicians, professors of faculties, and members of the diplomatic corps.

MEANS OF DETECTING THE SOPHISTICATIONS OF OLIVE OIL WITH OTHER OILS.—The oils employed at Marseille for the adulteration of olive oil are the oils of colza, sesame, cotton, and earth-nuts, Colza oil is detected by means of the sulphur which it contains; 10 grms. of the sample are saponified in a glass capsule with an alcoholic solution of caustic alkali free from sulphides. The mixture is stirred with a silver spoon, and if this is blackened, colza, or at least some cruciferous, oil is present. For the detection of the oil of sesame a little sugar is added to hydrochloric acid at 30° (Baume?) which is then mixed with an equal bulk of the oil in question. The mixture is well shaken up, and the least traces of oil of sesame are indicated by a red coloration. For the detection of cotton-seed oil there is added to the sample an equal volume of nitric acid at 40°. On stirring the mixture takes a coffee color. The detection of oil of earth-nuts is less simple. The sample is saponified with an alcoholic solution of potash, the soap separated as completely as possible, heated to expel the alcohol, and treated with enough hydrochloric acid to neutralize the alkali. The supernatant fatty acid—arachidic acid—is collected and dissolved in boiling alcohol, from which it separates in a characteristic white nacreous form.

ELECTRIC LIGHTER OF M. DESRUELLES.

This is a small apparatus, simple and practical, which will certainly be very highly appreciated by smokers and, in general, by all persons who are often in need of fire or light. It is one of the most direct applications of the drying of piles of all the systems by the process of M. Desruelles. This process consists of introducing in the piles, in the place of liquid, a kind of amianthus sponge that is afterwards filled with acid or some suitable solution. We thus gain by having a pile *dry* to some degree, which can be removed, displaced, or reversed without the liquid pouring out; this has its advantage for movable machines, such as portable lamps, piles for bells on board of ships, railroads, etc. The introduction of this inert substance diminishes the volume of the liquid; without saying that the electromotive force of the pile is not at all affected, its interior resistance is increased. This is of no importance in the case which we are now considering. The lamp consists of a small round box of wood, in which the pile is placed; over this box is placed a small lamp with oil; a platinum spiral in juxtaposition to the wick serves to produce the light.



The pile is an element to the bichromate of potash, in which the liquid is replaced by a kind of amianthus saturated with a bichromatic solution similar to that of the pile jar.

The zinc is hung from a small lever which it is only necessary to touch lightly in order to bring the zinc in contact with the sponge; the circuit is then formed, the zinc is attacked, and the current produced traverses the spiral, which reddens and inflames the oil. The pile once charged will serve for several hundred lightings. When the spiral no longer becomes red hot, the sponge must be replaced—a very simple operation. When the small lever is not pressed upon, the zinc is raised and kept thus from the action of the liquid which the sponge of amianthus absorbs. M. Desruelles constructed on the same principle a lighter to gas burners, in which the pile is placed at the extremity of an arm which is long or short, according to the height of the burner. This small domestic apparatus can be seen at the Electrical Exposition, where its practical working is shown.

INTERNATIONAL CONGRESS OF ELECTRICIANS.—Professor G. F. Barker, in a letter to the *American Journal of Science* says:

The exhibition as a whole has been a decided success. It has brought together an immense mass of highly interesting material. There are in all something over 1500 exhibitors, of which one half are French, 155 Belgian, 115 English, 114 German, 81 Italian, 72 American, 39 Austrian, 32 Russian, 21 Swedish, 13 Swiss, 17 Spanish, 13 Norwegian, 11 Dutch, 5 Danish, and 2 Japanese. Of decided novelties, there are more in the United States section than in any other. Edison has made a wonderful exhibition of his inventions, and his rooms are thronged continually. The principle discovered by him that an electric current varies friction, the so-called motograph principle, together with the applications of it practically, are beautifully illustrated. The principle of the varying resistance of bodies which imperfectly conduct, whenthey are subjected to pressure, a principle which he was the first to investigate and to apply, is exhibited in a large series of instruments, one set of which traces the progress of development of the carbon telephone. The system of incandescent lighting which he has perfected is shown in all its details, from the unique dynamo machine of low resistance and high electromotive force, the street conductors with their connections, safety-catches, expansion-caps, etc., the ingenious meter and the house conductors with their incombustible covering, to the fixtures with double conductors and safety catches, and lastly to the incandescent lamp itself. Dolbear exhibits a new electro-static telephone which performs admirably and which consists simply of two thin metal plates, connected to the secondary wire by an induction coil. They are oppositely charged by the coil and so attract each other. Gray's harmonic multiple telegraph is in successful operation and Bell's original photophone is also exhibited. The most original thing exhibited in the French section is the secondary battery: Planté exhibits several forms of it, Faure shows the improvement which he made by covering the plates with minium, and lastly Meritens is working a still newer form, in which only lead plates are used, but a large number of them are put in a small space. In the historical line the collection in the exhibition is unrivaled. The pile of Volta, the electroscopes of Galvani, the thermopiles of Nobili and Melloni, the electro-magnetic induction ring of Faraday, the first magneto-machine of Pixii, the rheostats and telegraphs of Wheatstone, the telegraphs of Sœmmering, of Steinheil and of Gauss and Weber, the continuous current-machine of Pacimotti, the electro-thermic and electro-motor apparatus of Becquerel, the electro-capillary apparatus of Lippmann; all these and many more are here collected. And as for arc lights, the exhibition at night is like day. The Brush machine and light are in great favor. A large lamp of this sort just put up has carbons two inches in diameter, and is claimed to give a light of 80,000 candles.

BOOKS RECEIVED.

A TREATISE ON THE METHOD OF GOVERNMENT SURVEY, with complete Mathematical, Astronomical and Practical Instructions. By SHOBAL V. CLEVENGER. Second Edition, revised. D. Van Nostrand, 23 Murray street, New York.

This excellent treatise will be found of the greatest value to all engaged in government land surveying, and appears to surpass all its predecessors in its completeness and adaptability for practical work. Dr. Clevenger is one of our most esteemed contributors, and our readers are aware of the thorough nature of all literary productions which proceed from his pen. The present treatise on government land survey is exhaustive of the subject, and has been accepted by the highest authorities as an authoritive manual.

The angle of position and the distance of the satellite, p and s, will be computed by the formulæ

$$s \sin p = \frac{a}{\rho} f \sin (F + u)$$

$$s \cos p = \frac{a}{\rho} \,.\, g \sin (G + u),$$

where ρ is geocentric distance of Mars. The values of a, and of μ, the mean distances and the mean daily motions of the satellites are as follows:

Phobos.	Deimos.
$a = 12''9531$	$a = 32''3541$
$\mu = 1128°8405$	$\mu = 285°1632$

The quantity u for each satellite is given for the corresponding dates in the columns u_1 and u_2. For elongations the value of u is given by the equation

$$\text{tang } 2u = - \frac{f^2 \sin 2F + g^2 \sin 2G}{f^2 \cos 2F + g^2 \cos 2G}.$$

Thus for Dec. 20, $u = 325°83$ at the elongation, and in the case of Deimos $s = 53\ 7$. Near the conjunctions this satellite passes within $2''5$ of the centre of the planet, and the apparent ellipse will be very eccentric. Calling the brightness of the satellites unity on October 1, 1877, the brightness of the next opposition will be as follows:

1881 Nov. 16 brightness = 0.303
Dec. 14 " = 0.399
1882 Jan. 13 " = 0.330

The brightness of the satellites on November 16 will be a little greater than when they were last observed with the 15-inch refractor of the Harvard College Observatory.

On account of the greater distances of the planet from the Earth and Sun, these satellites will be faint next December, but as the planet will be in declination + 26°, they will be within the reach of several large telescopes, and it is possible that a good series of observations may be obtained. The elongation will occur in the angles of position 68° and 248° nearly, and the satellites should be looked for carefully at such times.

After the next opposition I hope to unite the observations of 1877, 1879 and 1881 in a new determination of the orbtis.

U. S. Naval Observatory, Washington, *June* 22, 1881.

The absorption of ultra-violet rays by certain media is being investigated by M. De Chardonnet. One method adopted is to direct a beam through a liquid in a trough with parallel glass or quartz sides, to Poitevin's photochromic paper (which indicates by change of tint, the presence of actinic rays). In a second method, a solar beam from a heliostat is sent through a slit, an objective of quartz and Iceland spar, and a prism of the spar, to a photographic plate or fluorescent screen; then a trough half filled with liquid is put before the slit. The author finds that the liquid circulating in plants, or impregnating roots and fruits have all an avidity for chemical rays. Fluorescence does not seem to be directly related to intensity of actinic absorption; thus decoction of radish absorbs less than decoction of potatoes, yet the former is without the property, while the latter is not. White wine is weakly fluorescent; red wine does not fluoresce. Of the few animal liquids examined, blood is found a powerful absorbent; but the aqueous humour of a calf's eye, and the albumen of eggs, have no action on chemical rays. Distilled water, alcohol, sulphuric ether, collodion, and solution of cane sugar are also inactive. Gelatine intercepts all the chemical rays, and it is sensibly fluorescent.

A PAPER on the "Electrical Resistance and the Coefficient of Expansion of Incandescent Platinum," by E. L. Nichols, Ph.D., was read at the Cincinnati Meeting of the American Association for the Advancement of Science, August, 1881, fully reported in *Amer. Jour. Science*, November. In his discussion of the subject, the author after showing the discrepancies in the formulæ of resistances as obtained by Siemens, Benoit, Matthiesen, and other physicists, draws the following conclusions: —

1st. The formulæ in question are based for the most part upon unwarrantable suppositions, such as the constancy of the specific heat of copper and of platinum; the constancy of the coefficient of expansion of the latter metal, and upon the accuracy of certain very doubtful values for the boiling points of zinc, cadmium, etc.

2d. That, aside from the inaccuracy of those data, the varying resistance of different specimens of platinum renders any formula for the calculation of temperature of that metal from its electric resistance applicable only to the identical wire for which the law of change of resistance with the temperature has been determined.

3d. That from the data at command we are not in position to calculate the temperature of an incandescent platinum wire from its change of resistance, nor from its length, nor indeed in any other manner, further than to express the temperature in terms of the length or the resistance of the wire.

4th. That, owing to the great variations shown by different specimens of platinum as regards its resistance, the determination of the expansion of the wire is to be preferred, whenever practicable, to the measurement of its conductivity.

CORRESPONDENCE.

The Editor does not hold himself responsible for opinions expressed by his correspondents. No notice is taken of anonymous communications.]

To the Editor of "SCIENCE."

Dr. Rogers seems again to misunderstand. It was not his quotation from Faraday that, was objected to, but the use apparently made of it to support his strange "questioning of the dogma that 'gravity acts in versely as the square of the distance,' on the ground that if that force is weakened by the earth's being removed to aphelion, it could not again bring back the body to perihelion." Any attempt to sustain that position by the authority of Faraday must certainly be a failure. Your correspondent seems not to distinguish between the definition of the force of gravitation, to which Faraday pertinently objected, and the law of gravitating action to which I particularly referred, and concerning which Faraday says, in the sentence immediately preceding that quoted by your correspondent, "It will not be imagined for a moment that I am opposed to what may be called the law of gravitating action, that is, the law by which all the known effects of gravity are governed:"—the very "dogma" your correspondent assumed to question!

GEO. B. MERRIMAN.

EDISON'S METHOD OF PRESERVING ORGANIC SUBSTANCES.

In a recent number of this JOURNAL,* we published a report by Mr. Otto Hehner, an official analyist of London, England, who had endeavored to trace the cause of the gastric disturbances, which were traceable in persons who had consumed preserved articles of food put up in tin cases. This poisoning had been attributed by some to traces of lead dissolved from the solder with which the tins were closed, but Mr. Hehner, although admitting the occasional presence of lead in such cases, found on a careful analysis of both vegetable and animal foods thus prepared in tin cases, that the trouble was caused by tin.

With one exception he found that the whole of the samples contained more or less tin, many to such an extent that abundant reactions could be obtained from two or three grammes of the vegetable substances; whilst of the animal foods one of the soups contained thirty-five milligrammes, one of the condensed milks eight milligrammes, and oysters forty-five milligrammes of tin to the pound.

In reply to the question whether tin when thus taken up in the system was injurious or not, he states that as forensic literature does not furnish a positive and satisfactory reply, he endeavored to settle the question by making a few experiments.

These experiments which will be found on page 507 of this JOURNAL, produced results which caused him to draw the following conclusions: "it plainly follows that while stannic compounds are not injurious in the doses given, tin in the stannous condition, is a virulent irritant poison."

*" SCIENCE," No. 69, October 22, 1881.

These facts induced Mr. Hehner to demand some other and improved method of packing preserved food other than by the use of tin cases.

A remedy appears to hand at a most opportune moment. In the Patent office reports for October 18, last, we find that Mr. Edison has invented a method of preserving articles of food in glass vessels from which the air has been exhausted and a high vacuum produced. The glass vessel is then hermetically closed by sealing off the channel to the air pump, the envelope produced being essentially a homogenous piece of glass. This invention appears to meet the difficulty experienced in the use of tin cans and promises great results in offering a method of preserving fruits and other organic substances in which their original purity and freshness is maintained to a great degree, and the introduction of mineral poisons rendered an impossibility. The specification, as usual, is very brief and we hope to present our readers with a more detailed description of this interesting invention, on a future occasion.

ALCOHOLIC TRANCE.

At a meeting of the New York Medico-Legal Society, held at the Hall of the Academy of Medicine, November 2, Dr. Crothers read a paper on "Alcoholic Trance." The main point of the paper consisted in an attempt to establish the existence of a trance-like condition in inebriates. In this condition they were supposed to commit all sorts of ridiculous, or injurious, or even criminal actions, without a subsequent recollection of what they had done. Dr. Crothers related cases, the like of certain of which no other physician has yet seen or reported, and the like of which it may be quite safe to say no other physician is likely to record in the future. One was that of an engineer who ran a Mississippi steamer an entire trip without knowing it; another of a gentleman who regularly woke out of his "trance" at a railroad station, and was compelled to ask his fellow passengers where he was; a third, a house-painter, who would regularly climb to the top of a house, paint a whole story correctly, come down and "wake up." Other cases were still more complicated, and evidently called into action the *risorius* muscles of the Doctor's audience. Among the less remarkable instances was one of a hack-driver who became a confirmed drunkard, and several times went to States Prison, finally dying there, after being convicted of stealing horses; and of a solicitor, who had fits of jealousy and suspicion concerning his wife, and made a number of wills in a trance-like state.

Dr. Spitzka stated that he would like to ask the reader of the paper two questions. As far as he could gather, the reports were all obtained from third parties. His first question was whether Dr. Crothers had ever himself seen patients in this alcoholic "trance?"

Dr. Crothers replied that he had.

Dr. Spitzka reiterated that in that case the attendant phenomena had not been described by the Doctor in a convincing manner. His second question was, whether the hack-driver referred to had exhibited any inequality or anomaly of the pupils, the facial folds or tremor of the tongue and hands?

Dr. Crothers replied that he had manifested none of these symptoms, after some hesitation.

Dr. Beard took the floor. His remarks were not of such a nature as to permit the reporter to follow him, but

he read an extract from the *Journal of Mental Science*, which he claimed showed the awakening interest manifested by Europeans in "unconscious states." The Doctor then wandering off to the fall of a Swiss mountain and to Astronomy, was called to order, and subsided.

Dr. Spitzka, without desiring to introduce personalities into the discussion, remarked that it was a pity the preceding speaker had not turned back a few pages in the *Journal of Mental Science* and read the extract relating to the collapse of Dr. Beard's demonstration in England, and how Dr. Beard had failed to come forward with a paper he had announced before a scientific body. As to the paper read that evening, he regretted to say that instead of science being behind in its views on the question of alcoholism, it was the paper which was far from being up to the science of the day. He would call the attention of the reader to Magnan's work, in which he would find such of his cases as had the strongest semblance to reality, carefully described under the heads of alcoholic stupor and alcoholic epilepsy. As to the hack-driver's case, that was an evident example of a well-established and well-known form of disease, namely—alcoholic paralytic dementia. He was surprised to find such a common manifestation of alcoholism as tremor reported absent by Dr. Crothers. He was still further surprised to find such ordinary everyday and characteristic symptoms of chronic alcoholism as delusions of marital infidelity, morbid suspicion, inconsistencies of behavior, stupor and amnesia erected into trance-like states. Nowhere in the paper did the author give any evidence that he made that distinction between Dipsomania, Chronic Alcoholism and Acute Alcoholic Delirium, which was the A B C of our knowledge of the subject. The speaker concluded by regretting that the first time in years that so important a matter was brought before the Society, it was brought forward in so imperfect a form, and coupled with a term "trance," which in the past history of the Society had certainly acquired no good odor.

Dr. Girdner endorsed the preceding speaker's remarks, and gave an analysis of the ordinary effects of alcohol on the mind, which he referred to dynamic interferences. He concluded by objecting to the acceptation of such views as Dr. Crothers advanced until they could be better substantiated, as their acceptation would involve some remarkable medico-legal consequences. He did not believe that alcoholism, aside from its effect in producing chronic insanity, should constitute an excuse for crime. He thought that a crime committed in a drunken excess should be punished like any other crime, because the person, by his own agency, put himself in a proper condition to commit such crime.

Mr. Eller, of the New York Bar, stated that the view last announced by the preceding speaker was not a sound one in law; it was certainly not the one entertained by lawyers. He alluded to the great injustice done by police justices in sending persons to the workhouse on the complaint of any two (possibly) conspiring persons, that such person was a "habitual drunkard." He thought that term required definition.

Dr. Crothers, in closing the discussion, among other remarks of a general character, stated that our knowledge of alcoholism was not at all perfect, and that his views were an addition to science, notwithstanding what had been alleged that evening.

M. PICKET has examined seven varieties of steel (chiefly from a Sheffield and a Vienna house) with regard to magnetic power *Arch. des Sciences*, August 15). This power he finds to depend on the presence of carbon in the iron, and the aggregation of these substances. One of the two steels giving the best results had ⅞th per cent of carbon. Samples with 1½ and 1⅛th per cent were inferior.

NEW YORK ACADEMY OF SCIENCES.

October 24, 1881.

SECTION OF PHYSICS.

Vice-president, Dr. B. N. Martin, in the Chair.

Thirty-one persons present.

Mr. W. Le Conte Stevens read a paper, of which the following is an abstract.

WHEATSTONE AND BREWSTER'S THEORY OF BINOCULAR PERSPECTIVE.

For some time after the publication of Sir Charles Wheatstone's essay (1) in 1838, on the Physiology of Vision, this subject was studied with much zeal by Sir David Brewster, whose name is permanently associated with the lenticular stereoscope, an instrument now familiar in every household. Although the theories advanced by these two physicists to account for the illusion of binocular relief have since been shown insufficient, their mode of accounting for the estimate of distance as perceived in the stereoscope has been quite generally accepted. In 1844, Brewster published an essay (2) "On the Knowledge of Distance given by Binocular Vision," in which he elaborated and abundantly illustrated the idea that the apparent distance of an object is determined by the intersection of visual lines. The stereoscope had already been explained as an instrument by which rays of light from two slightly dissimilar pictures were made to enter the eyes, as if coming from a single object into which they are combined in front, and on each point of which the visual lines could be made to meet. Thus, in Fig. 1

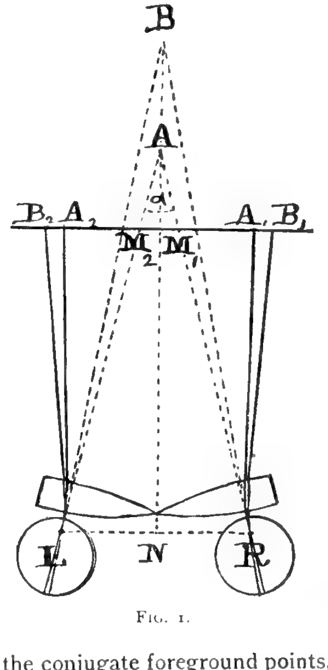

FIG. 1.

if rays from the conjugate foreground points, A_1 and A_2, be deviated by the semi-lenses, they appear to have come from A. In like manner, the background appears at B. If i = interocular distance RL., and a = optic angle, then for the distance of A we have

$$D = \tfrac{1}{2}\ i\ cot\ \tfrac{1}{2}\ a$$

From this formula it is obvious that D ceases to have any positive finite value when the visual lines cease to converge.

If the semi-lenses be taken away, and A_1 and A_2 be

(1) Phil. Transactions, 1838, Part II. Reprinted in Phil. Magazine, s. 4, vol., III., April, 1852.

(2) Edinburgh Transactions, vol. XV., Part III., p. 360.

removed to M_1 and M_2 respectively, while the convergence of visual lines remains unchanged, the images still appear at A and B. Wheatstone seems to have been the first to show experimentally that the illusion of apparent solidity can be obtained in this manner from a pair of projections representing the same object from slightly different points of view. If the eyes be properly trained, the visual lines may be directed to points whose distance is greater or less than that of the objects regarded at the same moment, and Brewster described many striking illusions thus obtained without the aid of the stereoscope. The principle applied by him, as described in the paper to which reference has been made, may be briefly given, and his results can be easily tested by anyone who is accustomed to analyzing his own visual sensations. Upon a uniform horizontal surface (Fig. 2) let two lines, A C and B C, be drawn, forming a small angle, β, with its vertex toward the observer. Let the eyes, R and L, be placed above this. If they be directed to the point, C, this appears in its true position. If the right eye be directed to B and the left to A, the axes meet at P; this point Brewster calls the binocular centre; and since the retinal images of B and A correspond, the visual effect is that of the union of these two external points at the binocular centre. Sweeping the glance toward C, the two lines appear united in the air, and P C is the apparent position of the combination, intermediate in direction between two monocular images, which may be disregarded or hidden from view with screens. If the convergence of visual lines be now diminished, the binocular image is lost until the right eye becomes directed to A and the left to B. The two points appear united at P′, and the line P′C now appears in the air on the further side of the surface. If the convergence be increased till P is again the binocular centre, and the face be lowered and withdrawn till the eyes are at R″ and L″, then C P″ becomes the position of the variable external image. And if lowered until R″L″ coincides with the surface, C P″ vanishes at the moment of becoming coincident with the prolongation of G C, the median of the triangle A C B.

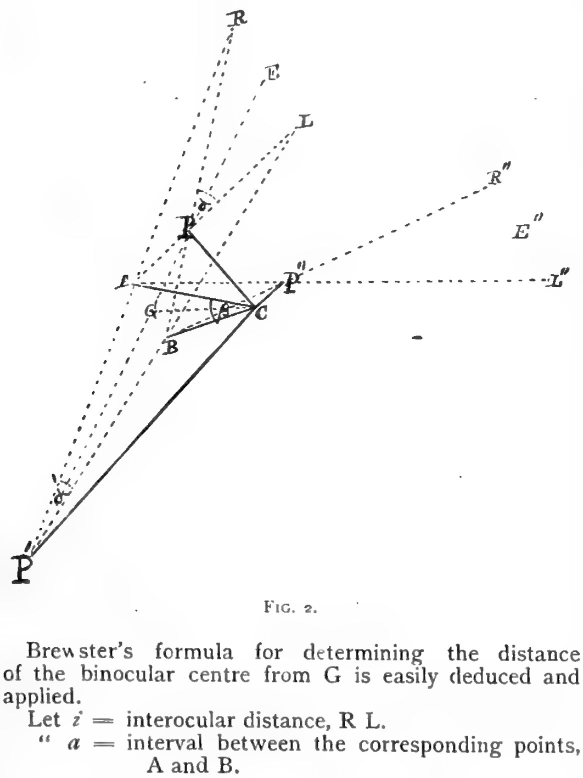

FIG. 2.

Brewster's formula for determining the distance of the binocular centre from G is easily deduced and applied.

Let i = interocular distance, R L.

" a = interval between the corresponding points, A and B.

Let b = distance, G E, between card and observer.

" x = distance G P, or G P′, which is positive when measured toward the observer, negative in the direction opposite. Then, observing the usual rule of signs, we have, by Geometry,

$$x = \pm \frac{a\,b}{i \pm a}$$

Applying this formula, Brewster constructed a table of distances for the binocular centre. For negative values it is seen that x becomes infinite when the visual lines become parallel; and, if they be slightly divergent, the binocular centre is far in the rear of the observer. Either of these conditions would make binocular vision impossible if the theory be correct. In testing the experiment with trained eyes, it is found quite possible to secure binocular fusion of the images of A and B when the interval between these points equals or slightly exceeds the interocular distance. It is also found that fusion of the images of the whole line at any given instant is impossible, especially when the angle β is large, or the lines are viewed very obliquely, as from R″ and L″. If the images of A and B fall on corresponding retinal points, the resulting sensation is binocular fusion, whether the visual lines be convergent, parallel or divergent; and the images of any two points nearer or farther apart cannot fall on corresponding retinal points at the same moment with those of A and B, though small differences are easily neglected. Whatever may be the importance therefore of optic convergence, as a factor ordinarily in determining the binocular judgment of distance, it has no such exclusive and measurable value as that attributed in Brewster's experiments; and the apparent distance of objects viewed through the stereoscope is obviously not determined by intersection of visual lines, if conditions are such as to render these parallel or divergent. The visual effects of optic divergence can be more conveniently studied by using stereographs than by the method already described, and a modification of Wheatstone's reflecting stereoscope affords the best means of measuring variations of the optic angle. As the lenticular stereoscope, however, is now almost universally employed, it is important that this instrument, as found in the market, be examined first.

By diminishing the natural convergence of visual lines, the stereoscopic effect of binocular relief can be quite easily obtained, while gazing upon a stereograph, without any instrument, when the interval between corresponding points of the two pictures does not exceed that between the observer's optic centres. This distance does not often differ very much from 64 mm., which may be taken as an average value. In Fig. 3 the distance between the two central dots is 50 mm. If the reader will fix his gaze upon a point ten feet off, just visible below the edge of the page, and then suddenly raise the visual lines to the figure without changing their convergence, he will see three circles instead of two; the central one moreover will appear as the base of a cone whose vertex is pointed toward him, but capped with a small circle. A little attention then will reveal the fact that when the dots are seen distinctly and singly, the small circle is double and slightly indistinct, and *vice versa*.

On stereographs, however, the interval between corresponding points is always greater than 50 mm. As the result of measurement made upon the foreground intervals of 166 cards, European and American, taken at random, the mean value I have found to be 72.9 mm., the maximum being 95 mm. If binocular combination is secured without the stereoscope, therefore, optic divergence is nearly always necessary. To ascertain the extent to which this is counteracted by the semi-lenses of our best stereoscopes, 30 pairs of these were kindly loaned me by Mr. H. T. Anthony, of New York. With very slight variation, their focal length was found to be 18.3 cm., and their deviating power not sufficient to prevent the neces-

sity of optic divergence, when the pictures are binocularly regarded through them, if the stereographic interval exceed 80 mm. As this limit is not unfrequently exceeded, optic divergence is often practiced unconsciously in using the stereoscope. Every oculist is familiar with the mode of using prisms to test the power of the muscles of the eyeballs, for both convergence and divergence of visual lines, and knows that 4° or 5° of divergence is not uncommon. Helmholtz (3) refers to the use of stereographs for the same purpose.

But familiar as is the production of optic divergence by artificial means, little or nothing seems to have been written in regard to the modification which the possibility of it imposes upon the theory of binocular perspective held by both Wheatstone and Brewster, accepted by most writers on vision since their time, and abundantly reproduced in our text books on Physics.* Of these I have not been able to find one that gives any account of the stereoscope except on the hypothesis that the visual lines are made to converge by the use of this instrument. On the uncertainty attached to the judgment of absolute distance from convergence of visual lines alone, Helmholtz (4) has written more fully than any one else. It is unfortunate that no English translation of his masterly work on Physiological Optics has ever been published. Although he gives no analysis of the visual phenomena produced in binocular fusion by optic divergence, his discussion of the judgment of distance would certainly tend to cast some doubt upon the explanation of vision through the stereoscope, as found in our text-books. And yet Helmholtz himself employs Brewster's theory in his mathematical discussion (8) of stereoscopic projection. This discussion, on the data assumed, is a model of elegance; but it contains no provision for divergence of visual lines. It is strictly applicable to the conditions involved in taking photographs with the binocular camera, and to the projection of images viewed in the stereoscope when the convergence of visual lines is identical with that of the camera axes, but not otherwise. Instead of human eyes we may assume a pair of camera lenses, an interocular distance apart, and a pair of sensitized plates behind them. Helmholtz's formulas enable us to determine the stereoscopic displacements in the images projected. If proofs from the negatives thus obtained be inverted and placed in front of a pair of eyes in such manner that the visual lines passing through corresponding photograph points shall bear to each other the exact relation that existed between the secondary camera axes that terminated in them, these two points will appear as one, and nearly at the distance of the real point in space to which the camera axes were converged. The effect is much the same as if the eyes, with normal convergence of visual lines, had been substituted for the cameras. But if the proofs be too near together or too far apart, increase of convergence makes the whole picture seem nearer, while divergence makes it farther. The relation between the different parts having been fixed at the time the picture was taken, increased convergence makes the distance from background to foreground seem less, divergence makes it greater. No one can have failed to notice the gross exaggeration of perspective often seen in the stereoscope, when the pictures are so far apart as to make the visual lines parallel or divergent, while the angle between the camera axes, when they were taken, was relatively large. But in no case do these conditions cause variations of such magnitude as Brewster's theory of binocular perspective would demand. This is easily illustrated with Wheatstone's reflecting sterescope. (5) Suppose the stereograph to represent a concave surface with the opening toward the observer, and that the arms of the instrument are properly adjusted. If they are pushed back, so as to make the visual lines divergent, the cavity apparently recedes and deepens; if pulled forward, so as to make them strongly convergent, it seems to approach and grow shallow. The apparent diameter of the image enlarges in the first case and diminishes in the second. Wheatstone notices this last variation in the account which he gave of his invention and its applications, in 1852, in the Bakerian lecture before the Royal Society (6); but, strange to say, the variation which is produced in apparent distance and depth under the same conditions seems to have escaped his notice, and the possibility of using his instrument to test the peculiarities of binocular vision with divergence of visual lines, seems not to have occurred to him. For the refracting stereoscope, however, like Brewster, he constructs a table of apparent distances corresponding to various optic angles, and applicable in using the binocular camera for the purpose of taking slightly dissimilar pic tures of the same object. He adds, (7) "when the optic axes are parallel, in strictness there should be no difference between the pictures presented to each eye, and in this case there should be no binocular relief; but I find that an excellent effect is produced, when the axes are nearly parallel, by pictures taken at an inclination of 7° or 8°, and even a difference of 16° or 17° has no decidedly bad effect. There is a peculiarity in such images worthy of remark; although the optic axes are parallel, or nearly so, the image does not appear to be referred to the distance we should, from this circumstance, suppose it to be, but it is perceived to be much nearer." This would not have seemed anomalous to Wheatstone, had he supposed binocular vision possible with divergence of visual lines, and entered into an analysis of the resulting visual phenomena. This analysis will be given in a future paper.

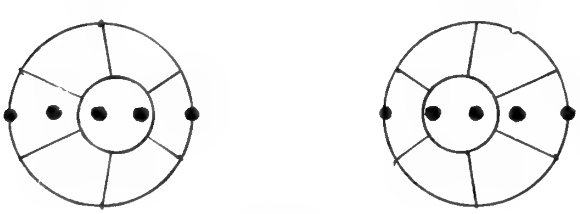

FIG. 3.

THE WATERS OF PARIS.

IN one of the previous numbers, *La Nature* gives an account of the work of an English observer, Mr. J. Hogg, on the waters of London. But since 1850, Mr. Hassall[a], at the request of the inhabitants of London, examined the degree of purity of the potable waters of that city, and more recently, Professor Farlow, of Boston, make an analogous work at the request of the citizens of that city.[b] M. A. Gérardin[c], however, has studied this question with a certain authority, by observing the cryptogamic vegetation in small streams of water which receive the waste products from the factories and manufactories on their banks. M. Gérardin observed that such industry favored the development of certain particular species which were

* Nov. 15th. Since the above was put in type, I have received from Prof. C. F. Himes, of Carlisle, Pa., an article written by him in 1862, in which he mentions his successful attainment of binocular vision by optic divergence, and criticises Brewster's theory of distance in relation to the stereoscope. Though his observation was independent, as my own was also, I find that he was preceded by a German, Burckhardt, in 1860 or 1861. I have already referred to Helmholtz in this connection (*Am. Journal of Science*, Nov. 1881, p. 361) and therefore have claimed no priority in discovering the possibility of this unusual, but still voluntary, employment of the eyes. It is the more remarkable that in our text-books the assumption should be so universal, that convergence of visual lines is a necessity in binocular vision for the determination of the apparent point of sight.

replaced by others in places where a different industry was in operation.

It is in this same order of ideas that the Administrator of Bridges and Roads of the Seine and Oise sent us lately a difficult question to answer. The question was to disinfect a river on the environs of Beaumont, which, during the heat of summer, was poisoned by a cryptogam of the genus Leptothrix. This vegetable is an aquatic and filaceous fungi which thrives and grows on the refuse of factories. The only answer to make was the well-known axiom: *sublata causa tollitur effectus.*

M. Neuville, the author of the memoir of which we are treating, is astonished that a work similar to that which he has undertaken, has not yet been done for the waters of Paris, whose sources are different, and which, consequently, do not present an equal degree of purity. Placing himself in a purely utilitarian point of view, he seeks to enlighten the administrator and the public on one of the indispensable sources of nourishment, that is to say the water consumed each day, by making use of his knowledge of cryptogams, and chiefly those of the family of Diatoms, for the study of which he had a predilection.

The complete purity of water is not always on account of the greater or less number of organic matters that it contains; it must be that these matters have a purifying character in themselves, and this condition obtains only when they are living vegetable growths, containing chlorophylle or green matter, having the property of freeing the oxygen which is dissolved in the water, on the one hand, and of absorbing, on the other, the carbonic acid gas which makes the water unfit to drink. Aquatic plants, then, are useful to the water which gives them shelter, yet with the condition that their bodies do not, by their accumulation, counterbalance the salutary effects.

Another cause very often acts to give water unhealthy properties. The lime salts which it holds in solution, and sometimes in great quantity, cause troublesome and sometimes serious diseases. The carbonate, but above all the sulphate, of calcium, makes the waters selenitic, as it is said, and then they become unfit for the cooking of vegetables, do not dissolve soap, and are indigestible. It is possible, however, for water to dissolve soap and nevertheless to cook vegetables; this occurs when in place of sulphate of calcium it contains magnesium.[d]

The waters of the source are often sought after for their limpidity and freshness, which does not always imply that they are really potable; it is even probable that if the waters of our rivers were taken at their source they would not have the qualities which they acquire after a journey of several miles. But when these rivers pass through an important manufacturing city, the injections, the impurities of all sorts which they receive will rapidly change their qualities; stocked, so to speak, in the passage by the city, they are yet able to improve themselves somewhat after a new journey in the country, which permits them to deposit the foreign matters which contaminate them. There are these elementary considerations which should always insist that the waters which supply a city should be taken above and not below the city.

Borrowing from the interesting works of M. Miquel, the savant of the Observatory of Montsouris, whatever they contain of use to his work, M. Neuville, among other things, reproduces the following table of comparison for the use of the reader, and shows what organisms the waters from the source and of different qualities can contain, observed with considerable magnifying power:

PROPORTION OF LOW ORGANISMS CONTAINED IN DIFFERENT WATERS.

	Microbs by hund. cube.
Water of condensation	0.2
Rain water	35.0
Water of the Vanne	62.0
" " Seine, in Paris	1200.0
Sewer water	20000.0

It is indispensable that analyses of this nature should be made rapidly, because in a short time the microbes grow in a great degree, and will no longer give exact figures.

The method which M. Neuville has followed does not consist of chemical analyses of the waters of Paris, which had been done long before by well-known scientists; it is rather a kind of statistics of the foreign matters contained in each of them, and which the use of the microscope reveals.

The waters submitted to his examination are those of the Marne, taken at Saint-Maur and Charenton; of the Seine, at the Port-à-l'Anglais, at the bridge of Austerlitz, taken at Chaillot, Auteuil, and at Saint-Ouen; the waters of the canal of Ourcq, of the Vanne, of the Dhuis, of Arcueil, of the sources of the Nord of Paris, of the artesian wells at Grenelle and Passy, finally that of a well of the left bank of the Seine.

A constant quantity of five litres of water was taken at the middle of the above-mentioned streams, or at the inlet of the waters of the sources; then after a settling of 12 hours, by means of an appropriate siphon, he decanted until it was reduced to 300 grammes. The contents were turned into a graduated gauge and after rest, by the use of a small pipe be gently raised the liquid in order to leave but a deposit of two to three centimetre cubes. It is this deposit which is directly submitted to microscopical observation, after having been put in cellular preparations before being preserved. Observation was made on a determined number of preparations, all sketched in a light room, and the sum of the latter serves to form one of the plates which accompany this article, which contains seventeen. A diagram, or schematic table, indicates the result of chemical analyses and of microscopical observations made for the Seine in its journey through Paris.

The water of the Marne taken at Saint-Maur, is relatively rather pure; yet organic matters are found in great abundance in it; but they are, above all, living matters, and more purifying than corrupting (Fig. 1.) They are a part of the Desmids in the green matter and belong to the genus *Pediastrum* (No. 9) or *Raphidium* (No. 10); or else of filaceous algæ (No. 11) of the genus *Ulothrix*. On the other hand, and much more abundant are the Diatoms with silicious carapace, and, for the most part, gifted with movements of translation very curious to observe. Such are the genera *Sirurella* (No. 1), *Nitzschia* (No. 2 and 3), *Cymatopleura* (No. 4), *Cynedra* (No. 5), *Diatoma* (No. 6), *Pleurosigma* (No. 7), etc., or even Infusoria (No. 13), which make prey of several of these small growths; but, above all, the organic remains. Finally the mineral matters which, in the water of the Marne river, are always more or less muddy, form the small chrystalline groups in the preparation (No. 15). This water is then very good; but on approaching its confluence, that is to say, at Charenton, not only the Diatoms are increased in number, but the Infusoria abound in it as well as detritus, which probably is due to the inhabitants of the Marne at this place.

In the water of the Seine taken at the Port-à-l'Anglais (fig. 2), a very great proportion of organisms is found. This point of the river, intended at one time to furnish Paris with a very potable water, has lost its value on account of the factories and manufactories which are built on it above the city, and the length of the small streams of water which it receives in these places. Desmids are found in it the genus *Closterium* (No. I), *Scenedesmus*

[a] A microscopic exam. of water . . . of London, 1850.

[b] Remarks of some Algæ found in the water . . . of Boston, 1877.

[c] Rapport sur l'altération, la corruption et l'assainissement des rivières, 1873.

[d] Translated from *La Nature*.

(No. 2), *Raphidium* (No. 9), *Tetraspora* (No. 10), and other Algae as *Chlamydococcus* (No. 11) or *Ulothrix*. Infusoria equally (*Chætonotus* [No. 20], *Brachytous* [No. 23], *Euglena* [No. 12]) and several species of Diatoms already named or a little different. But that which is striking is the already notable quantity of organic remains, fragments of plants (No. 24), mycelium of mushrooms (No. 18), and an eel (No. 17), moving about in the middle of all this multitude, and, in fig. 2, crossing a spicule of Spongille (No. 15).

The water taken at the bridge of Austerlitz is more charged with detritus; the purifying algæ disappear and diatoms are rare. It is infusoria and their bodies which predominate, then finally there are remains of tissues of linen or cotton, of vegetables in decomposition, etc., which the waters of Bercy, of Rapée and Bièvre brought.

If now the water of the pump of Chaillot is examined (fig. 3), the maximum contamination of the Seine is attained. (If this is not, however, the water taken at Saint-Ouen; but at this place the stream has received, as is known, the sewer collector at Asnières, which is a serious cause of infection of the water for a long distance.) The quantity of carbonic acid has already increased, and the oxygen grown less.

In the Chaillot water (fig. 3) there are scarcely any more algæ, here and there remains of conferva (*Cladophora* [No. 14] or some rare specimens of more reduced species (*Pandorina* [No. 1]), *Chlamydococcus* [No. 5], *Sirurella* [No. 2], *Stauroneis* [No. 3], *Epithemia* [No. 4]), yet most often there is only the silicious carapace, void of endochrome, of these last diatoms. On the other hand, the deposit of detritus is dominant in it: muscular fibres, (No. 10), vegetable cellules (No. 11), then myceliums of inferior fungi, and lastly eels (No. 9). Yet there is still more: some microscopic crustaceans appear (*Daphnia pulex* and others [Nos. 7 and 8]), the whole associated with earthy or indeterminable remains.

M. Neuville disputed the opinion of M. Frankland who refuses to admit that rivers purify themselves. He maintains, which seems to be perfectly demonstrated, that after a tranquil journey without receiving other impurities, a river purifies itself, little by little, by deposition, either on the bottom of the bed, or on the banks, of the substances which it held in solution. The harmful matters held in solution are eliminated and they disappear; the carbonic acid becomes exhausted little by little and the oxygen, on the other hand, returns in proportion.

During the war of 1870–71, the forced stopping on the rivers which habitually received the injections of factories and of industries polluting these streams, had changed their conditions. Thus the Bièvre, tainted from Arcueil to its arrival in the Seine at Paris, had again become limpid, and fish had made a home in it, coming from the parts above Arcueil, although however the bottom of the bed of the Bièvre was at this moment covered by a thick bed of mud nauseating at ordinary times.

The water of the Seine at Saint-Ouen became again more impure than any other part; but, as has been said, this was due to the sewer collector of Asnières. The carbonic acid which, at the bridge of Austerlitz, was represented by 16.2 by hund. cube, reached here the proportion of 65, that is to say the maximum for the waters of Paris. Living creatures here are very rare; but the remains of stuffs: linen, yarn, cotton, animal and vegetable fibres abound here. It is no longer a deposit, it is a real soup. The chlorides, the sulphates, and the sal ammoniacs, as well as sulphuretted hydrogen, are largely represented here. Finally further on, where the Seine passes by St. Denis and receives from it some quantity of refuse, vegetation is no longer found in it, and the bottom of the stream is nothing but a blackish and contaminated mud, as M. Gérardin observed it.

The canal waters of Ourcq have been for a long tim the principal source of the supply of Paris. They ar selenitic; but yet M. Neuville does not consider them the worst waters used in the city. A great number of algæ live in them, this being in their favor, and their relative tranquillity is also one of the causes of this notable growth of vegetation. The numerous boats which sail on these waters and the warehouses bordering this canal, where unloading is done, must prove sources of pollution of these waters? Their hydrometric degree is 30° to 31° while the mean of the waters of the Seine is between 17° and 20°, but this does not constitute in the eyes of M. Neuville a plausible reason of inferiority for the waters of Ourcq. It is their stagnation which ought to be the dominant cause of their depreciation.

Figure 4 represents the composition, in organisms, of the waters of the Vanne. It is, according to microscopical observations as well as according to the official reports, the best of the waters of Paris. M. Belgrand says: "comparison was not possible between the excellent waters of the Vanne and those of the Seine and the Ourcq, which, warm in summer, cold in winter, agitated and not transparent in all seasons, are besides tainted more and more by the residue from industrial and human refuse. After a journey of 176 kilometres by means of closed inlets, the waters of the Vanne arrive at the reservoirs of Montsouris and can furnish 100,000 metres cubes of water in 24 hours. Limpid, fresh, exempt from organic matters, it unites all perfections, says M. Neuville, it is water that I wish to see distributed in all Paris."

Several algæ of good quality, such as *Ulothrix* (No. 7), *Melosisa* (No. 2), *Meridion* (No. 1), *Navicula* No. 3), and *Synedra*, are the respectable inhabitants of these waters; here and there some vegetable growths and earthy remains, and finally some crystals of carbonate or sulphate of calcium (No. 11).

The waters of the Dhuis (fig. 5) only arrive at the reservoirs of Ménilmontant, associated with those of the Surmelin. At their point of junction, those of the Dhuis appear rather pure but nevertheless they are agitated and have need of rest. It is a remarkable thing that the microscope reveals no algæ in them; on the other hand, organisms of another order are met with, some filaments of Mucorinées (No. 1), mycéliums (No. 2), and some earthy or organic remains (Nos. 4, 5, 6). According to all appearances, these waters are not sufficiently oxygenated, and a journey a little prolonged in the open air and in the light will make them perfect.

Rivalling with the waters of the Vanne for purity and freshness, the reputation of the waters of Arcueil has been known for a long time (fig. 6); they were so named because they flow through the valley of the Bièvre over an aqueduct at Arcueil. But in truth, they have come from the village of Rungis since the Roman epoch, for these are the waters which supplied the baths called baths of Julius Cæsar or thermæ of Cluny. To the Roman aqueduct, of which several traces remain, succeeded that which can now be seen, built by Desbrosse in 1624, which has to conduct the waters of Rungis to the palace of Luxembourg and in the Saint-Jacques quarter. Advantage is taken of this monument, solidly constructed, to build above it the new aqueduct for the waters of the Vanne, which are conducted to the basin of Montsouris. M. Neuville says "with difficulty can be seen in them, several Vorticelles and Oscillaries (Nos. 1, 5, fig, 6), then several diatoms (*Gomphonema* [No. 3], *Nitzschia* [No. 2]) and lastly some salts of calcium, chrystallized and precipitated from their solution by the loss of a portion of carbonic acid. It is water of good quality, which can be improved by means of successive cascades, and it is unfortunate that we have not more of it.

The sources of the Nord of Paris offer but little interest. Given up to the consumption of the inhabitants of Paris from the end of the twelfth century, they were for a long time the only waters which supplied the fountains of the capital. These, with the waters of Arcueil are the most ancient known. They are furnished by

FIG. 7.—Water of the Well of Grenelle.

FIG. 8.—Water of the Artesian Well of Passy.

THE WATER SUPPLY OF PARIS.

Saint-Gervais and the heights of Belleville. Their quality leaves much to desire.

"Essentially selenitic, their hydrometric degree reaches enormous proportions: 100 degrees to 150 degrees according as the waters of Saint Gervais and of Belleville are more or less mingled." They contain very little organic matters, some rare algæ and many calcareous crystals.

The well of Grenelle, become celebrated, was commenced in 1833 and only finished in 1841. It was on the occasion of its boring that the relations of the elevation of temperature to the depth of the soil observed by Arago and Walferdin, were stated; that is to say, with every 32 metres the temperature rises one degree.

The water of the well of Grenelle (fig. 7) lacks oxygen which it can gain in the basins of the Pantheon where it is conducted. This water is limpid, indicates at its outlet about 28 degrees, and is very nearly pure from all organism, since it only contains some traces of mycélium of mushrooms (No. 2) and, here and there, several Diatoms (No. 1) probably drawn from the tubes through which it flows. The traces of sulphuretted hydrogen which it contains, impairs a little the quality of this water, but not enough to make it unfit for consumption.

The water of the well of Passy, perforated from 1854 to 1861, can be compared with that of Grenelle (fig. 8). The results which the piercing of this well caused are known; the sale of the water of Grenelle was made considerably less. The carbonate of lime, as well as the bicarbonate of potash, are abundant in both. All things equal, moreover, M. Neuville gives his preference for the waters of Passy rather than for those of Grenelle. Several algæ are found in them (*Calothrix* [No. 8], *Rhizoclonium* [No. 5], *Cosmarium* [No. 1]. Glœocystis [No. 9]); several encysted infusoria (No. 2), and a few unimportant organic remains.

Lastly, the waters of ordinary wells are potable only when they are not found in a great city. The varied infiltrations, the connection with the soil, and the industries which can contaminate them, are considerations which must be taken into account in deciding the quality of the waters of wells, and which can render them unfit for consumption. They contain at Paris much of the nitrate and sulphate of lime, and they are also very much charged with organic matters in a state of decomposition; but of algæ there is no trace and there are, here and there, several microscopic crustaceans. It is above all in the neighborhood of cemeteries that the waters of wells should not be used except for gross purposes. This advice is upheld by the studies of M. Belgrand, who has observed that, in the environs of Père-Lachaise and of the cemetery of Montparnasse, the waters of wells were stocked, above all during the heat of summer.

Basing his results on microscopical analyses, M. Neuville arranges the waters of Paris in the following order to indicate their degree of purity: 1, waters of the Vanne; 2, of the Marne at Saint-Maur; 3, of the Marne at Charenton; 4, of the Seine at Port-à-l'-Anglais; 5, of the canal of Ourcq; 6, of Arcueil; 7, of the sources of the Nord; 8, of the wells of Passy; 9, of Grenelle; 10, of the Dhuis; 11, of the Seine at the bridge of Austerlitz; 12, of a well on the left bank; 13, of the Seine at Saint-Ouen; 14, at Auteuil; 15, at Chaillot.

TIDAL POWER AT BRISTOL.—At a recent meeting of the Town Council of Bristol a motion was brought forward, but not adopted, that "instructions be given to the sanitary authority to cause inquiries to be made into the tidal power of the Avon with a view to its being utilized for working electric lights for the city, the storage of motive power and other purposes, and that scientific aid be employed for the purpose."

THE EVOLUTION OF FLYING ANIMALS.

BY CHARLES MORRIS.

Continued from page 536.

Yet there is one instance of a leaping animal in which a partial flight has been gained in this manner. We allude to the flying-fish. Whatever first induced this creature to spring from the water through the impulse of its swimming motion—whether the pursuit of enemies, or some other cause—at any rate its fore limbs were already developed into wing-like organs, through their use as fins. The flying-fish does not really fly. But an increased spread of its supporting fins, which act as parachutes, would enable it to make longer leaps, and natural selection has undoubtedly produced this extension of the fins.

Land animals present us with several instances of this parachute motion. And significantly it never arises in earth-leaping, but always in tree-leaping animals. Among mammals we find three instances of such a habit, in widely separated families, embracing the Flying Squirrel, the Flying Phalanger, and the Flying Lemur. Among reptiles there is one instance, the Flying Dragon. The three mammalian genera mentioned include a number of species, and an imperfect flight is gained in the same manner in every case. During their so-called flight the limbs are extended almost at right angles to the body, and the skin of the sides has been developed until it is expanded into a broad membrane between these limbs, which, in the case of the Flying Lemur, extends from the nape of the neck to the tail. In their bold leaps from the branches of trees these creatures are partly supported by their membraneous wings, so that they descend slowly and easily. Some of them can even slightly vary the direction of their motion, so as to pursue insects.

The flying reptile, the little Draco Volans, gains its support in a somewhat different manner. In this case the extended membrane is supported, not upon the limbs but upon the false ribs, which grow out horizontally from their vertebral connection to a considerable distance, giving the animal a wing-like expansion of its sides.

We may readily conjecture the method in which such an organization was gained. The smaller tree dwelling animals are exposed to attacks from foes, the same as all other animals. Or, if carnivorous, they need to pursue their prey. In both these cases the power to make long leaps from branch to branch, or from tree to tree, is so obvious an advantage, that it is not surprising that many animals have become very bold and skillful in this particular. Many of these animals have also the habit of crouching on the branches of trees for concealment, their legs being extended side-wise, and their bodies flattened. This position of the legs in rest would most probably be retained during the leaping motion in which they are not employed. If, then, in any case, the width of the body should be increased, as by a chance extra expansion of the skin of the sides, supported by the outstretched limbs, the animal would be borne up by the air, and could make a longer leap. Such a conformation would aid it in flight or pursuit, and natural selection must operate to retain any such special advantage of form. It certainly seems very probable that the supporting membrane of these creatures was thus developed, and that the Flying Dragon gained its rib expansion through a similar process.

These cases may seem of little importance in an investigation of the origin of the flying power in birds; yet they are, in reality, of considerable importance. They point significantly to the most probable method of flight development, namely, as the result of an original leaping habit, from branch to branch or from tree to tree. Although the above cases are instances of parachute motion only, not of true flight, yet we have strong reason to believe that the earliest flying animals gained their power of flight as a direct extension of the above method.

In the incessant battle for existence among animals the possession of powers of flight are, in certain directions, so specially advantageous, that any accident of conformation, aiding animals in any degree to support themselves in the air, seems very likely to be preserved and to be added to. At present, however, when the field of air is so fully occupied, and there are so many vigorous carnivorous birds constantly seeking for poorly defended food animals, the tendency to develop powers of flight is checked. The aerial motion of the leaping animals mentioned is not such as to greatly expose them to danger from this source. But were their powers of flight increased, so that they could support themselves longer in the air, and move out from the immediate shelter of trees, they would be exposed to attacks from carnivorous birds, and such an imperfect flight must prove a special disadvantage. Their weak flight would expose them to a danger from which they could escape neither by rapidity of motion, nor by a return to the shelter of the forest. Thus the existence of these strong carnivorous birds operates as a decided check on the development of any other form of flight, and it is very unlikely that the leaping creatures mentioned will ever develop a more efficient flight.

There is another illustration of the same principle. The true flying mammals, the bats, perhaps developed their powers of flight at the same geological age as birds did. Thus there was no special hindrance to their evolution. It might seem curious to some, however, that they have failed to gain the same extensive habitat as birds; that they are exclusively crepuscular or nocturnal in their habits, while the birds are almost exclusively diurnal. And yet this difference must have arisen in consequence of a long-continued conflict between bats and birds, in which birds conquered. If we consider that the flying organs of birds are more efficient than those of bats, the whole question is answered. The birds drove the bats back into a field which they did not care to occupy. The fight was for the possession of the air during the day. The birds conquered. The bats were forced to content themselves with nocturnal flight and the imperfect food-supplies which the night yields, while the birds proudly held the dominion of day. It was a case somewhat similar to that which we have already considered, of the supremacy of mammals over reptiles; and the disappearance of the flying Pterosaurs of the far past may possibly have been due, both to the superiority of flying powers and to the more efficient vascular system of birds over flying reptiles.

But there was a period in which the haired animal had not yet succeeded the scaled animal, in which hairs had not been specialized into feathers, and in which the broad fields of air were free to the first occupant, and contained no active carnivoræ ready to check the development of flight in its incipient stages. Were such the case now, our Flying Squirrels, etc., might gain more efficient powers in this respect, and evolve true flight. We may safely come to this conclusion from the fact that certain lizards gained powers of flight in the early days of bird evolution, and apparently by a direct continuation of the process which we perceive in the Flying Squirrels. The expanded skin between the legs was merely a thin, naked membrane in these lizards. It apparently spread wider and wider, until it extended to the extremities of the toes. But this condition would only produce a more efficient parachute motion. For flight to arise a movement of the fore limbs must be employed, and this may have originated in the effort to keep the body horizontal and prevent its anterior extremity from sinking. Such a movement, with the possession of such a membrane, would yield an imperfect flight. But for the flight to become perfect, in such an animal, the membrane must become still more extended, and the movement of the fore limbs more efficient. This extension was gained by the gradual outgrowth of the fourth finger, to whose tip the membrane had already extended. By the preservation of favorable variations in this direction, it is very likely that the immensely extended flying finger of the Pterodactyle, the bird-like conformation of its skeleton, and its probably more efficient lung action, were gradually gained; and that it thus developed from an original tree-leaping into a flying reptile.

The advantages of an aerial residence, at that early period when the atmosphere had not yet been preempted by vertebrate inhabitants, were so many and great, that the selective principle must have proved of particular efficiency in this direction. Even a long leap from a solid support infested by many enemies, through an aerial field devoid of enemies, was highly advantageous, and the development of flying powers may have been preceded by the appearance of many animals possessed of a parachute motion. Such animals would leave no geological record, as their motion did not necessarily modify the osseous framework of the body. There are comparatively few of them now, since the advantage to be gained by such powers is greatly reduced. But it is very obvious that any extension of this power, assimilating it to true flight, must have proved far more advantageous. An animal capable of supporting itself in the air, at this early period, was exceptionally free from danger, while its chances to obtain food were greatly increased. The better flyers were, of course, the more secure, and the original partial flight must have rapidly developed into the most perfect flight of which such a membranous wing extension was capable. Not until these flying reptiles began to prey on each other was there any check to their evolution and diversity of formation. The remains of some twenty different species have already been discovered, and this is indicative of hundreds, perhaps thousands, of diverse species of these strangely flying Pterosaurs.

A somewhat similar instance of early and perhaps general possession of the atmospheric field is afforded in the case of insects. Some peculiarity of formation, perhaps the remnant of an original dorsal gill, gave them a structural organ capable of partly aiding them in leaping and of being modified into a membranous wing. But as in vertebrates so in insects, the field of air became in time so fully occupied, and the claimants for its food supply so numerous, that the less vigorous flyers or those adapted to specially terrestrial food, descended to the earth again, and in time lost the power, with the loss of the desire or need, of flight.

Some such fate seems to have overtaken the Pterosaurs. For the possession of the field of air was sharply contested by two other classes of animals, both of which had already stepped beyond the reptilian rank, and become hair-covered and warm-blooded, and one had gained the still more advanced condition of the mammalian organization. The contest between birds, bats, and Pterosaurs, was not alone a battle of flying carnivoræ, but a struggle for common supplies of food, in which the most vigorous flyer was most likely to win. As a probable consequence of this contest the birds have gained the diurnal possession of the air, the bats have become adapted to nocturnal food supplies, and the Pterosaurs have disappeared. They were probably vanquished in the fight, and gradually resumed terrestrial habits, or died out.

So far as we are aware the evolution of flying mammals was much later than that of birds. But the geological record is so incomplete that bats may have existed at a much earlier date than their discovered remains seem to show. They are found in Eocene deposits, and the bird remains yet found in earlier deposits are very few in number of instances or species. In considering the development of bat flight we are in the same line with those already examined. It is a development of the skin into a flying membrane. But in this case, in addition to the extension of this membrane between the fore and

hind limbs, it is also extended between the fingers of the fore limbs. Possibly in the early flying efforts of bats the fingers were extended in such a manner as to render any accidental growth of skin between them an advantage. Differences in the locomotive habits, and in the foot development, of the progenitors of flying reptiles and flying mammals, may account for this greater extension of the flying membrane in the case of the latter. Naturally such an advantage was seized upon and improved by natural selection. The membrane extended to the tips of the fingers, the fingers themselves grew much longer, and in time the fore limb lost all its powers as a walking organ, but became developed into an efficient flying organ, Bats, by this specialization of their fore limbs, ceased to be quadrupeds, though they never became true bipeds. Sleep and flight constitute the measure of their existence.

Thus the development of all flying vertebrates other than birds pursued the same general course. It began with the extension of the skin of the sides, so as to serve for parachute motion; and ended with an extension of the fingers of the fore limbs, an extension of the membrane to the tips of these elongated fingers, and a flying motion of these limbs. In necessary connection with these were concomitant internal changes, the whole anatomy of the animal becoming adapted to its flying habits.

But in the development of bird flight quite a different mode of evolution appears. Flight is here attained not by a special adaptation of the skin, but of the dermal covering. This covering was probably not the hair in its full modern sense. It was a primitive derivation from the reptilian scale, which secondarily became the avian feather and the mammalian hair. The feather of the bird agrees with the scale of the reptile in being developed in little hillocks upon the skin. The hair of the mammal developed in closed follicles within the skin. There thus has been a specialization in both, with the production of a change in the terminal character of the feather and in the dermal origin of the hair.

The progenitors of birds were either land or tree dwelling reptiles; most probably the latter. We have seen the extreme improbability that any leaping motion from the earth developed into a flight. We have also seen how natural it is for animals to leap from the limbs of trees, and that, in several modern instances, a degree of aerial support has been thus developed. But in such a leaping motion it is highly probable that some animals would make other efforts for support in the air besides the horizontal extension of their limbs. The swimming motion is a very natural one. It is naturally adopted by all land animals which fall into the water, and the webbed feet of swimming birds have been produced by it in the same manner as the webbed fingers of flying bats. Let us now consider some early animal, so far advanced beyond the reptilian ranks as to have become warm blooded, and covered with the primitive form of hair, arboreal in its habits, and accustomed to make long leaps from limb to limb. It is by no means improbable that some such animals would seek to swim in the air. A rapid motion of the fore limbs could not but aid in keeping the body horizontal, and if these limbs were covered with thick hair this must aid in breaking the fall of the animal. Any such habit could have but one result. A thicker hairy covering of the fore limbs, and even of the whole body, would prove an advantage to the animal, and these thickly matted hairs would tend to spread laterally, precisely as we find in the tails of Flying Squirrels and Phalangers. A still further advantage would be gained were these hairs rough instead of smooth on their edges, so as to cling together, and prevent the air from passing between them.

Such a swimming motion, performed by the fore limbs principally,—the hind limbs being the leaping organs,—and aided by the lateral outgrowth, and the "felting" of rough edged hairs, would, from its inception, be more than a parachute motion. It would be incipient flight from the first, a swimming in the air. The essential advantages gained by longer and longer leaps must tend to preserve any favorable conditions of the hair, and we can readily conceive the rough edges of the hairs extending into interlocking feathery expansions. In fact it is not difficult to imagine the slow evolution of true feathers in this manner, since every incipient approach to the feather must prove advantageous to the animal in its aerial motion.

But every better adapted movement of the fore limbs must prove similarly advantageous. Not only any variation from hairs towards feathers would be advantageous, but also any variation from a swimming towards a flying movement of the fore limbs. Of course the process must have been a slow one. It was necessarily slow also in the case of the bat and the Pterodactyl. But in all these cases every increment of variation from leaping towards flying was advantageous, so that there was no hindrance to a continual evolution towards full powers of flight.

But the development of the fore limbs into feathered wings unfitted them more and more for walking organs. The slowly developing bird must have trusted more and more to its hind limbs for support. Its arboreal habit developed the toes of these limbs into grasping organs. The original quadruped in time became a true biped, with a foot specially adapted to grasp the rounded surfaces of the limbs of trees, and so changed in position as to fall under the centre of gravity of the body. Hairs became feathers, the bones of the fore limbs aborted in part and became wing bones, and the original tree leaping reptile became a flying bird.

We may close with a very brief further consideration. In the first place it is highly probable that only quite small animals first gained this flying habit. Considerable weight would hinder its development. But after it was once gained there would be no special hindrance to increase in size in the newly evolved species. Yet a very great increase in size would so greatly increase the muscular effort necessary to flight that the larger birds would most likely spend a considerable portion of their time upon the earth. And in many cases the increased weight which is apt to arise from diminution of muscular exercise might render a resumption of the flying habit impossible. Such birds would lose their aerial powers, and become true land bipeds. We may ascribe the land residence, and the aborted wings, of the Ostrich, Cassowary, &c., to some such secondary process of evolution. On the other hand, many virtually land birds have become so by an adaptation to food in the obtaining of which flight was no advantage. Organs not used soon lose their muscular vigor, their size decreases, and gradual abortion takes place, unless adaptation to some new function gives them a special development in this new direction, and checks their tendency to disappear.

II.

STONE IMPLEMENTS IN THE DRIFT.*

By Watson C. Holbrook.

Many stone implements have been found deeply buried in the clay and gravel of Whiteside county, Illinois. Mindful of the many sources of error, and fully conscious of the many grave and serious questions involved, I have endeavored to examine with care and attention every one of the finds. The first is a black chest spear head about five inches long found incased in a block of granular stalagmite. This specimen was found in a light-blue clay. Above this clay was an alluvial deposit about five feet thick. Some pre-historic man must have left his spear head in a cave or hid it in a fissure of rock. Layer after layer of stalagmite was found. The spear's head

* A. A. A. S., Cincinnati, 1881.

was first covered by this incrustation of limestone, but in the course of time was completely buried in the thin, ribbon-like layers of this stalagmite. Then the floor of the cave was broken up, and the detached piece containing this specimen was carried here by water, or ice, or both, and here it has remained imbedded in this blue clay till all of the alluvium has been deposited. Several arrow-points have been found buried seven or eight feet below the surface of the earth. I have carefully examined two of these finds. They were buried in a tough, compact clay. They were found by workmen while cutting into the hillside and grading the public roads. A small arrow point was found by a friend of mine while digging a well. It was twenty-four feet below the surface of the earth. It is a well-made and beautiful arrow-point, and my friend will not part with his valuable specimen.

FRENCH ACADEMY OF SCIENCES.

August 8, 1881.

MINERALOGY.—M. Klein presents a communication on different solutions of very great density, which can be advantageously utilized in laboratories to separate pulverulent mineral particles from foreign bodies. The salts employed by M. Klein are the tungstoborates of cadmium, nickel and cobalt. The density of the solutions of the last two salts is 3. 4; yet M. Klein prefers to them the solution of tungstoborate of cadmium, whose density is only 3. 2, but which is quite transparent, while the others are very colored. The tungstoborate of cadmium can, besides, be obtained in crystals; it melts at a temperature of 75°, and becomes a transparent liquid, whose density is 3. 6.

PHYSICS.—M. Ancelin described a method of heating intended to replace foot-warmers of water. His system is based on the fact that every body which passes from a liquid to a solid state gives off its latent heat of fusion.

M. Ancelin encloses some acetate of soda in a metallic vase, which is then heated to a temperature of about 80°. Then left to itself, the apparatus cools little by little to about 59°; the acetate of soda then commences to solidify, and gives off its latent heat. While the solidification continues, the vase remains at the same temperature. Boilers heated in this way will remain hot four times as long as by the use of water, about twenty to twenty-two hours.

EXTRACTION OF SULPHUR.—M. Dubreuil, who has devised a new method for extracting the sulphur of Sicily, announces that he has found in the mother waters of the salt marshes of Palermo, charged with chloride of magnesium and boiling at 120°, a suitable substance to separate from the sulphur the earthy bodies which accompany it.

FOR the unities of electric measures there are adopted the fundamental unities—centimetre, gramme, second, and this system is briefly designated by the letters C. G. S. The practical units, the *ohm* and the *volt*, will retain their present definitions; the ohm is a resistance equal to 10^8 absolute unities (C. G. S.), and the volt is an electromotive force equal to 10^9 absolute unities (C. G. S.). The practical unit of resistance (ohm) will be represented by a column of mercury of 1 square mm. in section at the temperature of 0° C. An international commission will be charged with ascertaining for practice, by means of new experiments, the height of this column of mercury representing the ohm. The name *ampère* will be given to the current produced by the electromotor force of 1 volt in a circuit whose resistanse is 1 ohm. *Coulomb* is the quantity of electricity defined by the condition that in the current of an ampère the section of the conductor is traversed by a coulomb per second. *Farad* is the capacity defined by the condition that a coulomb in a condenser, whose capacity is a farad, establishes a difference of potential of a volt between the armatures.

COMET (*g*) 1881, SWIFT.

At eleven o'clock last evening, Director Lewis Swift, of Warner Observatory, discovered the seventh comet of the year in the Constellation of Cassiopeia in a line between Polaris and the great cluster in Perseus, a trifle nearer Polaris. It is nearly round, faint, has a slight central condensation, but no tail is yet visible. Its right ascension is one hour and fifty minutes, (1 h. 50 m). Declination north seventy-one (71) degrees, and its motion slow westward. Estimated diameter, about four minutes. As the comet of 1812 is anticipated from this quarter, it may be the great Pons Comet. This makes the sixth comet discovered in this country since May 1st, Swift getting the two hundred dollar Warner prize twice. The fifteen hundred dollars given in comet prizes during the past twelve months by Mr. Warner has evidently given an extraordinary impetus to astronomical study in this country. Director Swift, of the Warner Observatory, will visit Egypt, by the generosity of the founder of the Observatory, in December, 1882, to observe the total eclipse of the sun and verify his celebrated discovery of an intra-mercurial planet in 1878, which has been so much disputed by astronomers. C. S. WHITTLERE,

Sec'y. Roch. Astro. Society.

WARNER OBSERVATORY, ROCHESTER, N. Y., *November* 17, 1881.

COPYING INK FOR READILY TRANSCRIBING LETTERS WITHOUT A PRESS.

A paper on this subject by Professor Attfield, F.R.S., &c., was read at the last annual Pharmaceutical Conference at York, England. The author stated that for the past thirteen years all letters, reports, &c., that he had written had been transcribed into an ordinary thin-paper copying-book with no more effort than was employed in using apiece of blotting-paper. It had only been necessary to place the page of writing, note size, letter size, or even foolscap, in the letter-book, and use a leaf of the letter-book just as one would use a leaf of blotting-paper. The superfluous ink that would go into blotting-paper went on to the leaf of the letter-book, and, showing through the thin paper as usual, gave, on the other side of the leaf, a perfect transcript of the letter. Any excess of ink on the page, either of the letter or of the copying paper, was removed by placing a sheet of blotting-paper between them and running one's hand firmly over the whole in the ordinary manner.

This ready transcription was accomplished, as would be anticipated, by using ink which dried slowly. Indeed, obviously, the ink must dry sufficiently slowly for the characters at the top of a page of writing to remain wet when the last line was written, while it must dry sufficiently fast to preclude any chance of the copied page being smeared while subsequent pages were being covered. The drying must also be sufficiently rapid to prevent the characters "setting off," as printers term it, from one page on to another after folding.

The author then alluded to some difficulties attending the employment of the ink which had prevented its becoming an article of wholesale trade, but, he said, any chemist and druggist could make it and sell it, giving directions for use to customers. He himself had used it from year's end to year's end without any trouble whatever. It would be particularly useful to professional men and private persons.

The principle of the method of preparation consisted in dissolving a moderately powerful hygroscopic substance in any ordinary ink. After experimenting on all such substances known to him, he gave the preference to glycerin. Reduce, by evaporation, ten volumes of ink to six; then add four volumes of glycerin. Or manufacture some ink of nearly double strength and add to any quantity of it nearly an equal volume of glycerin.

SECONDARY BATTERIES.—J. Rousse.—In order to accumulate electricity for the production of light or motive power, the author has arranged secondary batteries, which differ from those of M. G. Plant. At the negative pole he uses a sheet of palladium, which, during the electrolysis, absorbs more than 900 times its volume of hydrogen. At the positive pole he uses a sheet of lead. The electrolysed liquid is sulphuric acid at 1-10th. This element is very powerful, even when of small dimensions. Another secondary element which has also given good results, is formed at the negative pole of a slender plate of sheet-iron. This plate absorbs more than 200 times its volume of hydrogen when electrolysed in a solution of ammonium sulphate. The positive pole is formed of a plate of lead, pure or covered with a stuatum of litharge, or pure oixide, or all these substances mixed. These metallic plates are immersed in a solution containing 50 per cent of ammonium sulphate. Another arrangement is at the negative pole, sheet-iron; at the positive pole a cylinder of ferro-manganese. The electrolysed liquid contains 40 per cent ammonium sulphate.

CONSTITUTION OF THE MILKY WAY.—When the milky way is regarded with an indifferent eye, it seems that its brightness is the same in all parts. But it is quite otherwise when the relative luminous intensity of its different portions is measured. It is then found that the milky way is composed of a series of luminous plates separated from each other by darker portions. Thirty-three of these nodules have been counted, the centre of which is more brilliant than the borders, and it is stated that they are arranged nearly mathematically along a great circle of the celestial sphere.

AN EXPLANATION.

To the Editor of "SCIENCE."

DEAR SIR,—In giving the specific rotatory power in my article "Amylose" in SCIENCE of Oct. 1st this year, I used the expression (a) to designate the specified rotatory power for the *teinte de passage* since that is the usual ray employed. On the other hand I used (a)j to designate the same property for the yellow ray, meaning by the yellow ray the monochromatic sodium flame.

Since, however, it is the usual custom to designate the "rose-purple" transition tint by (a)j as if it were a yellow ray and the sodium ray by (a) D, I desire to make this explanation of the symbols used.

Respectfully,

H. W. WILEY.

LAFAYETTE, IND., *Nov.* 5, 1881.

OBSERVATIONS AND RESEARCHES ON BLOOD-STAINS.—D. Vitaci—Attention has been recently called to a reaction discovered by Schœbein—the blue coloration produced by a mixture of oil of turpentine and alcoholic tincture of the resin of guiacum, on the additionof a little blood or a very dilute solution of hæmoglobin. It is said that this reaction is preferable to any other, not excepting that founded on the formation of crystals of hæmine and on spectroscopic observation, and that none of the substances capable of simulating blood-spots give the same opaque blue color. The author, however, shows that all substances capable of acting as direct or indirect oxidising agents are capable of producing the same reaction.

This satellite is therefore near the predicted place. An hour later Phobos seemed to be visible, also near the computed position, but the sky had become a little thick and I could not be certain of seeing this satellite.

The planet will continue to approach the earth until December 21, and the satellites will become brighter. It is possible, therefore, that they may be observed for nearly two months during the present opposition.

THEORY OF THE MOON'S MOTION.*

About a year ago the Vice-President of the Physical Section of our chief scientific association remarked, in his farewell address: "there are many subjects in astronomy that need investigation, but in most cases the labor required is very great, and the completion of the work would occupy a long time. * * * The lunar theory has been a vexed question for the last two centuries, and may remain so for a long time to come." If persistent, painstaking, and conscientious effort have aught to do with such a matter, we must add to the list of distinguished lunar theorists, including Plana, Damoiseau, Hansen, and Delaunay, the name of Stockwell. We cannot say that his researches have yet met with that notice to which they are perhaps rightly entitled. Mr. Stockwell has published a number of monographs on many points connected with the lunar theory during the last six or seven years; and his works show great familiarity with, and expertness in, the involved computations of this sort of astronomical research.

If we may judge from the appearance of the pamphlet before us, Mr. Stockwell has now quite terminated his lunar investigations, and intends to complete the publication of his finished theory of the moon's motion at some early date. In his Introduction he has sketched the early historic development of the question with that explicitness which we should expect rather to have seen in some thorough elementary text-book; strangely, he devotes twice as much space to the ante-Newtonian aspect of the problem as to the most remarkable developments of the mathematical theory which have occurred since his time. He makes no mention of Damoiseau, who takes high rank not only among pure lunar theorists, but among the constructors of tables of the moon. His tables are well known to have been the first ever constructed from pure theory.

Though the age of the great lunar investigators is now gone, there are some very surprising results of Mr. Stockwell's "new method of analysis" to which the attention of the few theorists now working at the moon's motion might well be directed. He instances several comparisons of the values of his co-efficients with those obtained by Delaunay in his very refined development; in one case he obtains, by a rapidly-converging series of four terms, a result identically the same with that of Delaunay's series of seven terms; and remarks, "the four terms of my development are more accurate than the seven terms of Delaunay's, since the seventh term of the latter series is thirty times greater than the fourth term of the former." There is nothing new in the fact that the sum of a very small number of terms should come out equal to a very large series, but if theorists can be brought to acknowledge the essential accuracy of the "new method," Mr. Stockwell must no doubt be credited with effecting an enormous advance in mathematical astronomy. Mr. Stockwell has shown satisfactorily to himself the correctness and value of his method, and the facility of its application—he must now address himself to the equally difficult task of making others see it in the same light.

It seems a wholesale assertion on the part of Mr. Stockwell that there are "several terms of considerable magnitude in the theories of La Place, Plana, Pontécoulant and Delaunay, which are not functions of the disturbing force;" and we should, at first blush, be inclined to place much confidence in his demonstration that the general integral assumes the indeterminate form in special cases which occur in those theories. It is certainly a most important oversight, and leads us to believe that the lunar theorists who followed La Place would have done much better to have built up theories of their own with entire independence of what anyone else had done. It is a remarkable fact if this discovery has been left for Mr. Stockwell to make. He concludes: "if the computations of the present work are correct, astronomers have carried their approximations to terms of the *fifth*,

* John N. Stockwell, Ph. D. (Introductory.)

sixth, and *seventh* orders of magnitude, before those of the *third* and *fourth* had been correctly computed. This seems to be a sufficient reason for the nearly stationary condition of the lunar theory during the past three-quarters of a century, notwithstanding the great efforts which have been made to perfect its solution. Its advancement has been blocked by the obstacles thrown in its path by analysis itself; and we may therefore reasonably hope for substantial improvement in the theory and tables when they are no longer embarrassed with equations which have no existence in nature."

We may remark that there are two ways in which the correctness of Mr. Stockwell's conclusions may be tested: first, a mathematical expert competent to pronounce upon his theoretic processes should go over his work with the most searching criticism in every detail; and second, his theory should be compared with observations. But this latter would be a task of such immensity that no astronomer unassisted would hope for its completion.

NEW YORK ACADEMY OF SCIENCES.

Oct. 31, 1881.

The President, Dr. J. S. Newberry, in the Chair.

Twenty persons present.

The following paper was read by Mr. John H. Furman:

"The Geology of the Copper Region of Northern Texas and the Indian Territory."

The well-marked cretaceous beds of Parker County, Texas, extend for 30 miles north of west from Weatherford, on the road to Graham. They consist of strata of shelly limestone, sandstone and shaly clay, the latter grayish or reddish in color. An occasional thin seam of soft coal is found; and the water is strongly impregnated with lime. A stratum of sandstone stretches for thirty miles N. W. from Fort Worth. In this rock springs are found containing sodic carbonate, similar to the waters of the artesian wells of Fort Worth, Tarrant County, at a depth of about 270 feet. Towards Graham, the country assumes a semi-mountainous appearance, and, for twenty-five miles or more, sandstone ridges alternate with prairies, the hills being covered with scrub oak. Some of the ridges attain an elevation of two or three hundred feet above the prairies. The strata are horizontal, and large portions of the original surface have been carried away by erosion. The upper stratum is in many places a conglomerate, made up of small pebbles. In this region the seams of coal met with are generally soft, and the only workable bed known is one about three feet thick, yielding a fair quality of bituminous coal, which crops out and has been traced for several miles near the Clear Fork of the Brazos river in Young County. This supposed coal region has a general N. E. and S. W. direction.

Approaching Graham the prairies begin to resemble the plains; and the ridges, capped with sandstone, show bases of mottled reddish-colored shales, or clay; salt springs and salt streams are found, indicating the border of the great alkaline region. From Graham to Fort Griffin in Shackleford County, thence north in Throckmorton County, the country rises. Every few miles a steppe is mounted, the face of the escarpments showing horizontal thin limestone strata. The same features continue, and then the country slopes towards the Brazos river.

Turning westward through Haskell County, the surface lowers again towards the Brazos, the river coursing south to north, and a plain is crossed, the ground differing from any observed. The soil is mixed and covered with gravel, in many places several feet deep. The pebbles vary in size from half an inch to an inch and a half in diameter, and consist of feldspar quartz, porphyry, and basalt. On the western side of Haskell County the copper bed is reached not far from the Brazos river; and west of the copper a great belt of gypsum hills, several miles in width, extends northward, parallel with the copper bed, into the Indian Territory. Gypsum occurs there in most of its forms, including selenite which has been locally mistaken for mica.

On reaching a scene of attempted mining operations in search of supposed veins of copper, a very short examination convinced me that no vein would ever be discovered. Denudation has laid the bed bare, sweeping away the larger portion uncovered and leaving only patches; but these were sufficient to give a clear conception of the mode of occurrence. The copper-bearing stratum is an ashy-colored clay shale, more or less tinged with green, the upper portion showing the deep green carbonate of copper, usually two or three inches thick. Overlying this stratum is a cap-rock of gypsiferous sandstone, about three feet thick, with a layer ⅛ to ¼ inch thick, impregnated with carbonate of copper, as though it had soaked it up from below. Underneath the gray or green bed an intensely red clay shale is generally found. Nuggets of copper are scattered over the surface of the red bed, with pieces of cuprified wood and nuggets of iron pyrites. In the wood the original structure in many instances is perfectly preserved, also appearing cuprified in all stages of decay, as though it had become half rotten before the petrifaction was effected. The overlying sandstone frequently contains biscuit-like concretions of gypsum. Juniper trees abound and also cover the gypsum hills, the perfectly preserved cuprified wood, with its knots and bark, showing a fac-simile of that growth. I found in the gray bed fragments of wood partially unaltered, as though it had just commenced to absorb copper; also large pieces of coal, three or four inches or more in diameter, the cracks of the same piece being filled with crystalline carbonate of copper, or with white gypsum, thus appearing veined with copper and gypsum. In parts of the bed remaining the resemblance to piles of ashes and charcoal is strikingly deceptive; in one shaft, sunk to a depth of about thirty feet, the horizontal position of the strata was confirmed, the shaft passing through the cupriferous gray bed, and then through a succession of layers of red shale and soft red sandstone, in which not a trace of copper was found. The gray stratum extends seventy-five feet or more under a point of the gypsum hill. In a tunnel traversing this stratum I noticed occasionally pebbles belonging to the gravel drift. This copper formation has a general north and south course, usually less than fifty yards in width, and was traced for a distance of eight or ten miles to the southern boundary of Haskell County.

At one point the gray bed lies between beds of sandstone; the red bed does not appear, and the underlying sandstone strata are almost white, laminated, and very hard. The bed is more than two miles distant from the gypsum hills; the gravel drift is noticeable and even abundant. Observing the nuggets of copper ore and the drift pebbles lying about in places on the red bed, the idea forced itself upon me that there might be a remote connection between the two. However, the nuggets of ore are evidently concretions, and no pebbles occur in the gray bed. The gypsum range extends several miles across, with a western declivity similar to that on the eastern side. A plain, a little over one hundred feet below, reaches beyond to the foot of the great Llano Estacado. On these hills and on this western plain the gravel drift is wanting.

The copper bed was traced five miles further to the north; also in Knox county, not far from the Wichita river, and forty miles or more north of the southern portion of Haskell county, besides learning its supposed occurrence north of the Wichita river. The copper band

here lies between the sandstone and gray bed, with the red beds beneath. Eastward, between the Brazos and Wichita rivers, the gravel drift is abundant, with many stones of greater diameter. At the "Narrows," between the Wichita and Brazos rivers, the width is only sufficient to admit the passage of a single wagon. Continued caving in of the bluffs of the two rivers has widened an immense eroded area, rendering a large surface valueless, and while the channels of the rivers are several miles apart, their junction is only a question of time. In the copper region of the little Wichita river, near the centre of Archer county, the ore occurs under the same general conditions, with a different course, N. E. and S. W. and copper nuggets, coal and cuprified wood are found.

Embedded in the overlying sandstone, in some instances several feet above the gray bed, the sandstone frequently attains a thickness of more than fifteen feet. The cuprified wood is altogether different from that of Haskell county, and resembles the wood of the mesquite tree, which I found scattered about. The gravel drift here is identical in character with that of the region further west, and pebbles occur in the gray copper-bearing bed beneath the sandstone. The extension of the gravel drift of Haskell county, beyond the Brazos river system, its absence west of the gypsum hills, the larger size of the pebbles in Knox county, bordering the Wichita river, and the occurrence of the drift only in the vicinity of the copper-bearing lines mentioned, and in Archer county, suggested to me a possible relationship of some kind between the two, perhaps their origination in the same region.

Between the Wichita and Pease Rivers I crossed several copper-bearing beds, having a general northeast and southwest direction. In Wilbarger County the gravel drift is in great quantity, and boulders from three to seven inches in diameter occur. In places, and having a northeast and southwest bearing, heavy deposits or lines of gravel and boulders attract attention, appearing as though a great flow towards the southeast had met obstructions along its course, the great incline of this region being directed toward the southeast. Beyond Pease River the gravel drift lessens, but the large boulders are occasionally seen as far west as the gypsum hills. Not far north from the centre of Hardeman County I again found the Haskell County copper bed, the accompanying sandstones being thin and much mixed with gypsum. The copper bed reaches higher than the surrounding country, except the gypsum hills to the west. From this high locality of the copper, known as Prairie-dog Mounds, the country inclines on one side northward to a creek emptying into Red River, and on the other side southward to the Pease River.

South of these mounds, where only here and there patches of the bed are preserved in the midst of a general erosion, I found the largest mass of copper ore thus far discovered, consisting of an aggregation of cuprified wood, resembling the trunk of a tree, more than one foot in diameter. Beyond Red River the bed continues to the vicinity of the Salt Fork of Red River, distant but little over 20 miles from the Wichita Mountains of the Indian Territory. The bed probably continues nearly to the western end of these mountains, and here must be found the true centre of elevation and the origin of the gravel drift. The Haskell County copper bed was also traced south to the Wichita River, thus establishing its continuity from the southern portion of Haskell County, through Knox and Hardeman Counties, into the Indian Territory, a length of more than 100 miles. Subsequently, the northern end of the bed was found a short distance from the western end of the Wichita Mountains, on the south side of the range. The copper formations of Archer and Wichita Counties continue through Clay County to the Red River boundary of the Indian Territory. The gravel drift does not extend to the north of the Wichita Mountains, but a limestone district occurs about 20 miles in width, that reaches probably as far out to the north, from the Wichita Range, the course of the latter being east and west. This limestone area may be called mountainous, is much disturbed and tilted, and is similar in appearance to the metalliferous limestone formation of Mexico. The Wichita Mountains are mainly made up of porphyries, trachytes and basalt, and appear to be two parallel ranges with transverse ranges and small valleys between. About 12 miles west of Fort Sill an extensive body of hornblende slate makes its appearance between the two main ranges. The drift from the mountains extends to the south and southeast. It is found as far west as the Haskell County copper bed, and as far east as the Archer County copper bed is known. The river channels of that section of the country have been formed since this drift period. The development of the Wichita Mountains seems to have marked the close of a period of uplift and simultaneous erosion.

These mountains have the same general appearance as the Rocky Mountains, which pass through the western portion of Texas and the State of Coahuila, Mexico; and it has been a matter of much interest to observe that similar drifts of local origin are frequently met in the latter regions. The Wichita Mountains appear to be identical in origin with the Rocky Mountains, and constitute the most eastern spur of that system. In Northern Mexico short ranges are encountered, striking east and west, and of these the Wichita Mountains appear to be a reproduction. The Wichita Mountains will be found to contain mineral deposits, possibly of some value; veins of copper ores do exist 40 miles west of Fort Sill, near Otter Creek, in the mountains; but I am convinced that the copper bed or stratum of Northern Texas will prove of no commercial importance.

Prof. Newberry remarked that the communication of Mr. Furman was of great interest, since no accurate description had before been given of the geological

structure of the region where the copper occurs in northern Texas and the Indian Territory. He had received specimens from that region long ago and recognized their similarity to the copper ores of New Mexico, where in the upper portion of the Triassic formation copper forming concretions and replacing wood occur in many localities, and have been more or less mined for. In one locality near Abiquini very extensive galleries have been cut in the sandstone in search of copper which there replaces branches and trunks of trees and forms concretions which are irregularly scattered through the rock. Here the work was done by the early Spanish explorers perhaps 200 years ago, and the remains of the furnaces in which the copper was smelted are still to be seen at the mouth of the mine. Still further west, in southern Utah, the same formation carries copper and considerable silver, at Silver Reef enough to pay well for mining, but in no locality yet known are the deposits of copper ore sufficiently concentrated and continuous to make mining for that material profitable, so it would doubtless be found in Texas and the Indian Territory. The copper was deposited with the Triassic rocks from a shallow sea in which an unusual quantity of copper was held in solution. This impregnated the sediments found at the bottom replacing wood and forming as nodules about some nucleus. The aggregate quantity of copper in this formation was enormous, but, except where by the erosion of the beds it accumulated at the surface and could be picked up without any expense in mining, it would hardly pay to attempt to obtain it by ordinary mining processes.

The wood replaced by copper Dr. Newberry said was undoubtedly all coniferous, and different from any now living. The beds which contained the cuprified wood also contained much that was silicified. Of this he had examined many specimens under the microscope and had found the peculiar dotted cells which are characteristic of the coniferæ, and these grouped in such a way as to prove the trees to have belonged to the Araucarian group of conifers. So far as yet known the angiosperms, or higher order of plants, did not make their appearance on the earth's surface until after the copper bearing rocks of the southwest had been deposited.

THE AMERICAN CHEMICAL SOCIETY.

The November meeting of this Society was held on Friday evening, November 4th, with Vice-President Leeds in the Chair.

The following gentlemen were duly elected members: Dr. C. W. Volney, Dr. Witthaus, Messrs. C. E. Munsell, W. W. Share, J. D. O'Connor, and Day. The first paper of the evening was "On some New Salts of Thymole Sulpho-acid, and some new facts concerning the same," (a second paper) by Mr. J. H. Stebbins, Jr., S. B. The sodium salt having the formula

$$C_6H_2\,(CH_3)\,(C_3H_7)\,(NaSO_3)\,O\,Na+2\tfrac{1}{2}H_2O$$

was described, and also the free sulphur salt had its characteristics enumerated.

Mr. Stebbins followed with a second paper "On the Combination of Diazo Compounds with Thymole Sulpho-Acid."

In this he described the experiments which he performed in his work, the results of which were given in the first paper. Both were technical and not of any popular interest.

The third paper was by Dr. C. W. Volney, and was entitled, "The Constitution of the Explosive Derivatives of Glycerine."

In this communication the author tried to prove that the nitro-glycerine was composed by the substitution of the nitrogen trioxide (NO_3) instead of the nitrous oxide NO_2, making the formula $C_3H_5\,(NO_3)_3$ instead of $C_3H_5\,(NO_2)\,O_3$, and secondly, he showed how it was possible to substitute chlorine for the nitrogen trioxide and so produce a new explosive compound.

This paper provoked much discussion on account of the theoretical arrangement of the atoms necessary to sustain Dr. Volney's statement.

Subsequently the Committee on Nominations reported that the following ticket was recommended to the Society for their votes at the December meeting.

Corresponding Secretary.— P. Casamajor.

Recording Secretary.—J. H. Stebbins, Jr.

Treasurer.—M. Alsberg.

Librarian.—Geo. A. Prochazka.

Curators.—A. J. Rossi, Wm. Rupp, A. A. Fesquet.

Committee on Publications.—Arno Behr, A. R. Ledoux, H. Endemann.

Committee on Nominations.—A. H. Elliott, O. H. Krause, J. P. Battershall, J. B. F. Herrishoff, T. O'C. Sloane.

Board of Directors.—P. Casamajor, J. H, Stebbins, Jr., H. Morton, C. F. Chandler, M. Alsberg, E. R. Squibb, W. H. Nichols, W. H. Habershaw, E. Waller, A. H. Gallatin, Geo, A. Prochazka.

ON THE NATURE OF THE DIPHTHERITIC CONTAGIUM.

By Dr. H. C. Wood.

The lecturer began by stating that the researches which formed the basis of the present address had been made under the auspices, and, indeed, at the suggestion, of the National Board of Health, by Dr. Henry F. Formad and himself, who were jointly responsible for the facts and inductions and jointly deserving of whatever reprobation or approbation might be due. The full text of the work is now in the hands of the National Board, and will be shortly published by them as an appendix to their annual report, and the lecturer desired that criticism be withheld until this was done, as the memoir will contain much that cannot be spoken of in the present lecture.

In the spring of 1880 work was begun by inoculating rabbits with diphtheritic membrane taken from the throats of patients at Philadelphia. An account of the labors of the following summer has been already published, but it seems necessary to epitomize them here. It was found that only in a very few cases was anything like diphtheria produced in the rabbit by inoculating with the membrane. The inoculations were practised by putting pieces of the material sometimes under the skin, sometimes deep in the muscles. Many rabbits died after some weeks, not of diphtheria, but of tuberculosis. In a series of experiments it was shown that this tuberculosis was an indirect and not a direct result of the inoculation, and that any apparent relation between the two diseases is only apparent, not real. Next, the tracheas of a series of rabbits were opened and false membrane inserted. It was found that under these circumstances a severe trachitis was frequently produced, and was attended by an abundant formation of pseudo-membrane. Careful studies made of the false membrane of diphtheria and of this false membrane showed that the two were identical, both containing in abundance fibrin fibres, corpuscular elements, and various forms of micrococci. To determine whether other inflammations of the trachea than that caused by diphtheria or its membrane are accompanied by the formation of false membrane, a number of experiments were made, and it was demonstrated that the production of false membrane has nothing specific in it, but that any trachitis of sufficient severity is accompanied by this product. Careful studies also showed that this false membrane does not differ in its constitution from that of true diphtheria, except it be that the micrococci are not so abundant in it. We always found some micrococci, and in some of these traumatic pseudo-mem-

*An address made before the Academy of Natural Sciences.

branes they were almost as numerous as in the diphtheritic exudation.

Last spring we resumed our investigations. Having heard that there was a very severe epidemic in Ludington, Mich., Dr. Formad was dispatched to examine cases and collect material. He found a small town situated upon the shore of Lake Michigan, in the centre of the lumber region, with inhabitants mostly engaged in the lumber trade and in managing very numerous large sawmills. The town was all built upon high ground except the Third Ward. This occupied a low swamp which had been filled in largely with sawdust. The soil was so moist that a hole dug in it would fill at once with water, and but few houses had any attempts at cellars. It was in this district that the disease had prevailed. Almost all the children had had it, and one-third of them were said to have died. Dr. Formad examined a large number of cases, obtained a supply of diphtheritic membrane, and brought home pieces of the internal organs of a child upon whom he had made an autopsy. In every case the blood was found more or less full of micrococci, some free, others in zoogl œa masses, others in the white blood-corpuscles. The organs brought home also all contained micrococci, which were especially abundant in the kidneys, where they formed numerous thrombi, choking up and distending the blood-vessels. In the summer of 1880 we examined the blood of several cases of endemic Philadelphia diphtheria, and in no case found any new elements in it. But during the present summer we have found micrococci in the blood of Philadelphia diphtheritic patients, showing the differences in the disease are simply in degree, not in kind.

Experiments were now made with the Ludington material upon animals. Inoculations were practised under the skin, deep in the muscles, and in the trachea. In all cases the results were similar. A grayish exudation appeared at the seat of inoculation, along with much local inflammation, the animal sickened, and in the course of a few days death occurred. The local symptoms increased and widened. In some cases the false membrane spread from where the poison had been put in the trachea up to the mouth. The blood examined during life or after death was found to contain micrococci precisely similar to those found in the Ludington cases, and in a few instances micrococci were found in abundance in the internal organs. Studies made upon the blood of these animals, as well as upon the Ludington cases, show that the micrococci first attack the white blood-corpuscles, in which they move with a vibratile motion. Under their influence the corpuscles alter their appearances, losing their granulations. They finally become full of the micrococci, which now are quiescent, and increase until the corpuscle bursts and the contents escape as an irregular, transparent mass full of micrococci, and form the so-called zoogl œa masses. In the diphtheritic membrane the micrococci exist frequently in balls, and it is plain that these collections are merely leucocytes full of the plant. The bone-marrow of the animals were found full of leucocytes and cells containing micrococci.

The question now arose, is the disease produced by diphtheritic inoculation in the rabbit diphtheria? We concluded that it is, because the poison producing it is the same, the symptoms manifested during life are the same, and the post-mortem lesions are identical. The contagious character of the disease is retained, as we succeeded in passing it from rabbit to rabbit.

Our next series of experiments were directed to determining whether the micrococci are or are not the cause of the affection. The experiments of Curtis and Satterthwaite, of New York, have shown that the infectious character of diphtheria depends upon its solid particles; for when they filtered an infusion of the membrane it became less and less toxic in proportion as the filtration was more and more perfect; and when the infusion was filtered through clay, the filtrate was harmless.

The urine of patients suffering from malignant diphtheria is full of micrococci, and may contain no other solid material. Following the experiments of Letzerich, we filtered this urine and then dried the filter-paper. Upon experiment we found this even more deadly in its effects than is the membrane. The symptoms and lesions following in the rabbit inoculation with such paper are precisely those which would have ensued had a piece of diphtheritic kidney or membrane been employed. This experiment shows that the solid particles of the membrane, which are the essential poison of malignant diphtheria, are the micrococci, which must be either the poison itself or the carriers or producers of the poison.

Leaving for a while this point, I will next direct your attention to our culture-experiments. These were performed in the manner commenced by Klein and that recommended by Sternberg. The first method seems to us the best for the purpose of studying the development of the micrococcus itself; the second the best for the obtaining of it in quantity for experimentation.

We cultivated micrococci from the surface of ordinary sore throats, from furred tongue, from cases of mild diphtheria as we commonly see it in Philadelphia and from Ludington cases. We found, in the first place, that there were no differences to be detected in the general or special appearance of the various micrococci, and no constant differences in size. We found that they all formed similar shapes in the culture apparatus; they had this difference, however,—whilst the Ludington micrococci grew most rapidly and eagerly generation after generation up to the tenth, those from Philadelphia diphtheria ceased their growth in the fourth or fifth generation, whilst those taken from furred tongue never got beyond the third transplantation. Various culture-fluids were used, but the results were identical. We conclude, therefore, that as no difference is detectable between the micrococci found in ordinary sore throat and those of diphtheria, save only in their reproductive activity, they are the same organisms in different states. As the result of some hundreds of cultures, we believe that the vitality of the micrococci under artificial culture is in direct proportion to the contagious powers of the membrane from which they have been taken. We have made many inoculations with cultivated micrococci and have succeeded in producing diphtheria with the second generation, but never with any later product. This success, taken in conjunction with the urine experiments already spoken of, seems to us sufficient to establish the fact that the micrococci are the *fons et origo mali* of diphtheria. The experiments of Pasteur and others have proven that it is possible for an inert organism to be changed into one possessed of most virulent activity, or *vice versa*, and we believe that we can offer direct proof that the micrococci of the mouth are really identical in species with the micrococci of diphtheria, and do not merely seem to be so. We exposed the Ludington membrane for some weeks to the air in a dried condition. There was no putridity or other change detectable in it; but, whereas formerly it had been most virulent, now it was inert, and its micrococci not only looked like those taken from an ordinary angina, but acted like them. They were not dead, they had still power of multiplication, but they no longer grew in the culture-fluid beyond the third or fourth generation. Certainly they were specifically the same as they had been, and certainly therefore the power of rapid growth in culture-fluids and in the body of the rabbit is not a specific character of the diphtheria micrococcus.

As is well known, Pasteur attributes the change from an active to an inert organism to the influence of the oxygen of the air upon the organism. Whether this be true or not of the diphtheria micrococcus is uncertain, but the effects of exposure of the dried membrane seem to point in such direction.

With the facts that are known in regard to the clinical history of diphtheria and those which we have determined in our research, it is easy to make out a theory of the disease which reconciles all existing differences of opinion and seems to be true.

A child gets a catarrhal angina or trachitis. Under the stimulation of the inflammation products the inert micrococci in the mouth begin to grow; and, if the conditions be favorable, the sluggish plant may be finally transformed into an active organism, and a self-generated diphtheria results. It may be, however, that by appropriate treatment such a case is arrested before it fairly passes the bounds of an ordinary sore throat. Every practitioner knows that such diversity does exist. Again, conditions outside of the body favoring the passage of inert into active micrococci may exist, and the air at last become well loaded with organisms, which, alighting upon the tender throats of children, may begin to grow and themselves produce violent angina, trachitis, and finally fatal diphtheria.

In the first instance we have endemic diphtheria as we see it in Philadelphia; in the second, the malignant epidemic form of the disease as it existed in Ludington. It is also apparent that in the endemic cases the plant whose activity has been developed within the patient may escape with the breath, and a second case of diphtheria be produced by contagion. It is also plain that as the plant gradually in such a case passes from the mild to the active state, there must be degrees of activity in the contagium, one case being more apt to give the disease than is another; also that the malignant diphtheria must be more contagious than the mild endemic cases. We think there is scarcely a practitioner who will not agree that clinical experience is in accord with these logical deductions from our experimentally determined premises.

It yet remains for us to investigate as to what are the conditions outside of the body which will especially favor the production of active micrococci, and also to study the effects of agents in killing these organisms; for it is very apparent that local treatment of the throat must often be of the utmost importance, and that it will be far more effective if it be of such character as to kill the micrococci, and not simply be anti-phlogistic in its action.

SOLAR PARALLAX.

In an elaborate paper, given in full in the *American Journal of Science*, for November, Professor William Harkness draws the following conclusions:—

For convenience of reference the limiting values of the solar parallax, found by the various methods described in the foregoing pages, are presented here. It should be remarked, however, that in selecting these values the results of all discussions made prior to 1857 have been omitted; except in the case of the transit of 1761, and the smaller of the two values from the transit of 1769.

I.—Trigonometrical methods.

Mars, meridian observations	8″.84	—	8″.96
" diurnal observations	8.60	—	8.79
Asteroids	8.76	—	8.88
Transit of Venus, 1761	8.49	—	10.10
" " 1769	8.55	—	8.91
" " 1874	8.76	—	8.85

II.—Gravitational methods.

Mass of the earth	8″.87	±	0″.07
Parallactic Inequality	8.78	—	8.91
Lunar Inequality	8.66	—	9.07

III.—Photo-tachymetrical methods.

Velocity and light equation	8″.72	—	8″.89
Velocity and Aberration	8.73	—	8.90

To obtain a definite value of the solar parallax, it would now be necessary to form equations of condition embodying the relations between the various elements involved; to weight these equations; and to solve for it by the method of least squares. But what is the use? It is perfectly evident that by adopting suitable weights, almost any value from 8″.8 to 8″.9 could be obtained, and no matter what the result actually was, it would always be open to a suspicion of having been cooked in the weighting. We only know that the parallax seems to lie between 8″.75 and 8″.90, and is probably about 8″.85. Attack the problem as we will, the results cluster around this central value. All the methods give a probable error of about ±0″.06, and no one of them seems to possess decided superiority over the others. We have nearly exhausted the powers of our instruments, and further advance can only be made at the cost of excessive labor.

In the beginning of the eighteenth century the uncertainty of the solar parallax was fully two seconds; now it is only about 0″.15. To narrow it still further, we require a better knowledge of the masses of the earth and moon, of the moon's parallactic inequality, of the lunar equation of the earth, of the constants of nutation and aberration, of the velocity of light, and of the light equation. All these investigations can be carried on at any time, but there are others equally important which can only be prosecuted when the planets come into the requisite positions. Among the latter are observations of Mars when in opposition at its least distance from the earth, and transits of Venus.

In 1874 all astronomers hoped and believed that the transit of Venus which occurred in December of that year would give the solar parallax within 0″.01. These hopes were doomed to disappointment, and now, when we are approaching the second transit of the pair, there is less enthusiasm than there was eight years ago. Nevertheless the astronomers of the twentieth century will not hold us guiltless if we neglect in any respect the transit of 1882. Observations of contacts will doubtless be made in abundance, but our efforts should not cease with them. We have seen that the probable error of a contact observation is ±0″.15, that there may always be a doubt as to the phase observed, and that a passing cloud may cause the loss of the transit. On the other hand, the photographic method cannot be defeated by passing clouds, is not liable to any uncertainty of interpretation, seems to be free from systematic errors, and is so accurate that the result from a single negative has a probable error of only ±0″.55. If the sun is visible for so much as fifteen minutes during the whole transit, thirty-two negatives can be taken, and they will give as accurate a result as the observation of both internal contacts. In view of these facts, can it be doubted that the photographic method offers as much accuracy as the contact method, and many more chances of success?

The transit of 1882 will not settle the value of the solar parallax, but it will contribute to that result, directly as a trigonometrical method, and indirectly through the gravitational methods with which the final solution of the problem must rest. As our knowledge of the earth's mass may be made to depend upon quantities which continually increase with the time, it will ultimately attain great exactness, and then the solar parallax will be known with the same exactness. Long before that happy day arrives the present generation of astronomers will have passed over to the silent majority, but not without the satisfactien of knowing that their labors will contribute to that fullness of knowledge which shall be the heritage of their successors.

EPHEMERIS OF THE SATELLITES OF MARS FOR THE OPPOSITION OF 1881.*

By H. S. Pritchett.

Owing to the greater distance from the Earth and the Sun, the present opposition of Mars will not be so favorable as the two preceding ones ; still these distances will be sufficiently small to permit many useful observations of physical phenomena, and, in the case of large telescopes, observations of the satellites. In one respect, the planet is much more favorably situated than in the former oppositions referred to, since it reaches this year a declination of 26° north, and hence will be observed at a much higher altitude. Physical observations, either measures or drawings, by amateur astronomers with good glasses, if carefully made and published, will be useful when finally reduced and compared.

During the last opposition several series of micrometric measures of the diameter of the planet were made by observers with good telescopes which showed curious differences both between themselves and when compared with the results obtained from the heliometer. Some of these measures seemed to show an appreciable flattening at the poles, while others showed no such flattening. It will be interesting to have these measures repeated during the present opposition, with a careful discussion of the sources and effects of personal error.

The satellites were observed last opposition with at least one of the large reflectors, with the great refractor at Washington, with the 15-inch refractor of the Harvard College Observatory, and with the 12¼ inch refractor of the Morrison Observatory, and were seen with other instruments. Before December 1st of this year the satellites will be considerably brighter than when last observed in 1879 with the Harvard College refractor, and also brighter than when last observed with the Morrison Observatory refractor. It seems possible, therefore, that they may be seen this year with telescopes even of moderate size.

The following ephemeris (derived from the elements of Prof. A. Hall, A. N. No. 2394) has been computed at the request of several observers, and will be found convenient for any who may wish to observe these satellites. In connection with the discussion of the relative merits of reflectors and refractors, excited by the observations of these satellites, it may be interesting to many to try if they can see them.

In the case of Deimos, the outer satellite, the ephemeris gives the Washington mean times of the east and west elongations, together with the position-angle and distance at the time of elongation. In the case of Phobos only the times of western elongations are given, as the revolution time is very short and the times of eastern elongations may be obtained by a simple interpolation. The aberration time is not included in the time given, but it may be taken from the table at the end if desired, the effect of the aberration being to make the satellites about five minutes late at each elongation. The relative brightness on different days may be obtained from the same table, taking the brightness on Nov. 20 as unity. As was shown by the observations of 1879, Prof. Hall's elements are very nearly correct, so that the correction to this ephemeris will be quite small.

* Read before the St. Louis Academy of Sciences.

Deimos.

From this it will be seen that Phobos, even on the most favorable date, will be only about 14" distant from the limb of the planet. In 1877 this satellite was observed with the 12¼ equatorial of the Morrison Observatory when only 7" distant. In the present opposition the satellite will be much fainter, but on the other hand the brightness of the planet will be considerably diminished. It seems possible, therefore, that this satellite may be seen with glasses of moderate size.

WASHINGTON UNIVERSITY, *Nov.*, 1881.

ELEMENTS OF QUATERNIONS.*

BY A. S. HARDY, Ph. D., Professor of Mathematics, Dartmouth College.

The American press may be expected to teem for the next twenty-five years with elementary treatises on quaternions, and as this work of Professor Hardy's is, we believe, the first of the series, it merits on this account the more attention. The book has a quite neat and attractive exterior, and the mechanical execution is very fair, though a few defects in letter press and engraving are noticeable. The experiment of printing small Alphas with an oblique line through them seems to be a failure. See pp. 45 and 60.

We cannot think the title happily chosen. There is an incongruity, if not positive impropriety, in assigning to a scant text-book intended for beginners in the class-room a name associated these fifteen years with the great and classic work of Hamilton. This however, is a matter of taste. One of the most important and difficult steps in the logical development of the calculus of quaternions, to which their inventor gave no little attention, is that of assigning a versor power to a vector, or of representing rotation by a symbol that had hitherto been appropriated exclusively to vection or translation. This, in the book before us, is disposed of in a few lines, when, even in a treatise where brevity must be studied, it is well worthy of as many pages. There is, also, throughout the work, an unfortunate fondness for the plane, where quaternions are often at a disadvantage, and where their real power and usefulness cannot be exhibited. The author may have intended to thus avail himself of the student's greater familiarity with the geometry of the plane, while introducing him to a new method; but it ought to be borne in mind that one of the chief claims quaternions have on the teacher of geometry is that they are specially fitted to free the student from the too prevalent restriction of his conceptions to two dimensions. A curious example of this tendency of the book is afforded near the end in applications to loci. Here the author systematically interprets equations as relating to the conic sections, when in reality they frequently relate to quadrics of revolution, the restriction to plane loci having been eliminated in the process of their formation; and when he comes "to transform the proceeding equations into the usual cartesian forms," instead of substituting a trinomial for the variable vector, he imposes a restriction to two dimensions by adopting a binomial, and of course comes out with a plane section in place of the surface itself. Notwithstanding these imperfections, Prof. Hardy has evidently studied his subject and written his book with some care, and with a view to the requirements and opportunities of those for whom it is intended, and it will doubtless prove useful as an introduction to quaternions.

LARGE TELESCOPES.

PROFESSOR EDWARD C. PICKERING makes the following suggestion in regard to mounting a telescope on a new plan. He says:—"The small amount of work accomplished with large telescopes has often been the subject of unfavorable comment. This criticism applies with especial force in America, where there are nearly a dozen telescopes having an aperture of a foot or over, besides two of the largest size now in course of construction, and two of twenty-six and twenty-four inches aperture which are unmounted and have been for several years perfectly useless. Among so many it seems as if one might be spared for a trial of the following plan, which, if successful, would produce at a small expense far more work than could be obtained with a mounting of the usual form.

Suppose that the telescope is placed horizontally at right angles to the meridian, and that a plane reflector inclined to its axis by 45° is placed in front of it. This reflector may revolve around an axis coinciding with that of the telescope. Such a mounting has been used in transit instruments, and gives much satisfaction in the meridian photometer of the Harvard College Observatory. The principal difficulty with a large instrument would lie in the flexure of the reflector. This difficulty has, however, been overcome in a great measure in reflecting telescopes by various ingenious devices. In the present case, since the reflector rotates only around one axis instead of two, the problem is much simplified. A slight motion at right angles of perhaps 5° would be a great convenience, as will be shown below, and would probably be insufficient to materially affect the flexure. It may be said that it is more difficult to make a plane surface than one that is curved. But the principal effect of a slight curvature would be to change the focus of the telescope, the aberration being much less than the effect of the varying flexure. Let us admit, however, that the best definition cannot be obtained, in considering the purposes to which such an instrument could be applied without disadvantage.

Many advantages will be apparent on comparing such a mounting with an equatorial. Great steadiness would be secured, since the mirror would be the only portion moved, and this would be placed directly upon a low pier. Instead of a large and expensive dome which is moved with difficulty, the mirror would be protected by a small shed, of which the roof could be easily removed. It would therefore be opened and ready for use in a very short time, and would quickly take the temperature of the surrounding air. The object-glass would be mounted directly upon a second pier, and, as it would not be moved, would be in very little danger of accident. The tube could be made of tin or other inexpensive material, as its flexure is of no importance. It could easily be protected from the changes of the temperature so troublesome in the tube of a large equatorial. If preferred it might even be exhausted of air, or filled with hydrogen, and the effect of the changes of temperature thus greatly reduced.

The eyepiece could be mounted on a third pier, and would be so far distant horizontally from the mirror and object-glass that there is no reason that it should not be inclosed in a room which may be warmed. The comfort in winter of working in a warm room will be appreciated by those who have used a large telescope in a cold climate. The result is sure to be an increased precision in

the observations, and a possibility of prolonging them over longer intervals. A similar effect is produced by the constant direction of the line of sight. No especial observing chair is needed. There is no limit to the size of the attachments which may be made to the eyepiece, since they need not be moved. This is a great advantage in certain spectroscopic and photometric measurements. A strong wind interferes seriously with many observations, as it is impossible to make a telescope so stiff that it will not be shaken by sudden gusts. In the plan here proposed the mirror alone is exposed, and its surface is too small to give trouble.

By means of a long handle the position of the mirror may be regulated from the eye-end, and the declination of the object observed read by small telescopes. If the mirror can be moved at right angles to the meridian 5° from its central position, an object at the equator may be followed for forty minutes, and other objects for a longer period. Without this motion an object may be followed for three or four minutes by moving the eyepiece alone. Clockwork may be applied to the mirror, or less easily to the eyepiece. The focal length may be increased almost indefinitely if desired, and certain advantages will be thus attained in the diminution in the defects of the object-glass, although those of the reflector will not be affected. If the telescope is to be erected at a great elevation the advantages of the present plan are at once apparent. Many nights of observation would be secured which otherwise would be lost owing to the wind and cold. The simplicity in the construction of the building would be a great advantage, as a large dome in so exposed a situation would be kept free from snow with much difficulty, and might be a source of danger in winter storms. If found impracticable to observe during the winter, it would be possible to have a duplicate mounting below, and remove the lens and mirror from one to the other.

It is evident that the saving of cost would be very great, not only in the observatory building aud dome, but in the tube, observing chair, clockwork, &c.

If a reflector could be constructed whose surface was the portion of a paraboloid whose abscissa equalled that of the focus, the instrument could be much simplified. No object-glass would then be required, the reflector taking the place both of mirror and lens. All the light intercepted by the objective would thus be saved, and but a single surface need be adjusted and corrected. With the advance in mechanical methods this does not seem wholly impracticable, especially with a mirror of long focus. Since the final correction must always be made by hand, it makes but little difference what is the exact form of the surface.

In any case it would be a great advantage that the mirror could be reground, repolished, or resilvered without moving it from its place. It would only be necessary to place it horizontally, and the grinding machinery could be kept permanently near it. If plane, the perfection of its form could also be tested at any time by setting it on edge, and viewing the image it reflected by a collimating eyepiece attached to the large telescope. Another method would be to place a heliotrope a few hundred yards to the north or south of it, and the light from this would form an excellent artificial star, available whenever the sun shone.

The greatest advantage is the rapidity with which observations could be made. No more time would be lost in identification than with a transit instrument, so that a large number of objects could be examined in the course of a single hour. Any one who has worked with a large telescope knows how much time is lost in opening and closing the dome and in finding and identifying minute objects.

Let us now consider to what purposes a large telescope mounted as suggested might be applied.

1. Sweeping. For the discovery of new objects this mounting presents especial advantages. It might be used for the detection of new double stars, of nebulæ, of red stars, or of objects having singular spectra, as planetary nebulæ, banded stars, and variables of long period. Suppose that the field of view had a diameter of somewhat over one minute of time, and that a small motor was attached to the mirror which would move it uniformly over 5° in declination in this time, and then bring it quickly back to its first position. The observer would then have presented to him a series of zones 5° long and one minute wide. The sweeps should overlap by a small amount, so that the entire region could be covered in a single evening. The observer could have a few seconds rest between each zone, while the motion of the mirror was reversed. If an object of interest was suspected, it could be located by merely noting the time at which it was seen. The right ascension would be given directly, and the declination would be found by interpolation from the time of beginning and ending the sweep. An examination of the object and a determination of its exact location should be made on another evening.

2. Measures of position. For many purposes positions could be determined with this instrument as in a transit circle. It would generally be better, however, to make the measures differential, leaving the mirror at rest and observing the transits of the object to be determined and of two or more companion stars. The method of the ring micrometer might be employed, or some modification of that with inclined lines. In the latter case the zero of position could be found by the transit of preceding stars, by setting the reticule by a divided position circle, or perhaps better by keeping it in a fixed position, determining the direction of the lines once for all, and applying a correction for the declination of the object observed. Stars could be compared differing nearly a degree in declination, as the eyepiece could be moved without danger of disturbing the reticule. For the same reason the star could be followed for three or four minutes, and its transit over a great number of wires observed. It is here assumed that the distortion produced by the mirror is not very great. A slight distortion would do little harm, as it would be the same for all stars of equal brightness. If the stars differ greatly in brightness, the observer should determine his personal equation between them in any case, and the same operation would eliminate the effect of the distortion. The large aperture of the instrument would permit the observation of stars quite beyond the reach of any meridian circle. The faintest asteroids could thus be readily measured, and could probably be followed in many cases on successive evenings to their stationary points. Zones of stars could be observed very conveniently for the formation of charts or catalogues, for the discovery of asteroids, stars with large proper motion, &c.

Probably the definition could not be sufficiently good for the measurement of the closer double stars, but if clockwork was attached, faint companions could be measured, or approximate positions of the coarser pairs determined very rapidly. The positions of nebulæ could also be observed with a view to detecting their proper motion. Stars having a large proper motion might be observed, and the observations so arranged that any very large parallax would be detected. A similar search for a large parallax of variable stars, short-period binaries, minute planetary nebulæ, or stars having singular spectra, might lead to interesting results. The argument that no ordinary star is very near does not apply to such objects.

3. Spectroscopy. The increased dimensions which could be given to the spectroscope, and its steadiness, would compensate in a great measure for a defect in definition. By Zöllner's reversion spectroscope the slit might be dispensed with, and also the necessity of clockwork. So many stars could be observed in a single evening that systematic errors could be in a great measure eliminated, and as the spectroscope would not be moved, we should have a great assurance that the deviations were

real. Of the 6000 nebulæ hitherto discovered we know nothing of the spectrum of more than 300 or 400, while the observation of all the others with a large horizontal telescope would not be a very formidable undertaking. It would also be interesting to observe the spectra of all the clusters. It is possible that some may consist of stars having singular spectra, or even of disconnected nebulous masses, in fact forming clusters of planetary nebulæ. The interesting discovery by Dr. Copeland that Burnham's double nebula in Cygnus is gaseous, shows the same tendency to aggregation in these bodies as in stars. Observations of the spectra of all the red stars and variables would also probably lead to interesting results.

4. Photometry. Should the instrument be devoted to photometry numerous problems suggest themselves. Variable stars could be observed near their minimum when too faint to be identified with an equatorial without great loss of time. Faint stars in zones or faint companions to bright stars could be measured very rapidly. The relative light of all the asteroids would be an interesting problem. Many coarse clusters appear to consist of stars of nearly equal brightness. Their light compared with their distances apart might aid our study of their formation. Another useful investigation would be to measure the brightness of all the nebulæ.

In the application of physics to astronomy doubtless many other problems will suggest themselves. Thus no satisfactory results have been obtained in the attempt to measure the heat of the stars with the tasimeter. The use of this instrument would be vastly simplified if it was placed on a solid pier near the ground, was not moved during the observation, and could be perfectly protected from other changes of temperature than those which it was intended to measure.

As either of the problems proposed above would occupy the time of a telescope for at least one year, it is obvious that there could be no difficulty in keeping such an instrument occupied indefinitely.

The horizontal mounting is especially adapted to an elevated position, and would permit the use of a telescope where an equatorial mounting would be quite impracticable. On the other hand, to an amateur, or for purposes of instruction, an instrument which could be set quickly from one object to another, and where the observers need not be exposed to the cold, would offer many advantages. The impossibility of observing far from the meridian would be less important with a large instrument, where the number of objects to select from is very great.

There are certain purposes to which this mounting could not be advantageously applied. The study of close double stars and other objects requiring long examination and very perfect definition could be better left to other instruments. The sun, moon, and planets can also generally be better observed off the meridian. If, however, the entire time of an instrument can be employed to advantage, and it can collect several times as much material as an instrument of the usual form, it is no evidence against its trial that there are certain problems to which it cannot be advantageously applied.

The working force required for such an instrument should consist of at least one observer, an assistant to record, and a number of copyists and computers to prepare the working lists, reduce the observations, prepare them for the press, and read and check the proof-sheets. A large volume of valuable observations could thus be produced every year, which would require at least double the time and money to produce by the same telescope mounted equatorially. The difference in the amount of work will be evident when we compare the number of objects observed with a transit instrument per night, with those observed with an equatorial. A hundred objects in various declinations might be examined in a single evening, while it is seldom that the same number could be identified and measured by an equatorial in a week.

ON MAXIMUM SYNCHRONOUS GLACIATION.*

By W. J. McGee.

In the development of knowledge of the cosmos, the tendency has ever been to look at first upon all phenomena as mystical and incomprehensible; and only after repeated observation and much study has it been decided that any class of phenomena may be the result of the operation of the identical laws whose existence is established by every-day observation. Thus, in geology, catastrophism prevailed long, but finally yielded to a rational uniformitarianism; in general biology the idea of special creation has only given way to that of derivation within the memory of a child; and in anthropology the mystical view yet generally prevails. The narrow domain of glacial physics, as embodied in the glacial theory, is still in the transitional stage. When that theory was first acceptably propounded by Agassiz, the details were so varied, the recognized relations so unique, and the whole conception so grand and startling, that even the more conservative of those who early became its advocates, forgot for the time the necessity for keeping all assumed data within the bounds of actual observation or legitimate induction; and hence not the least valuable of the later contributions to the theory are those which bring out its relation to established laws. Such is the aim of the memoirs bearing the above title; the particular phase of the subject discussed being that known as the "ice-cap theory."

The conclusion of Tyndall that such a supply of heat as may be necessary to produce large quantities of aqueous vapor, and an area of sufficiently low temperature to not only condense but congeal the vapor brought to it, are the first requisites for glaciation, is adopted at the outset; but it is shown that while the regions which furnish and those which congeal the vapor may be contiguous, they must be quite distinct. There is no other substance than water in the solid state which will abstract heat from the superfluitant vapor with such facility as to form, when spread over the surface, a condenser of sufficient power to meet the requirement of glaciation; and such a condenser must so far exceed in capacity any tax that may ever be placed upon it, that it will *immediately* condense and congeal all moisture that may be brought to it by aërial currents; for if the vapor is not immediately condensed it will cut off radiation from the ice below, and thus accelerate melting; and if the vapor is only condensed but not congealed it will fall as rain, and every pound of it will melt 143 pounds of ice before it is itself frozen. *The integrity of the condenser hence depends on its capacity being far in excess of the work it may be called upon to perform.* Now if a condenser formed of an ice-sheet 1,200 or 1,400 miles in diameter on any part of the globe be assumed, it is manifest that the tendency of the accumulating ice will be to form an annular belt of maximum thickness, gradually attenuating toward the center of the area; for if the vapor-laden air were not immediately robbed of its moisture in sweeping over the condenser, the marginal portions of the ice would soon be destroyed. But no matter how perfect the condenser, glaciation can never occur unless there are ample quantities of vapor supplied to it; and the greatest possible accumulation of ice at any latitude may accordingly be regarded as proportional to the moisture conveyed thither. It follows that the greatest possible accumulation of ice in polar regions can never have been nearly as vast as that at lower latitudes during the quaternary; and indeed it was probably never much greater than at present. Geological evidence, so far as accessible, corroborates this view.

Similar conclusions are reached by an independent line of investigation. Within an extensive area covered by ice or snow, both aërial and aqueous currents would be either stopped or so modified as to be practically inopera-

* Reprint from Proceedings of the A. A. A. S., Vol. XXIX.

tive as distributors of heat. The temperature would hence become approximately proportional to the solar accession, which has been computed by Much for the various latitudes, and may be roughly reduced to thermometrical degrees by means of an easily determined constant. Moreover the presence of the ice would greatly facilitate both radiation and direct reflection of solar energy. The general diminution of temperature produced in this manner is calculated for each latitude; and from a comparison of these figures with actual temperatures, as recorded by Dove, the temperature of the whole hemisphere when the ice-sheet extends to any latitude is also computed. From the several figures obtained it appears that if the globe were encrusted with ice, the crust would probably (and indeed almost certainly) never be melted unless by proper terrestrial heat; while the temperature in polar regions, as well as over much of the ice-covered hemisphere, would sink so low as to practically eliminate all aqueous vapor and effectually prevent the further accumulation of ice. The annual variations in solar intensity would not materially affect the values obtained.

Since the results reached in the manner indicated embody values widely different from those of existing temperatures, and are hence *a priori* improbable, a detailed investigation of certain meteorological phenomena is undertaken in order to verify these results. The observed and computed temperatures of the northern hemisphere are first compared, and are found to indicate that the temperature-equalizing agencies are 1.5 times as effective in summer as in winter. The effect of atmospheric dryness in diminishing the effectiveness of these agencies is then found to be still greater. The values developed in the investigation of this subject demonstrate that the climatal perturbations previously pointed out as the necessary result of the considerable extension of a polar ice-sheet do not differ in kind, but only in degree, from those whose constant occurrence is a matter of authoritative record; and analogy with observed phenomena moreover indicates that the calculated extent of these vicissitudes is in perfect harmony with the magnitude of the formulated course.

The figures obtained incidentally demonstrate the existence of an empirical meteorological law, which may be stated as follows: *Any increase in thermometrical range is accompanied by a diminution in mean temperature.* Since the law strongly corroborates the results reached by the second line of investigation, it is quite fully considered, especially in its application to the present eondition of the two hemispheres. That hemisphere whose winters occur in aphelion experiences a greater variation in solar accession and consequently in temperature than the opposite one, and hence, according to the law, ought to have a lower mean annual temperature. The southern hemisphere is so situated at present; and accordingly, notwithstanding more favorable geographical and other conditions, its temperature is lower than that of the northern hemisphere. The bearing of the law on Croll's celebrated theory of secular variations in terrestrial climate is manifest.

Since it is developed in both lines of investigation that the accumulation of glacier ice is dependent upon, and in a general way proportional with, precipitation, the maximum accumulation at any latitude may be roughly computed. The final determination is as follows:

Latitude	40°	18,594 feet.
"	50	9,777 "
"	60	5,728 "
"	70	2,800 "
"	80	1,799 "
"	90	1,440 "

It may accordingly be concluded that a sufficient accumulation of polar ice to displace seriously the earth's center of gravity, or to influence the motion of middle-latitude glaciers, never can have taken place.

The nature and course of ice motion are discussed at some length; and the phenomenon is shown to be analogous to those exhibited by all classes of substances, though generally in a less striking degree. The "viscous theory" of Forbes is adopted with some modifications; and the principal objections thereto are considered. It is also pointed out that ice-streams are necessarily in tension, and hence that the central mass of an ice-field can exercise an influence on the motion of its peripheral portions. The assumption of a vast polar ice-cap to explain the motion of the quaternary glaciers accordingly appears to be not only unnecessary but incompetent.

GLUCOSE.

By Albert E. Ebert, Peoria, Ill.

The process of making glucose, or grape sugar, is as follows: corn, after being shelled, is placed in large tubs and soaked in hot water from a day and a half to five days, or even longer, the time depending on the hardness of the grain. If fermentation is not wished, the water is changed when the substance begins to sour. It is then ground, while wet, with ordinary burr stones, and with a stream of water running into the hopper with the corn. The meal, or "chop," is then run on vibrating sieves, made of fine silk bolting cloth, also fed with streams of water. By this treatment the starch, which washes through the sieves, is separated from the gluten and cellular matter, which waste portions go over the tail of the sieves, and after passing through rollers which squeeze the mass, and return the water to the sieves, is sold for feed. The portion which went through the sieves is run into tanks and settled, the water drawn off and the sediment again mixed with clean water and treated with alkali, about one pound of caustic soda, (more or less, according to the hardness of the water), being used for each bushel of corn. This treatment separates any traces of gluten from the starch, which is then run into metal-lined troughs or gutters about eight inches deep, from fifteen to thirty-six inches wide, and usually from one hundred to one hundred and fifty feet long. These are inclined slightly, and the water runs off at the lower end, leaving the starch as a sediment at the bottom. In some factories this starch mixture goes direct from the sieves to the gutters or "tables," as they are usually called. It is left to dry somewhat in the tables, and is then shoveled out. At this stage of the process it is known as "green starch." It is quite solid, but moist, containing about fifty per cent. of water.

Up to this point the process is the same as starch-making. Starchmakers take the green starch and wash it, some several times, by mixing it with clean water and allowing it to settle, then drawing off the water, and repeating the process. It is then sometimes bleached by chloride of lime or sulphurous acid, and after washing, settled, made into blocks about eight inches square, when it is dried in a kiln. For the finer grades, about half an inch of each side of the cake is shaved off when partially dry, the rest of the cake being wrapped in paper and put back into the kiln until it forms into little sticks or pipes.

For glucose, however, the green starch is made quite thin with water, and run into converters, usually after several additional washings. The converters are large wood tanks or tubs, where it is treated with acids, sulphuric being usually used, although muriatic, nitric, or even oxalic may be substituted. Sulphuric is preferred, as it is cheap and easily gotten rid of in an after stage of the process, when it has performed its work. The acid does not combine with the starch, but merely exerts a catalytic action; therefore the necessity of providing for its removal. While under the acid treatment the contents of the converters are heated to the boiling point by

means of steam pipes coiled inside the tubs, or by steam jets. Some use pressure converters, which are iron or copper tanks like a boiler, when the conversion is much quicker. The operator makes frequent chemical tests to determine when the starch is entirely converted into sugar, and when this is accomplished the mixture is drawn into another vat where the acid is neutralized with some form of carbonate of lime, as marble dust, chalk or whiting. The liquid is sometimes bleached by the use of sulphurous acid at this stage of manufacture. It is now a very dilute solution of glucose, and besides incidental impurities, contains sulphate of lime formed by the action of the sulphuric acid on the carbonate, and whatever carbonate of lime was used in excess of the sulphuric acid present. These are separated by straining through cloth or bag filters and afterward percolating through columns of bone charcoal, eight or ten feet deep. When decolorized, it is drawn into the "vacuum pan," which is a large, strong tank of iron or copper, with steam pipes coiled inside for heating, and from which the air is partially exhausted by an air pump, and in which the syrup is boiled down at a temperature of 100° to to 145°. When concentrated to a specific gravity of about 1400 it is drawn off and again strained or filtered, and is ready for the market as glucose, this being the commercial term for the syrup only. The term grape sugar is applied to the dry glucose, and this is produced by carrying the conversion further before neutralization.

The syrup is used, principally, for mixing with dark colored cane syrup for making light colored table syrups (nearly all the table syrups now sold contain it, and frequently from 75 per cent. to even a larger quantity), and also in making wine, ale, beer and vinegar. On a smaller scale it is used in tobacco manufacture, the adulteration of honey, fruit preserving, etc. Both the solid and liquid forms are largely used in candy making, for which it has several marked advantages. A syrup is prepared expressly for this use, in which the conversion of the starch into sugar is only partial, the syrup containing, of its solid matter, about eighty per cent. of the intermediate product, dextrin, and twenty-of glucose. The large consumers of glucose require slightly different syrups. Wine growers, for instance, use a syrup free from dextrin. Brewers desire a very small proportion of it, to give body to the beer, while vinegar makers use a syrup free from gum. The dry glucose, or grape sugar, seems, aside from its legitimate use in candy making, to be most largely in demand for the adulteration of cane sugar. No objections, save of a moral and financial nature, can be urged against this, but it is well to remember that for its value as a sweetener, compared with cane sugar at ten cents per pound, glucose is worth but four cents. So much has been written against the manufacture of glucose, on account of its use as an adulterant of cane sugar, that it is, perhaps, only just to say that it is certainly the least objectionable of any of the articles used for that purpose. It is perfectly wholesome, being in fact the physiological sugar, and has about two-fifths the sweetening power of cane sugar, which is more than can be said of terra alba, starch, bone dust, sand, etc., while its most probable impurity, calcium sulphate, can, from its insolubility, be present only in minute quantity, probably not more largely than in most potable waters, and is not in any sense noxious.—*The Druggist.*

SUGAR ANALYSIS*

This is an admirable manual of sugar analysis, and will prove a great boon to everyone engaged in sugar work. The *resumé* of the chemistry of the sugars with which the book opens is of especial value to the student who wishes to get a clear idea of this complicated subject. Perhaps it had been desirable to have had the book delayed a little longer in order to have incorporated the results of the last year's study in sugar analysis, but this objection would obtain equally against any book published at any time. Another valuable feature of the book is its collection of tables referring to all conditions of sugar analysis, viz, specific gravities, solubilities, etc. The author is careful to cite authorities for his statements, and thus anyone wishing to pursue any given topic further can readily do so without being at the trouble of hunting up each theme for himself.

There is, however, a vast mass of French and German literature on certain sugar compounds which might be very appropriately drawn upon in an exhaustive study of the chemistry of sugar, and which is of no use whatever to the analyst. There is much of this in the book before us, and while it detracts nothing from its merit as a help to the analyst, it certainly adds nothing to it.

That portion of the work which is devoted to the description of the optical examination of sugars is to be highly recommended. We have, however, used for three years a Schmidt & Hänsch polariscope, and were therefore a little startled to read "ordinary lamp light, and not the monochromatic flame, is required."

We doubt very much whether, in testing the accuracy of the scale of a polariscope, quartz plates of various thicknesses are better than solutions of pure sugar. First of all, the plates themselves would have to be tested, and this would require as much work and trouble as testing the scale directly with sugar solutions. If quartz plates could be secured which were absolutely accurate, of course this objection would not occur.

Among the sources of monochromatic light the author omitted to mention the new double burner of Laurent, which leaves nothing to be desired in the steadiness and intensity of the sodium flame.

There is one statement which the author makes in a note (p. 137) on Clerget's method of analysis that seems calculated to mislead. It is: "it must be remembered that the process is entirely inapplicable when any optically active body is present besides cane or invert sugar, and also if the invert sugar itself exists in an inactive condition as regards polarized light." In point of fact, any optically active body may be present without rendering the process inapplicable, provided it is not affected by the process of inversion. Thus, by Clerget's method we can accurately determine cane sugar in the presence of dextrose, maltose and glucose. In polarizing an inverted cane sugar, too, metal tubes should be used, since the temperature is more accurately obtained from an external thermometer than in a glass tube.

The author's directions for estimation of raw sugar and syrups are those which are generally recommended and employed. The description of these methods is full and admirably arranged. In fact, this praise can be bestowed on every part of the work. The only trouble about the methods is that if applied to the ordinary syrups of commerce they will give the most alarming errors.

The great fault of the work, in fact, is found in its failure to give reliable methods for the examination of the mixed sugars and syrups which are on the market to-day.

Perhaps, however, we should not say this is a fault of the book, it is rather a fault of science. To determine cane sugar, invert cane sugar, dextrose, dextrine, and maltose *exactly*, is a great problem which the author leaves untouched and which demands the careful attention of sugar chemists.

In papers read before the A. A. A. S., at the Boston and Cincinnati meetings, and published in the proceedings for the Boston meeting and in this Journal, Nos. 65 and 66, Prof. Wiley has shown the relation between rotating and reducing power in commercial starch sugars and also a series of determinations of cane sugar in mixed sugars.

Since the polariscope has grown to be the chief instrument in sugar analysis and starch sugars and syrups a common article of commerce and consumption the omission of any reference to those papers is a matter to be regretted.

* Manual of Sugar Analysis, by J. H. Tucker, Ph. D., Van Nostrand, New York, 1881.

NEW YORK ACADEMY OF SCIENCES.

November 7, 1881.

REGULAR BUSINESS MEETING.

The President, Dr. J. S. Newberry, in the Chair. Twenty-nine persons present.

A paper by Prof. P. T. Cleve, University of Upsala, Sweden, was read, by Prof. D. S. Martin, entitled

OUTLINES OF THE GEOLOGY OF THE NORTHEASTERN WEST INDIA ISLANDS.

(Abstract.)

Prof. Cleve's paper contained a resumé of his observations made during 1868–9, in and around the Virgin Islands, and published in the Swedish language in the *Trans. R. Acad. Sci.* of Stockholm, in 1871. He regards the whole group as of Cretaceous and Tertiary age, with the exception of Anegada, which, like the Bahamas, is post-pliocene.

The strike of the rocks, and the trend of the entire group, are approximately east and west. The rocks are various, largely eruptive and metamorphic. Of these, Prof. Cleve discussed somewhat fully the character and distribution of the following kinds:—1, Diorite; 2, Felsite; 3, "Blue-beach" (a peculiar volcanic breccia, locally so-called); 4, Diabase.

All these rocks have great thickness, and indicate long-continued volcanic activity. As in modern lavas, they present two types, basic and acidic.

Metamorphic slates are next described; and then a partly metamorphic limestone, occasionally with recognizable fossils, sufficient to fix the age as certainly Cretaceous.

Santa Cruz Island is then described, and referred to the same series as the Virgin group. All these islands thus indicate, by their east and west strike, and the great upturning of their rocks, that they were formed by a north and south pressure, forcing the Cretaceous and associated volcanic beds into a great line of anticlinal and synclinal folds. This period seems to have been about that of the white chalk; but the force continued to act during the succeeding Eocene time, though with diminishing intensity, as is shown by the less inclination of the Eocene beds. The Miocene strata are little disturbed, and the force would therefore seem to have spent itself by that period.

Prof. Cleve then refers briefly to the occurrence of similar metamorphic and volcanic rocks in the interior of the Great Antilles, and regards the entire series as having been formed by the same general movement of Cretaceous folding, the Virgin Islands forming the eastern extension of the line of elevation.

The Eocene strata are then taken up and discussed, as they occur in the islands of St. Martin and St. Bartholomew, just east of the Virgin group. Professor Cleve regards these islands as wholly of Eocene age, claiming that the eruptive rocks of which they mainly consist, are *interstratified* with the limestones, which contain fossils of the age of the Calcaire Grossier, of the Eocene of Paris. He then traces the occurrence of Eocene strata in Antigua, Guadaloupe, parts of Trinidad, and largely in Jamaica; and re-affirms his conclusion that the movement which raised the Great Antilles and the Virgin islands continued during the early Tertiary, though with lessening force.

The Miocene formation is then considered. It forms the small island of Anguilla, and occurs on several of the islands, south to Trinidad; but has immense development in the Great Antilles. It is chiefly a limestone series, is generally little altered from a horizontal position, and at times may be seen resting uncomformably on the Eocene. By this time, evidently, the disturbing movements had ceased to make themselves felt.

The later Tertiary rocks, Pliocene and Post-pliocene, have not been very clearly marked off from each other or from the Miocene. But to the Post-pliocene period are referred the Bahamas, Anegada, and the remarkable series of volcanic outbreaks that characterize the islands of Saba, St. Eustatius, St. Kitts, Nevis, Monserrat, Guadaloupe, &c. On St. Kitts, Prof. Cleve describes a limestone with over forty species of fossil shells, all but one of which are identified with living species of the Caribbean sea. The same is true of Anegada.

The elevation of the Miocene strata of the Great Antilles took place apparently by a "continental" uplift, whereby large areas of marine deposit were raised without folding or disturbance. Professor Cleve suggests that this movement may have been accompanied by a sinking of part of the sea-bottom in the Caribbean region to the south-east, and that on the limit between the areas of rise and of depression, fissures and faults may have occurred, through which these volcanic outbreaks of the Leeward islands found exit, in the Post-pliocene time.

DISCUSSION.

Mr. A. A. Julien confirmed the accuracy of these petrographical distinctions of the rocks of the Lesser Antilles, from the results of observation during a residence of four years on Sombrero and vicinity. The island of St. Eustatia consists mainly of volcanic ashes in a thick tabular and horizontal stratum with vertical faces along its coast. This is flanked on the south end by a volcanic cone with extinct crater, of which the bottom is occupied by a plantain plantation, but the sides are bare, and consist of a dark basaltic rock; and on the north end by two lower cones, not visited but probably volcanic. On the island of Saba the rock is light colored, rich in crystals of sanidine, and apparently a trachyte, constituting a remarkably sharp volcanic cone, with its sides deeply furrowed from top to bottom by eroded ravines; certain depressions upon the summit, resembling craters, present in some localities sulphur deposits which have been found of commercial importance.

However, the conclusion of Prof. Cleve, as to the recent age and eruptive character of most of the crystalline rocks of this region, appeared surprising in view of their metamorphic associates, and of their similarity to those of the Archæan areas identified by Hartt in Brazil. It was a question whether a nucleus of Archæan, or, at latest, metamorphic pre-Silurian rocks, in general highly tilted, does not form the axis of such islands as St. Martin, St. Barts, etc.

Prof. D. S. Martin questioned whether a corresponding movement of disturbance should not be also found in the Cretaceous strata of a region no farther removed than that of the vicinity of our own Gulf coast.

Dr. J. S. Newberry remarked that the importance of the subject of the age and origin of these crystalline rocks still demanded their re-examination and a review of Prof. Cleve's conclusions by some worker of experience in this peculiar field. One of the most interesting topographical features on this continent consisted in the line or axis of elevation marked by the Windward Islands, separating the deep basin of the Gulf of Mexico on the one side from the abyss of the Atlantic Ocean on the other. It presents a prolongation and connection of the mountain chains which run along the eastern border of the North and South American continents, in a course imperfectly parallel to that on the western border of these continents, with the gulf lying enclosed between these two great ranges. This axis has been the scene of violent volcanic action and has been supposed to mark the place of that mythical area of sunken land, styled Atlantis by the ancients. The tradition long current, recorded by Herodotus and others, points to a densely populated land west of Europe, covered with cities, and threatening the civilization of the Eastern hemisphere, which was punished by the gods by being sunk beneath the sea. According to the recent observations of an

English geologist, Mr. Thomas Belt, this legend may have had some foundation in the former existence of a continent, now submerged beneath the Caribbean sea, through which the peaks represented by the Lesser Antilles, constituted a mountain chain. Local disturbances have certainly affected this area, but we fail to find any evidence of corresponding disturbance in the Cretaceous strata of our southern States. except perhaps in continental elevations and depressions. Messrs. Guppy, Gabb, and others have studied the rocks of the region, but, up to this time, no one trained to the examination of the difficult phenomena and problems under discussion.

NOV. 14, 1881.

The President, Dr. J. S. Newberry, in the chair. Twenty-four persons present.

A paper was read by Dr. Alexis A. Julien on

THE EXCAVATION OF THE BED OF THE KAATERSKILL, N. Y.

(ABSTRACT.)

This paper was supplementary to one read before the Academy two years ago, concerning the phenomena of erosion, glaciation, etc., in the Catskill Mountains, in the vicinity of the Kaaterskill Clove.

Flexure of Strata.—Prof. James Hall has indicated the existence of four lines of flexure, running from N.E. to S.W., the synclinals occupying the summits of ranges, and Prof. Arnold Guyot locates one of these at Slide Mt. The dips at the entrance of the Clove vary from 8° to 10° to the W. N.W., becoming only 3° four miles to the westward, *i. e.*, more nearly horizontal towards a shallow synclinal fold supposed to occupy Hunter Mt.

One of the most interesting discoveries of Guyot was the linear series of three maxima of altitudes above 4000 feet, Slide Mt.; Hunter Mt. and Black Dome. The gentle flexure of the whole stratum required to produce this line of maxima may be thus shown in the range running S.E. and N.W. through Hunter Mt., 35 miles long. Toward the S.E., the descent from the crest of Hunter Mt. (Alt., 4038 feet), to Overlook Mt. (3150 feet), is 888 feet, in 9½ miles, equivalent to 1 in 56, or about 1°; toward the N.W., from Hunter Mt. to Utsyanthe Mt. (3203 feet) the descent is 835 feet in 25 miles, equivalent to 1 in 158, or less than ½°.

Another similar series of maxima, however, occurs further to the westward, consisting of Graham Mt. (3886 feet), Bear-pen Mt. (3545 feet), and Ashland Pinnacle (3420 feet), distant respectively 9, 12, and 15 miles westward of the former series. This southward convergence of the axes of these two folds may probably account for the increased protuberance and greater elevations in the Southern Catskills.

Newly determined altitudes.—Many new determinations have been made of points in the vicinity of the Clove by means of an excellent aneroid, with constant reference to the numerous stations in the vicinity whose altitudes have been accurately obtained by Guyot. A few are here subjoined:

	Feet.
Hotel Kaaterskill, on South Mt	2466
Parker Hill, summit	2565
Parker Mt., "high ledge."	2874
Clifton House	2101
Newman's ledge, on North Mt	2486
Gap between E. and W. peaks, North Mt	3116
Toll-gate on Mt. House road	760

Glaciation of summits.—All the crests near the Clove have been now examined. On none above an altitude of 2900 feet have glacial striæ been found, in part because they consist of thinly laminated flags deeply disintegrated by frosts. The highest striæ discovered were found on Parker Mt., "High ledge" (2874 feet), running S. 18° W. (magnetic), and under the roots of a large tree on the SE. slope of Round Top, at an elevation of 2871 feet, running S. 35° E. However, in all cases, a marked difference exists in the slope of different sides of a peak, the E .and S.E. sides presenting a precipitous face, and the other sides more or less of a gentle slope.

The highest striæ yet found in the Catskills occur on Overlook Mt., at an elevation of about 3100 feet, implying a depth of ice in the Hudson river glacier of about or at least 3200 feet. Within the Kaaterskill basin, several miles distant from the Hudson valley, the overflowing ice stream became shallower, having an altitude of about 3000 feet. It thus appears that the surface of the glacier inclined westward over these mountains, with a slope of 200 feet in 3 miles, 1 in 84, say about ½°.

The conclusions of the former paper have been confirmed by recent observation, viz., that two glacier streams have swept over these mountains, the Continental Glacier from the N. W., submerging and carving out the highest peaks, and the Hudson Valley Glacier from the N., later, more shallow, bearing along vast quantities of materials derived from the crystalline and lower Silurian rocks of the Adirondacks and of the Helderberg Mts., and strewing the whole region with their boulders; and that no local glaciers have existed in the Catskills after the retreat of the Hudson Valley Glacier.

Tilting of the Catskill plateau.—In the previous paper an explanation had been given of certain facts which seemed to indicate that the whole formation had been gently inclined to the East and then to the South-east, before assuming its present W. N. W. inclination, at a period far anterior to the Glacial epoch. A profile section of the ancient Kaaterskill valley, was exhibited, reaching from Haines' Falls nearly to the junction of the N. and S. branches of Schoharie creek, proving the gentleness of the slope, the absence of rock, and the existence of a deep and narrow buried cañon, now filled up with moraine material and a capping of peat.

A comparison of the altitudes of Prattsville (1164 ft.), a point on the Western axis, 12 miles distant from the Kaaterskill Clove, and of the lip of the stratum above Haines' Falls, (1857 ft.), at the head of the Clove, shows that a depression of the latter point below a line connecting these two points, even to the extent of a single degree, would cause a descent of nearly 700 feet from Prattsville to Haines' Falls, *i. e.*, toward the East. The excavation of the deep Kaaterskill and Plaaterkill Cloves could hardly have been effected by the small streams now occupying their beds. It is more probable that the Schoharie creek formerly flowed, at a higher level, to the east into the Kaaterskill Clove, and afterwards to the south-east into the Plaaterkill Clove, before the latest tilting of the plateau to the W. N. W. caused a reversal of the flow of the stream, in the very opposite direction, through the greater part of the same valley. An objection to this theory presented itself in the obstacle which has created a turn to the S. W. in the North branch of Schoharie creek, near its junction with the South branch. But on recent examination this was found to consist not of rock but of a huge mass of coarse moraine material deposited during the Glacial period on the southern slope of the Schoharie valley.

Sculpture of the plateau.—In a terrane consisting of strata which dip at varying and perhaps very high angles, the carving out of ranges and production of ravines and gaps may generally be assigned to the occurrence of flexures, of dykes or faults, or of beds whose material is unusually soft, fragile, or rich in minerals of easy decomposition. But the problem of topographical sculpture is less easily solved in a stratum like that of the Catskills consisting of a regular succession of layers which are horizontally homogeneous and from which the phenomena of disruption are absent. The original disintegration and erosion of the mass which resulted in the production of the ranges was perhaps mainly influenced by the direction of the jointage. With this the trend of the ranges in the vicinity of the Kaaterskill Clove appears to

coincide. The ravines, cloves, and deepest notches and valleys may be attributed to the streams of the present hydrographical basins, or to those connected with the ancient eastward and south-eastward inclination of the stratum already considered. But recent observations on the juxtaposition and coincidence of the highest gaps in successive parallel ranges may possibly indicate the remnants—in cross-section—of the beds of ancient streams at that level (about 3000 feet); this conclusion, if confirmed, would signify an inclination of the plateau to the N.N E. (or to the S.S.W.?) at a still earlier period, that immediately succeeding its elevation.

Kames.—In the upper basin of the Kaaterskill, several isolated hills of gravel, etc., occur at an altitude of 1924 feet, especially on the bank of the stream near the head of the Clove, which are probably kames; their materials, though largely angular, show traces of imperfect stratification. Near "Blythewood," on the North branch of the Schoharie creek, a curious conical and steep isolated kame rises 102 feet above the stream, made up of rounded pebbles of the Catskill grit, rarely a foot in length, overlying a layer of coarse moraine. Its elevation above the sea (1944 feet) exceeds that of any other kame yet observed, those of the Fintry Hills in England reaching 1280 feet, and those of the Androscoggin Lakes, in Maine, 1600 feet. A very interesting series of from eight to twelve very low kames—like parallel ridges, often curving, made up of large rounded boulders—was also found to follow the course of the Kaaterskill near Palenville, in the Hudson Valley, at the mouth of the Clove, at an elevation of about 700 feet; these probably mark the course of the sub-glacial stream which issued from the mouth of the Clove. The paper concluded with observations on a deposit of laminated sand underlying the ground moraine: on the feeble erosion of the slopes of the Clove during the period which has elapsed since the close of the Glacial epoch; and on a new section of the strata of South Mountain obtained from a new road-cutting.

DISCUSSION.

Prof. E. C. H. Day observed that one portion of Dr. Julien's remarks reminded him of an idea which had struck him many years ago with regard to the surface geology of a valley on the south coast of England, near Charmouth, in Dorsetshire.

The stream in the valley referred to finds its way to the sea through a narrow pass, which, as attested by the rapid wearing of the coast line and its present configuration, could only have been of (geologically speaking) very recent origin. How the valley could have been drained prior to the existence of this outlet was a question which might be met by various hypotheses, and one of these was that there might have been a slight unequal local change of level, sufficient to have had the effect of tilting the surface of the valley so that its waters were shed then in a direction opposite to that which they now take. This was nothing more than the veriest hypothesis made many years ago, without any subsequent attempt at verification. It may suggest, however, the possibility of such slight local changes occurring, in addition to the greater movements already distinctly recognized, and the desirability of careful investigation to discover whether such may not be traced in the altered direction of streams and in the existence of ancient and unused water courses—even in our own neighborhoods. It may be added that such local tiltings of parts of the earth's crust would necessarily influence the course of subterranean as well as of subærial waters, thus altering the distribution and force of springs at the surface.

Dr. J. S. Newberry stated that the Catskills presented a more complex bit of topography and geology, and one that had been more discussed than perhaps any other of similar area in the country. It was once supposed that these mountains were composed of a single geological formation, which, from this fact, was called the Catskill group; and it was supposed to be a detached table land, deeply carved by erosion. The late Col. Jewett, of Albany, found strata containing Chemung fossils in the Catskills, and from this inferred that the mountains were composed of Chemung strata. Prof. Hall and Prof. Guyot, with their assistants, then made a careful study, running through several years, of the topography and geology of all the surrounding region. Their labors established the fact that the Catskills are not an isolated mountain group, but belong to the Alleghany system and are formed by a series of folds or arches composed of the Chemung and Catskill rocks. Of these folds, the convex arches, as is usually the case, were cracked and broken and, therefore, yielded readily to erosion, while the concave arches, protected and solid, yielded less readily and, in time, by the wearing away of their surroundings, were left in relief, forming ridges with a synclinal structure. Hence it will be seen that the topography of the Catskill region is chiefly the result of erosion.

So far as regards the changes of level from subterranean causes, referred to by Mr. Julien, it would certainly be strange if the foundations of the Catskills were proved to be stable. The old name, "*terra firma*," once applied to the crust of the earth, is a complete misnomer, and it is really a type of instability. Probably throughout the globe local subsidence and elevation are constantly in progress. In the interior of continents we have no evidence or measure of these, but along coast lines the water line tells us that changes are constantly and everywhere taking place, in the relative level of land and sea. About New York the coast is sinking, though very slowly, while further north, in places, it is rising, and Greenland is sinking again. Back from the coast there is no such nilometer, and yet we have no reason to suppose that the earth is more fixed. Some indication is given by the reports of those who dwell in mountainous regions, of changes of level, which have shut from their view that which was before visible or revealed what was before concealed, but these observations have not been made with accuracy and cannot be depended upon.

In a recent paper before the Academy he had shown the vast changes which had occurred along the coast in this vicinity, viz., that the land once stood 600 feet higher than at present: that the Hudson river had then flowed by the city through a channel from 300 to 500 feet deep, now in large part silted up: that the Palisades then stood from 700 to 800 feet above the river: that the Housatonic then flowed through the East river into New York Bay: that a sub-tropical climate then prevailed throughout this region, with a varied and rich fauna and flora, extending up even to the Arctic Sea: that then a depression of the temperature and great change in the climate ensued, with a corresponding alteration of the fauna and flora; but that these changes were very slow and progressive—the snows, which at first rested temporarily upon the Catskill Mountain summits, became at last permanent, and resulted in local glaciers. These glaciers produced extensive erosion, cutting the channels along which they moved, deeply. A partial obliteration of their work then ensued through two agencies. First, a continental glacier advanced southward, overtopping all the mountains, grinding down the asperities of the surface, fillng old valleys, and banking up a great mass of debris along its margin—a part of which is now Long Island. Afterward the climate becoming milder, local glaciers were again formed similar to those which preceded the great Glacier, and partially obliterated or modified the results of the ancient erosion. It is a complex problem now to distinguish between the phenomena which have been respectively produced by all these glaciers in varied succession, by the erosion of streams, by flexures of the earth's crust, etc.

The excavating power of glaciers had been denied by Prof. Whitney, but ice, hundreds of feet and sometimes miles in thickness—as it was in the old glaciers—moving

with irresistible force, and having sand, gravel and boulders beneath it, or frozen into it, was the most potent agent of erosion known. The eroding power of the ancient glaciers, which once reached southward to Trenton and Cincinnati, was attested not only by the planed down rocks, but by the immense sheet of transported debris left by the glacier in its retreat.

The glaciated, planed, and polished rocks in the Western States are generally covered by a thick layer of clay, abounding in glaciated boulders. There are also other water-worn materials which have been transported, perhaps thousands of miles, representing the gravel bars, sand beds, etc., produced by sub-glacial rivers. Although the materials are entirely of glacial origin, all the stones are here usually rounded. We find in these deposits, called kames or eskers, the evidences of the action of running water produced by the melting of ice, their accumulation in heaps, ridges, etc., having been effected by local causes, waterfalls, streams upon or under the ice, etc.

The finer material produced by the same grinding action has been deposited along our coast in the vast masses of the Champlain clays. It is well known that the drainage of all glaciers results in milky streams; *e. g.*, those which descend from the Alps impart an opalescence to the Lake of Geneva, and the streams from the Cascade Mountains are clouded with silt derived from the small glaciers at their heads. So, during the Glacial period all the fine material was sometimes washed out of the glacial drift, leaving banks and ridges, kames, hogsbacks, etc., of gravel and boulders, and carried by streams to the coast and there deposited along shore in the Champlain clays. The fine flour and bran ground by the glaciers have been sometimes referred to different epochs, but they are produced simultaneously. The Glacial or Champlain clays are of great economical importance to the city as they are the brick clays of Croton Point, Haverstraw Bay, and other points along the Hudson. Their thickness reaches 100 feet along the lower portion of the Hudson river, 400 feet on Lake Champlain, 500 feet at Montreal, 800 feet at Labrador, 1000 feet at Davis' Strait, and 1800 feet at Polaris Bay. This indicates that the continent was depressed to this extent at each of these points, that the waters of the ocean extended through these valleys, and that here was dead water into which the glacier drainage flowed and was deposited.

In the vicinity of New York City it is evident that the glaciers everywhere overrode and disregarded the underlying topography. All the surface of the island is strewn with materials derived from the N. N. W., and the rock has been planished and striated with grooves running in that direction. The hills back of Yonkers are covered by trap boulders which have been conveyed across the river from the Palisade range on its western side, and it is plain that the Glacier completely disregarded the depression of the Hudson valley, filled it up to a greater or less extent with *debris*, and so rode smoothly over it. Afterwards this and the other valleys were more or less cleared out by the present streams, but a portion of their contents is generally left in their beds, the tunnel between this city and Hoboken being now driven in fact through a part of this clay deposit. On the east side of the city a narrow cañon, 300 to 400 feet deep, has been proved to underlie the East River; and it would have been a wiser and cheaper plan to construct a tunnel through the clay bottom, for communication with Brooklyn, in place of the present costly and to some extent insecure bridge.

Dr. Newberry finally expressed his interest in the careful study of the erosion and sculpture of the Catskills and desire for its continuance.

MRS. J. M. FISKE has left a bequest of $40,000, to establish a hospital for the use of the students of Cornell University.

RINGING FENCES.*

By PROF. S. W. ROBINSON, Ohio State University.

THIS sketch is mainly of a simple fact of observation. My attention was one day suddenly arrested while walking on a hard road alongside a picket fence by the peculiarity of the sound which reached my ear immediately following each step. This sound was first noticed to be very different from that perceived at other parts of the sidewalk. On instituting an inquiry for the cause of this difference the only one discoverable was a change in the construction of the yard fences along the sidewalk.

The peculiarity observed in change of sound was very marked when passing from a portion of the sidewalk opposite a board fence to parts opposite a picket fence. In the former position a quick drop of the foot upon the walk was accompanied by a simple sound or noise of short duration. But when opposite the picket fence the noise following each footstep was prolonged into a curious musical tone of initial high but rapidly lowering pitch, and with a duration of perhaps a quarter of a second.

This singular musical tone following, and due to the noise of a simple foot step, could only be accounted for on the supposition that each picket of the fence reflected the sound reaching it from the foot, the rapid succession of which, from the several pickets of the fence, resulted in the sound observed.

The duration of the sound reflected from the pickets at each step is evidently due to the different distances of the pickets from the ear of the observer, and the greater length of time required for the sound to travel to and from the more distant pickets. For instance, suppose the observer is walking along a stone or mastic walk at a distance of eight feet from the fence, the latter extending either way some distance along the street. The sharp noise of the footsteps returns from the nearest pickets first. Here the differences in distance from the adjacent pickets is slight, and hence the succession of reflected noises is rapid. But from more remote pickets the difference of distance is greater, and the succession in reflection less rapid.

In studying the nature of the resulting tone it is at once seen that the initial pitch is due to an almost infinite number of reflections or vibrations per second, while at the end of a quarter, or half, second the lines of advance and return of the sound are nearly parallel to the fence, and hence the pulsations have an interval of time equal twice the constant distance between pickets divided by the velocity of sound. For instance, if the pickets be four inches apart, or one-third of a foot, the terminal pitch would be one of about 1500 vibrations per second. The law of retrogression of pitch may be of interest. To express it as a function of passing time, let

d = distance from observer to fence.
a = constant distance between pickets.
v = velocity of sound.
n = number of vibrations per second.
t = the time following the initiation of the reflected tone.

Then by aid of a diagram we easily obtain the following relation between the above quantities, viz.:

$$\frac{v^2}{4\,a^2\,n^2} = 1 - \frac{d^2}{(v\,t + d)^2}$$

The curve for this equation is not easily classified. But by computing quantities and constructing a curve it is found to be very much like a hyperbola referred to its asymptotes, which indicates that the pitch falls rapidly at first, and less so subsequently.

Not only is the above described phenomenal reflection observed in connection with fences, but from any series of flat surfaces in steps, as, indeed, in the case of stairs under proper conditions. Such echoes have been observed from the steps in front of the State House, at Columbus, O.

THE AYE-AYE OR CHEIROMYS OF MADAGASCAR.

During the present year the Menagerie of the Botanical Garden has been enriched by the addition of several rare animals, and among others, by that of three Lemurs of Madagascar belonging to the strange species commonly called Aye-Aye, and scientifically *Cheiromys Madagascariensis*. The Museum of Natural History already possessed in its collection, not only the same species, obtained more than a century ago, by the explorer Sonnerat, but also several specimens preserved in alcohol or reduced to skeletons, which have been presented at more recent dates by M. de Lastelle, M. A. Grandidier and M. Meurand. The study of these different specimens and of those which the British Museum has procured, has at length led naturalists to the discovery of the true affinities of the Aye-Aye, and has decided the place it should occupy in classification, namely in the order of Lemurs. But, before coming to this conclusion, there was a great deal of hesitation and groping in the dark. Sonnerat, who discovered the Aye-Aye in Madagascar, considered it a squirrel having some connection with the Makis, soon after, Buffon found in it certain resemblances to the Tarsier, then Gmelin placed it decidedly in the genus *Sciurus* or Squirrel, under the name of *Sciurus Madagascariensis*; later still, E. Geoffroy Saint-Hilaire made a particular genus for this strange animal, namely *Daubentonia*, which G. Cuvier, agreeing with Geoffroy, afterwards changed to *Cheiromys*; finally Blainville maintained that the Aye-Aye belonged to the order of Lemurs, and he was successful, though not without difficulty, in establishing his views.

The Aye-Aye has nearly the height of a cat and resembles in a slight degree the Feline tribe in its short and globular head, erect and uncovered ears, eyes very open, nostrils oblique and pierced at the extremity of the nose, although it resembles a Squirrel in its slender toes, the color of the hair, and its bushy tail. But it differs entirely from both of these animals by the arrangement of its paws. In the Aye-Aye, indeed, the posterior limbs terminate as in the great majority of the Lemurs, in real hands, the thumb, however, being a little less developed than in the latter animals, and the anterior limbs present, at their extremities, singular anomalies. Here the thumb is no longer opposable to the other fingers and it carries, as the latter, a true claw, the middle finger is so slender that it seems withered, the fourth finger is a little less slender but still larger than the other, and finally, the little finger is very extended.

The dentition of the Aye-Aye differs in several respects from that of the other Lemurs; there are, indeed, two strong and sharp incisors in each jaw, four molars on each side of the superior maxillary and three molars only in the inferior maxillary; but no trace of canines, superior or inferior, can be seen in the adult, so that a wide space separates the incisors from the molars. Yet, this anomaly does not exist to the same degree at all periods of life, and, in the young, the dental system is least removed from the ordinary type, owing to the presence, in the superior maxillary, of a pair of small incisors.

Arrived at its full development, the Aye-Aye measures more than a metre from the end of the nose to the extremity of the tail, whose length is about equal to that of the body. It has smooth and slightly wart-like ears, uncovered nose, and lips ordinarily half open, exposing to view the incisors which, meeting two by two in a very prominent angle, resemble the beak of a parrot. Hair, bushy and very long, covers the whole of the body, the limbs and the tail, but does not present in every spot a uniform color; the hairs of the head and of the back are often white at their ends, while those of the breast and of the flanks are of a more or less brown, deepened by a yellow base. In the young, the whole front is also of a silvery white, and the dorsal line is marked by a band of the same color.

In Sonnerat's "Voyage aux Indes et à la Chine," some of the principal characteristics of the Aye-Aye are spoken of, but the portrait leaves much to be desired, and the author mentions but a few things on the habits of this curious representative of the fauna of Madagascar. This animal, says Sonnerat, appears to burrow, it does not see in the day, its eye is reddish and fixed like that of a screech-owl. It is very lazy and, consequently, very gentle. I have had the male and female and they lived only two months. I fed them with boiled rice, and they used in eating, the two slender toes of the fore-feet as the Chinese use chop-sticks. They are timid, fearful, like a great deal of heat, always roll themselves up in sleeping, lie on the side, the head between the fore-limbs. They were always lying down, and it was only on shaking them several times, that they would move at all.

Although this animal is very slow in movement, and seems to be torpid during the day, it has no relation to the *Unau* and the *Ai* of M. de Buffon. The name of Aye-Aye, which I have kept for it, is a cry of exclamation and astonishment among the inhabitants of Madagascar. This animal has been known to us but for a few years, because the western side, the part which it inhabits, is but little frequented; the inhabitants of the eastern side assured me that it was the first they had ever seen.

Fortunately, the successive observations on the *Cheiromys* at the Zoological Gardens at London and at Paris have completed the information given by Sonnerat on the manners and the diet of this species. The Aye-Aye is essentially a nocturnal animal; in captivity, it sleeps during the whole day, lying on the side, its body curled up and entirely covered by the bushy tail. During the night, on the contrary, it moves about continually, scratching and gnawing the walls of its prison. Frequently it hangs by its hind claws, and, in this position, it performs its toilet in the manner of certain Bats. In this operation it uses the third finger of the fore-feet, which it bends in the form of a hook in order to comb the tail and to adroitly wipe its front, the corners of its eyes, the nose, mouth and ears.

In eating, the Aye-Aye exclusively employs the left hand; it thrusts into the semi-liquid food which is given to it, the fourth finger, the longest of all, holding the third raised above the others, and the thumb, on the other hand, very low. The extremity of the anterior limb, thus arranged, describes a singularly rapid motion to and fro, and the lateral face of the fourth finger, passing every moment between the lips of the animal whose head is inclined on one side, places the food in the buccal cavity, over the tongue. At the same time, the cheeks and lips are in continual motion. "The Aye-Aye," says Mr. Bartlett, "can also advance its lips and lick in the manner of cats; but it does this but rarely. I have never heard it utter a single cry, emit any sound, during the long hours of night, and I never have observed that he was made uneasy by my presence. This Lemur seeks no species of insects, but readily feeds on a sort of pap made of milk, honey and eggs; it appears to love semi-fluid substances, soft and mucilaginous, while it rejects with contempt worms, grass-hoppers, and the larva of hymenopters. I have then the right to state that, in a state of nature, the Aye-Aye is not insectivorous. Seeing its strong and sharp teeth, I am inclined to believe that it cuts grooves in the bark of trees, in order to make the sap flow; it receives this in its mouth and it forms its principal nourishment. In support of this opinion, I state the fact that the animal frequently returns to the same spot on the branch or on the trunk, which it first attacked. It must also be stated that the Aye-Aye pays, so to speak, no attention to what it carries to its mouth. Having on several occasions withdrawn the dish which contained its pap, while it was eating, I saw with astonishment that it continued to direct its hand towards the spot where its food had been, and that it did not search for the latter until after having, for a long time, mechani-

THE AYE-AYE, OR CHEIROMYS OF MADAGASCAR.

cally executed prehensile motions. Such a stupid manner of acting is in complete contradiction to that which is observed among animals that devote themselves to the pursuit of other animals and feed on living prey; I presume, therefore, that the Aye-Aye feeds on vegetable substances. I have often seen it, after having swallowed a certain quantity of liquid food, devour a piece of bark."

The Cheiromys, at the Botanical Garden, given by M. Humblot and M. Archambault, act exactly like the one which has been so conscientiously studied by Mr. Bartlett, the Superintendent of the Zoological Garden of London. They sleep during the whole day, which is very annoying to the visitors desirous of seeing these strange animals, and, when the keeper tries to arouse them from their sleep, they show their ill-humor by attempting to bite and by endeavoring to retreat to the most obscure corner of their cage.

In Madagascar, the Aye-Aye inhabits the large forests, and are found not only in the western region, as Sonnerat thought, but also on the southeastern side, where it has been observed by M. Grandidier. According to the natives, it builds a real nest, of a spherical form, in which the female deposits and raises her young. This assertion without doubt merits belief, since in 1877, M. Soumage brought to France one of these nests, which was built on the forked-head of two branches, and which contained a female and her young. The walls of this nest were formed of rolled leaves of the Ravenala or *Tree of the Traveler*, covering an interweaving of twigs; it has on one side a very narrow opening.

The smallest of the other Lemurs—the Chirogales, the Microcebes and the Lepilemurs—have, it appears, similar habitats, and also interweave, with twigs and leaves, a home for their progeny, while the Makis, and all the higher orders of Lemurs, build no nests, and carry their young attached to their back or hung against their breast.—*Translated from La Nature.*

DETECTION OF OLEOMARGARINE.*

By P. Casamajor.

In the *Moniteur Scientifique* for April, 1881, is an article on Butter Analysis, in which are given the processes, used at the Municipal Laboratory, attached to the Prefecture of Police in Paris, for the detection of foreign fats in butter. This is followed by an account of an areometric method, used for the same purpose and based on the difference of density between butter and the fats with low melting point, extracted from tallow, which are made to resemble genuine butter, and which are known under the commercial name of *Oleomargarine.*

The sale of Oleomargarine has become so extensive in this country, that a purchaser of butter is never sure whether he is getting true butter or its imitation. In view of this fact, I have thought it useful to give a process, based on the difference of specific gravity between butter and oleomargarine, of such simplicity that it can be easily applied by any person having rudimentary ideas of manipulation.

Processes of this character are those which can be used with greatest efficiency to check adulterations. I have, in previous communications, given such processes for the detection of Starch Sugar mixed with Cane Sugar, and for the detection of starch sugar syrup, mixed with sugar house syrups.

Although my concern is principally with the difference of density between butter and oleomargarine, I propose to very briefly call attention to the processes used at the Municipal Laboratory of the Prefecture of Police, as these show important differences in chemical composition between true butter and its adulterant, which confirm the difference in the specific gravity. Such an important character as the specific gravity would not differ to any marked extent, without a corresponding diversity in the composition of the two substances.

One process used at the Municipal Laboratory is the following: the sample of butter to be tested is melted, so as to separate water, salt etc., which are deposited, and a certain amount of scum, which comes to the surface. Of the clear melted fat, under the scum, about 3 or 4 grammes are taken and saponified by 1 or 2 grammes of potassic hydrate. The fat and potassa should be mixed with 50 C. C. of alcohol. In about 5 minutes the saponification is complete, and the cautious addition of water should not produce any turbidity. If any takes place, the operation must be begun anew. The soap formed is afterwards decomposed with weak sulphuric acid, and the insoluble fat acids are collected and weighed. The result of a great number of experiments is that in butter the percentage of fat acids thus obtained is usually 86.5 to 87.5 per cent., and that sometimes, it is as high as 88 per cent. In animal fats from tallow the percentage of insoluble fat acids is 95½. The difference $95\frac{1}{2}-87\frac{1}{2}=8$ per-cent., is attributed to the absence in tallow of volatile and soluble fat acids which exist in butter.

Another process is given in which the result is obtained volumetrically, by estimating the quantity of potassa used in saponifying the fat. One gramme of butter requires 225 to 232.4 C. C. of potassa solution, while 1 gramme of tallow, or other animal fat of the same nature, requires from 195 to 197 grammes of the same potassa solution.

Mr. Charles Girard, director of the Municipal Laboratory, considers as adulterated any butter requiring, for saponification, less than 221.5 C.C., of the potassa solution. In some unfavorable cases this volume may represent nearly 30 per cent. of foreign fat.

The method for detecting the difference between butter and oleomargarine by the difference of specific gravity, is one proposed by Messrs. Leune and Harburet.

The butter to be tested is first melted so as to separate the pure fat from water, salt, etc. The clear melted fat is placed in a cylinder, heated by the vapor escaping from a water bath, kept boiling, but no part of the cylinder is to be in the boiling water. I understand that by heating in this way, the temperature of the melted fat remains at about 93° C. To determine the density of this fat an areometer is placed in it. This areometer is graduated in such a way that, in butter, it will sink to the lowest mark of the scale, while oleomargarine corresponds to the highest point in the graduation. The intervening space is divided into ten equal parts, each one of which corresponds to $\frac{1}{10}$ of oleomargarine, mixed with butter. More than 600 experiments made by Messrs Leune and Harburet with artificial mixtures show that, within an approximation of ten per cent., the instrument gives correct results.

Soon after this areometric method was published, it was announced that the difference of the specific gravities of butter and of oleomargarine, was too slight to distinguish the one from the other. As Messrs. Leune and Harburet had not stated what the specific gravity of each was, it was impossible to judge of the truth of this statement, and it became interesting to ascertain the facts of the case. The following process is the result of my attempts to determine the specific gravities of butter and of oleomargarine. I chose in the first place to ascertain the specific gravity of each at 15° C, which is the usual temperature for such determinations. The process consisted in finding for each a liquid in which, at 15° C, a portion of butter or of oleomargarine, freed from impurities by previous melting and containing no air bubbles, would remain in equilibrium in any portion of the liquid, without any tendency to rise to the top or sink to the bottom. The readiest liquid for this purpose was a mixture of alcohol and water, as this is easily prepared and it has no dissolving action on the fats to be tested. As the density of the liquid in which a body remains in equilibrium is the density of the body itself, the problem was narrowed down

* (Read before the American Chemical Society Sept. 1881.)

to finding the difference of density between two mixtures of alcohol and water of different strengths. It was found that pure butter, at 15° C, would remain in equilibrium in alcohol of 53.7 per cent. This corresponds to specific gravity 0.926. This butter was obtained from a gentleman, at whose country place the butter was made. I obtained oleomargarine from melted warm beef suet by pressure. At a temperature of 25° C, this expressed fat had the consistency of butter. The alcohol which at 15° C, would hold it in equilibrium had a strength of 59.2 per cent., which corresponds to a specific gravity of 0.915.

The question of the possibility of distinguishing butter from oleomargarine becomes equivalent to the possibility of distinguishing alcohol of 53.7 per cent., from alcohol of 59. 2 per cent. As this difference is 5.5 degrees of Gay Lussac's alcohometer, it is very evident that the specific gravity is a sufficient character for distinguishing butter from oleomargarine. This difference may appear more clearly to persons not familiar with alcohometry by stating that it is the difference between 0.926 specific gravity and 0.915.

By means of the tables of Gay Lussac and of Tralles,* it is a very easy matter to prepare alcohol of the required strength at any temperature, to be kept in bottles for future use.

As the expansion of fats is different from that of alcohol, it is advisable to bring the alcohol to 15° C, when making an observation, which can be easily done by any one provided with a thermometer.

To deliver the sample of fat on the alcohol, I have found that the best plan is to melt the fat and let a large drop of it fall into the liquid. The fat should be melted in a little spoon or a little scoop, and the drop should be delivered by bringing the spoon or scoop close to the surface of the alcohol. It requires a little practice to do this neatly, so as not to get an air bubble in the ball of melted fat. When an air bubble becomes imprisoned in the fat, I have had no difficulty in removing it with a strip of paper, while it lies on top of the alcohol. Sometimes the globule of fat only partially sinks in the alcohol; the top of it becomes flat and remains exposed above the liquid. A slight tap on the side of the glass is then generally sufficient to form a wave and sink the globule.

If we take alcohol of 56½ per cent., which represents equal volumes of alcohol of 53.7 per cent., and of 59.2 per cent., and if we deliver on the surface of this alcohol a globule of melted butter and one of oleomargarine, the butter will sink to the bottom and the oleomargarine will remain at the top, while the two globules are still warm and liquid. Afterwards, if the alcohol has a temperature of about 30° C, the butter will become solid, while the oleomargarine may still remain liquid. Then the butter will rise to the top of the alcohol, which is due to the expansion of butter on solidifying. If the alcohol be then kept for a few minutes, at 15° C, the oleomargarine will become opaque and remain at the top while the solid globule of butter will sink to the bottom.

If instead of taking alcohol of 56 per cent. we use alcohol of 59.2 per cent., oleomargarine will remain on top and butter will sink to the bottom at all temperatures above 15° C. At 15° C., oleomargarine will remain in eqilibrium in any portion of the liquid in which it may be placed.

If oleomargarine was always sold pure, the foregoing indications would be sufficient to distinguish it from butter, but the oleomargarine found in the market is always more or less mixed with true butter to improve its taste and appearance. This being the case, alcohol of 59 per cent. is not the proper liquid to detect oleomargarine. We should use alcohol of 55 per cent. and consider as oleomargarine any so called butter which will not sink to the bottom in alcohol of this strength at 15° C. This is founded on the fact that not more than ⅓ of butter is ever mixed with oleomargarine to improve its taste and appearance.

*See the excellent tables of Prof. Mc. Culloh.

Bearing in mind the experiments of Messrs. Leune and Harburet, already cited, the proportion of butter and of oleomargarine in a mixture could be easily detected by finding what strength of alcohol will hold in equilibrium at 15° C, a globule of fat under examination. As the difference of 59.2 and 53.7 is 5. 5, the proportion of oleomargarine is the difference between the strength of the alcohol and 53.7, divided by 5.5, or more conveniently multiplied by 0.18. If the alcohol required to hold a globule of fat in equilibrium at 15° C, has a strength of 57 per cent., then: $(57-53.7)\times 0.18=3.3\times 0.18=5.95$, or say $\frac{6}{10}$ of oleomargarine. If the alcohol had a strength of 58, then $58-53.7\times 0.18=4.3\times 0.18=7.72$, or about $\frac{8}{10}$ of oleomargarine.

The proportions of butter and oleomargarine in a mixture may be also determined without the aid of an alcohometer, by using the two solutions of 53.7 per cent. and of 59.2 per cent. These may be placed in graduated glasses and poured cautiously into a third glass, until an alcohol of sufficient strength is obtained to keep in equilibrium a globule of the fat under examination at 15° C.

The relative volumes of the two solutions used in making the mixture, give the proportions of butter and oleomargarine.

The accuracy of these calculations rests entirely on the results obtained by Messrs. Leune and Harburet. I have not verified them by experiment, and I do not clearly see their utility. When we buy butter it is interesting to know whether what we buy is pure butter or not. It is no palliation to the offence of selling oleomargarine for butter that the oleomargarine contains ¼ or ⅕ of real butter.

FILARIA OF THE HUMAN BLOOD.

The members of the Pathological Society, of London, recently enjoyed the rare opportunity (in this country) of seeing the filaria sanguinis hominis in the living state from a patient in the London Hospital suffering from hæmato-chyluria, under the care of Dr. Stephen Mackenzie. They were also enabled to hear from Drs. Cobbold and Vandyke Carter the facts at present known concerning filarious disease, whilst the observations related by Dr. Mackenzie, most patiently and carefully pursued for two months upon the case in question, were a valuable addition to these facts. In one important point these observations have resulted in a further discovery, to which we shall refer again. Our present purpose will be simply to gather up briefly the facts as detailed by these speakers, and to indicate their bearings upon the pathology of the obscure affections of the lymphatic system with which they are connected. In the first place we have now—thanks to the discoveries of Bancroft, Lewis, and Manson—a complete knowledge of the life history of the parasite. Like so many similar creatures, it presents us with an example of alternation of generations; or more correctly speaking, of the need of two hosts for its full development. The minute almost structureless worms found in the blood of the human subject in such vast numbers are the *embryonic* forms of the filaria which requires the mosquito in which to develop into the sexually mature worm. The mosquito feeding on the blood at night, when the filariæ are generally alone to be found, becomes gorged with them. Their growth in the mosquito has been traced by Lewis and Manson, and it is presumed that they are only liberated from the body of their host by its death in the water to which it always finally resorts. The nematoid is thus set free, and possibly undergoes further development; for the mature worm measures some three inches in length. Its passage into the human body is easily explained; and the analogy in this respect with the larger nematoid—the guinea-worm—is one which Dr. Vandyke Carter ably illustrated. Once within the human body, the worm lodges in the tissues, but as to its migrations, and, indeed, its ultimate resting-place, but little is known. It

would seem, from its discovery in a lymphatic abscess by Bancroft, and in a lymph scrotum by Lewis, to have a peculiar aptitude for selecting the lymph channels for its habitat; a selective power not more remarkable than that which urges the trichina to lodge in muscular tissue. This is further borne out by the fact that its embryos—the filaria sanguinis hominis—are met with in the blood and the urine of the subjects of chyluria and nævoid (or lymphatic) elephantiasis.

Now, although the various discoveries which have been made—at the expense of so much patient research and at such various times that, as Dr. Cobbold remarked at the meeting, they form each distinct "epochs"—have enabled us to form the above complete sketch of the life-history of the parasite, there are lacunæ still to be filled up. Thus knowledge is wanted upon the growth and migration of the parent worm after it has gained entrance into the human body, also as to its duration of life, and particularly as to the question whether it can take on the power of a sexual reproduction, and if so, for how long a time. The myriads of filariæ that are probably daily reproduced in the body of such a patient as that under Dr. Mackenzie's care seem to demand such a fact as alternate generations, and also to raise the question as to the time during which the process of reproduction can continue. There is no reason to believe that the embryonic filariæ in the blood can undergo further development within the human body; indeed, analogy, as well as the remarkable discovery of an intermediate host in the mosquito, are opposed to this notion. Again, filariæ have been found in the blood apart from chyluria or any outward manifestation of lymphatic derangement; but this is explicable if it be admitted that the adult worms may lodge in other parts of the body in communication with blood vessels alone. Conversely, chyluria may exist without filaria, and the case mentioned by Dr. Mackenzie, where the parasite was found in the man's blood in India, but could not be found when he came to England, is explicable on the view that though the parent organism might have perished, or yielded no more embryos, yet the change excited by its presence in the lymphatic channels, and therefore the chyluria, might still have persisted.

The precise mechanism of chyluria still requires to be explained, and until it is elucidated an important part of the subject will remain obscure. The question of the pathology of chyluria was, however, barely touched upon on Tuesday, Dr. Mackenzie limiting himself to the statement of the facts observed in his case; the most important in connection with the urine being that besides having all the chylous characters, it invariably contained more or less blood,—that passed by day containing more blood and filaria, that passed by night being more milky; and that filariæ were found in it, especially in connection with blood coagula. The most remarkable feature of the whole case lay in the periodicity shown by the filariæ in their time of appearance in the blood. During the whole period of the man's stay in the hospital his blood had been examined regularly every three hours, with the constant result that, by night, the filariæ abounded and by day were entirely absent. From 9 A. M. to 9 P.M. they were absent; they appeared at the latter hour and increased up to midnight, then decreased till at the first-named hour none were found. These observations entirely confirmed those of Manson, and particular stress was laid upon their nocturnal wanderings and the habits of the mosquito. It is certainly singular that the time selected by the mosquito should coincide with the presence of the parasite in the blood stream, and the connection of these two facts is not the least wonderful chapter in the life-history of the parasite. But whatever the explanation of the periodicity—Dr. Vandyke Carter pointed out that it was not invariable,—a valuable addition to our knowledge of it has been made by Dr. Mackenzie. He found that whereas the time of ingestion of food bears no relation to it, it is otherwise with the time of rest and sleep, for when the patient was up during the night and slept during the day the period of filarial migration was similarly inverted. Dr. Mackenzie did not venture to speculate upon these curious points. He wisely contented himself with laying the facts he had observed before the Pathological Society.—*Lancet.*

A VERY REMARKABLE METEOR.

On the evening of Wednesday the 16th, while sweeping the western heavens in search of comets, I was startled by a brilliant illumination to my right; looking up hastily, a bright meteor was seen moving rapidly along the north-eastern heavens. It started from a point about 3° north of Capella, and, traversing a path of about 10°, passed some 2° above *delta Aurigæ.* The flight of the meteor did not exceed three seconds, when it burst with a dazzling brilliancy, to be compared only to the whiteness of the electric light. At the moment of exploding it must have been at least five or six times brighter than Venus at her maximum. There remained in its wake—covering the full extent of its path—a thin reddish train; this drifted slowly among the stars towards the north-east, gradually collecting into a lightish cloud at its N.E. end. Noting the remarkable permanency of the train, I turned the telescope (a 5-inch refractor) upon it, and was surprised to see a very brightly glowing mass of pinkish smoke; the same material lay stretching out toward the southwest in a long, straggling strip; this trail was about one-fourth a degree in thickness, and could plainly be seen with the telescope for a distance of at least ten degrees. This mass of smoke drifted northeasterly over the stars, curling slowly, like a mighty serpent. It was knotted in several places with cumulous forms which were due probably to minor explosions in the meteor. The outlines of this wonderful train of celestial smoke were well defined; it did not diffuse itself in the atmosphere, but faded gradually from view. During the whole of its visibility it retained its pinkish color. The appearance of the meteor was at 48m. past 6. The train remained visible to the naked eye for about six minutes. In the telescope it was very distinct up to seven o'clock. At three minutes after seven it was still visible in the instrument. Meanwhile it had drifted about 4° to the north-east, becoming more crooked each moment as it curled about in the air. The remarkable duration of the train of smoke from this meteor—over fifteen minutes—deserves being recorded. E. E. BARNARD.

NASHVILLE, Tenn., *November* 21, 1881.

INSTRUCTIONS ISSUED BY THE INTERNATIONAL CONFERENCE FOR THE OBSERVATION OF THE TRANSIT OF VENUS OF 1882.

Contributed by M. BENJAMIN, Ph. D.

ARTICLE 1.—It is desirable, from a theoretical standpoint, that the telescopes used should be of as large aperture as possible. In practice, the difficulty of transportation on the one hand, and the necessity of observers at different stations having similar instruments, limits the apertures to from 0.12 metre to 0.15 metre (about 4½ to 6 inches).

In all cases the objectives should be as perfect as possible. Observers should give an exact description of the quality and defects of the objective, as also the eye-piece employed. Towards this end they should determine:

1. The form of the image of a good star in focus, as also the image of the same star at a point before and after coming into focus.

2. The separating power of the objective for double stars.

It will be useful to know also if the telescope is able to show the solar granulations on any favorable opportu-

nity, and also the degree of visability of these granulations during the transit.

ARTICLE 2.—It will be well to employ a reflecting prism, or a polariscopic eye piece, to diminish the heat and consequent danger to the observer's eyes.

If it be decided to use a silvered objective, a method which offers the great advantage of eliminating all the obscure heat rays and doing away with errors from distortion arising from heating of the interior of the tube, the excess of light may be absorbed by a neutral tint glass composed of two glasses of similar thickness, one being colored and the other colorless.

ARTICLE 3.—The eye-pieces should be positive, achromatic, and of a power of 150. The observations of contacts should be made in a field sufficiently clear to show plainly projected on the solar disc, two wires separated by a distance of 1″.

Means should be employed to remove as far as possible the effects of atmospheric dispersion.

The setting point of the reticule should be previously ascertained on the stars or by means of a collimator focussed to stars.

In cases of observation by projection, correspondent means should be employed.

ARTICLE 4.—The times corresponding to internal contacts may be defined as follows:

Ingress. The moment when an evident and, at the same time, persistant discontinuity in the illumination of the apparent limb of the sun joining the point of contact with Venus, disappears.

Egress. The moment of the first appearance of an evident and, at the same time, persistent discontinuity in the illumination of the solar limb joining the point of contact.

If the limb of two stars coming into geometrical contact, without obscuration or deformation of the interposed thread of light, the instant previously defined is that of contact.

If there be produced a black drop or ligament, well defined and as dark as the body of the planet, the precedingly defined instants, are for Ingress, that of definite rupture, and for Egress, that of the first apparition of the ligament.

Between these two extreme cases, other appearances may be produced when the instants of contact may be noted as follows:

If the limbs remaining without deformation, there is produced an obscuration of the luminous thread, without the shadow, however, being as dark as the body of the planet, the observer notes the instant of geometrical contact. The moment of the formation or disappearance of this shadow should also be noted.

If the shadow is almost or becomes quite as dark as the planet, the precedingly defined instant is that when this equality ceases or is established.

The observer should also note whether there is produced on the luminous thread, any fringes or any other distinct phenomena, and should note the moment of their appearance and disappearance.

It is generally desirable to note the time of occurrence of any distinct phenomena about the time of contact. Nevertheless it is a grave mistake, and one that should be guarded against, to multiply the noting of times near the occurrence of a contact.

The time of appearance of phenomena of a distinct character, should be mentioned only in such a manner as to be readily separated from other phenomena observed about contact.

It will be useful in all cases that the observer should illustrate his notes with a drawing made immediately after each complete observation of contact, in order to show more clearly the interpretation which he attaches to his description of the phenomena.

ARTICLE 5.—As the limb of Venus falls internally on the solar disc during internal contact, as has been noted in Article 4, the observer should indicate as closely as possible whether the moment when the limbs of Venus and the sun, apparently coinciding, seem to be lengthened out.

This observation, though rough, is still desirable as a check to the principal noted phase.

ARTICLE 6.—Notwithstanding the fact that observations of external contacts are subject to considerable uncertainty, the conference recommends that they be observed either by direct vision or by means of the spectroscope, and that the point on the solar disc, where the first contact takes place, be determined in an appropriate manner.

COMPTES RENDUS, Oct. 17, 1881, t xciii., p. 569.

BACTERIAN NOTES.

So long as the makers of microscopes do not place at our disposal much higher powers, and as far as possible without immersion, we shall find ourselves in the domain of the Bacteria, in the situation of a traveler who wanders in an unknown country at the hour of twilight, at the moment when the light of day no longer suffices to enable him clearly to distinguish objects, and when he is conscious that, notwithstanding all his precautions, he is liable to lose his way.—Cohn.

Bacteria were regarded as animals up to the time of Dujardin (1841), a kingdom—the *Protista*—midway between the animal and vegetable, being created by Haeckel for their especial benefit. Duvaine (1859) was, however, among the first to show clearly their alliance with the algæ. Cohn holds them to belong to the algæ, although from want of Chlorophyle, approaching the fungi. Magnin says, "If there are still some differences of opinion among naturalists as to the place of the Bacteria among the cryptograms, there is but one opinion of their vegetable nature." Sachs, however, solves the difficulty by uniting the algæ and fungi in a single group, the *thallophytes*, in which he establishes two series exactly parallel —one comprising the forms with chlorophyle, the other, the forms which are deprived of it."

"The Bacteria, then, resemble green plants, in that they assimilate nitrogen contained in their cells by taking it from ammonia compounds, which animals cannot do, They differ from green plants in that they cannot draw their carbon from carbonic acid, and only assimilate organic substances containing carbon, above all the hydrates of carbon and their derivatives; and in this respect they resemble animals."

Ehrenberg was the first to maintain that the motion of Bacteria depended npon the presence of vibratile cilia (observed by him in *spirillum volutans*), but although the cilia, denied at first by most microscopists, have been since seen in nearly all the bacteria, recent researches permit us to say that cilia exist without doubt in all true bacteria; the botanist who has best studied them, M. Walming for example, recognize that it is scarcely probable that these organs are the cause of their movement, for one meets some examples in which the body remains motionless, while the cilia are in violent agitation, and others in which the body moves, while the cilia remain inert or dragging behind.

Cohn explains the origin of the gelatinous substance in which the bacteria are included as being produced by a thickening or jellification of the cell membrane, but a more plausible view is that it is produced by a secretion from their protoplasm.

MR. A. AGASSIZ has printed in the *Proceedings of the American Academy* a biographical sketch of the late Count Pourtalès, together with a biographical list of his principal publications. Mr. Agassiz has also written a Review of Professor Haeckel's Monograph of the Acalephs in the August number of the *American Journal of Science.*

ATOMIC PHYLLOTAXY.

Gerber (*Chemical News,* XLIII, 242–43), says that "no simple relation exists among" his divisors, therefore they "have no value in themselves." There is, however, a relation which he failed to discover, for they are phyllotastic, as will be seen by the following comparison:

Gerber's Divisors.		Phyllotastic Divisors.	
H	.9997	$H = 0 \div 2^4$	.998
D_1	.769	$\frac{5}{13} \times 2\,H$	.768
D_2	1.995	$2\,H$	1.996
D_3	1.559	$\frac{5}{2} \times \frac{5}{8}\,H$	1.559
D_4	1.245	$\frac{5}{2} \times \frac{1}{2}\,H$	1.247

PLINY EARLE CHASE.

HAVERFORD COLLEGE, *Nov.* 10, 1881.

ON September 13, 1881, a red star was noticed at the Harvard Observatory in R. A. 16th, 31. 5 m, Dec. + 72° 32′. From the similarity of its spectrum to that of several known variable stars, it was presumed to be variable; and the suspicion was confirmed both by its absence from the catalogues, and by subsequent observation, which showed that its brightness was increasing. Information respecting it was sent by telegraph to Dr. Copeland, at Strassburg, by means of the telegraphic cipher devised by Messrs. Chandler and Ritchie.

THE Museum of Comparative Zoölogy, of Harvard College, has received a collection of ninety species of fossil plants from Cannelton, Pa. The species have been identified by Mr. Lesquereux, who pronounces the series one of the best made by Mr. Mansfield from that locality.

THE annual report to the government of India on the progress of the cinchona cultivation and its practical results is a document not only of great importance, but also of considerable interest. The success which was chronicled in previous reports has been well maintained under the superintendence of Dr. King, who has the responsible charge of the cinchona cultivation in Bengal. It will be remembered that the object to which efforts hitherto have been chiefly directed is the manufacture of a cheap febrifuge from the bark of the cinchona succirubra. The plantations of this tree which are now in existence are so extensive as to suffice for present and probable requirements, so far as the febrifuge is concerned. They contain more than four millions of trees, and from them 267,335 lbs. of red bark were obtained during the year. The yield per acre (1510 lbs.) is not, however, considered to be very good; 9296 lbs. of the febrifuge were made during the year, and 8653 lbs. were consumed, 5500 lbs. being used in the Government services and 3150 lbs. sold to the public. The demand for the febrifuge steadily increases, a satisfactory proof of its value, and the total amount manufactured from the commencement to March 31, 1881, is 36,639 lbs.

Financially the enterprise, initiated with such pains by Mr. Markham, must be regarded as a complete success. The actual profit on the year's working was eight per cent. on the capital of the plantation. This does not, however, represent the whole gain of the year. The price of quinine was very high, and the cost of the 5550 lbs., which would have been used by the Government had the febrifuge not been available, would not have been less than £48,000, while the cost of the febrifuge was only a sixth of the amount, representing a saving of at least £40,000.

METEOROLOGICAL REPORT FOR NEW YORK CITY FOR THE WEEK ENDING NOV. 26, 1881.

Latitude 40° 45′ 58″ N.; Longitude 73° 57′ 58″ W.; height of instruments above the ground, 53 feet; above the sea, 97 feet; by self-recording instruments.

SATURDAY, DECEMBER 10, 1881.

Sir—On the evening of November 24, I noticed that the spectrum of the star DM. $+36°$ 3987 has a bright band in the blue. The star, accordingly, belongs to the small class of objects which comprises Rayet's stars in Cygnus (near this one) and Oeltzen 17681, discovered here in 1880.

On November 25 I found a small planetary nebula, undistinguishable from a very faint star by the ordinary eye-piece, bnt detected by the character of its spectrum. Its place for 1880 is in R.A. $20^h\ 6^m\ 26^s.4$, declination $+37°\ 3'\ 25''$. It follows W. XX 200 eight seconds, three minutes of arc farther south, and is followed respectively $2^s.6$ and $2^s.3$ by two faint stars north $37''$ and south $20''$ of the nebula.

Cambridge, *December* 1, 1881.

Edward C. Pickering.

SHALER AND DAVIS' "GLACIERS."[1]

By W. J. McGee.

I. Introduction.—The extensive superficial modification of the globe accomplished through the agency of water in its three states of aggregation has been rendered possible by certain properties peculiar to this substance, chiefly (1) its powers of assuming the several forms of solid, liquid, and vapor within the narrow range of terrestrial temperature, (2) its enormous capacity for heat, and (3) its power of dissolving other substances.

The temperature of the earth's surface is indeed largely determined by the aqueous vapor contained in the atmosphere; for if it were not for this vapor the solar energy falling upon the earth would be radiated away almost as quickly as received, and could exercise but little influence upon temperature. The narrow range of terrestrial temperature since the beginning of the organic record attests the enormous capacity and marvelous delicacy of this temperature—equalizing agent, for within the limited bounds of the space separating earth and sun, the temperature varies from a hundred thousand degrees above to two hundred and fifty degrees below the Fahrenheit zero; though accidents in this adjustment are attested by the traces of successive ice periods in the geological history of the globe. The influence of liquid water in producing the various phases assumed by the earth's surface, during geological time has long been the subject of study; but it is only within the last forty years that the newly commensurate influence of ice has been detected.

II. *The existing glaciers of the earth.*—The most accessible of the existing glaciers are those of the Swiss Alps; and the best route for the student to pursue in entering this region is to pass up the valley of the Rhone.

Here, aside from the more obscure evidence of the former great extension of the glaciers, the various works of ice-action became constantly fresher in ascending the river until they disappear beneath the wall of ice constituting the terminal portion of the glacier. At the foot of this ice wall is an irregular mass of stones and earth—the *terminal moraine*—lying across the valley, cut in twain by the muddy stream emerging from a cavern in the basal portion of the glacier; and the ice itself is gullied by tiny rills and soiled with sand and dirt, and hardened with pebbles and rock fragments, which from time to time roll down its steep front, to the morainal heap below. When the glacier shrinks for several successive seasons, as occurs when the weather is unusually dry and warm, the stream flowing from it becomes a torrent, and the moraine may be separated from the ice front by a belt of striated and polished rock, but sparsely covered with coarse *debris*; but when the ice advances for a number of years the stream dwindles, and the sheet of earth and stones is pushed forward and crumpled up into a mighty embankment, rising into a range of irregular hillocks. Many such ridges attest the various periods of temporary advance in the history of most of the secularly retreating glaciers. On ascending the ice stream itself, the superficial rock-fragments, pebbles, and earth are found to lie mainly in parallel bands, or *medial moraines*; and on tracing these to their origin, each is seen to consist of the two lines of matter constantly tumbling down the valley sides or *lateral moraines* which are brought into contact whenever two glaciers meet and merge into one. Thus the number of branches uniting to form any glacier can be determined from the number of parallel bands on its surface. The ice-stream occupies a crooked and irregular valley, the rate of its motion varying with the declivity, regularity, and width of the channel, just as does that of liquid rivers; though wherever there are considerable irregularities in the channel the strain produces cracks and fissures which gradually widen and form *crevasses*, or even, where there is a sudden increase in declivity, separates the ice into a mass of irregular pyramidal blocks, or *seracs*; but when a more uniform stretch of gentle slope is reached the seracs re-unite, and the crevasses close, transforming the fragmentary mass again into a solid,

[1] "Illustrations of the earth's surface. Glaciers; by Nathaniel Southgate Shaler, professor of Paliontology, and William Morris Davis, instructor in Geology, in Harvard University, Boston. James R. Osgood & Co., 1881." Very large 4°, pp. i—vi and 1-198, pl. i—xxv and one unnumbered, with twenty-five unnumbered leaves discriptive of plates.

homogeneous whole. The channel is rarely so regular as to allow the ice to be altogether free from crevasses, however. Such fissures are invariably at right angles to the line of greatest tension, and greatly facilitate melting by increasing the exposed surface; and when the rills formed by superficial melting flow into them they may be converted into cylindrical shafts, or *moulins*, extending to the base of the ice. Thus both crevasses and moulins remain practically stationary, or rather, when either has passed beyond the obstruction or irregularity of the channel which produced it, it gradually closes, and another forms in the same place, with respect to the valley and not to the moving ice, as that which it originally occupied. Aside from the longitudinal medial moraines the surface of the ice is often indistinctly marked by depressed transverse bands within which wind-blown sand or dust accumulates (known as *dirt-bands*); which bands curve downward medially more and more toward the debouchure of the glacier, and thus attest the differential motion of the various parts of the ice-stream. There are, moreover, occasional scattered blocks of stone and small pebbles lying upon the surface of the ice. The larger blocks prevent superficial melting of the ice on which they rest, and hence become apparently lifted on columns of ice, forming *glacier-tables*, which sometimes reach a height of some feet; while the smaller pebbles, on the other hand, facilitate melting, and thus gradually sink into miniature wells perhaps several inches in depth.

Glaciers of the alpine type are supplied by the perpetual snows accumulating in the elevated valleys and plains intervening between the highest peaks. Over these snowfields—the *névé* or *firn*—the snow is generally granular and contains much air, especially near the surface; though where it is thick its basal portions may approximate true ice in structure. It is only when the névé passes over the considerable declivity generally separating the snow-field from the ice-stream proper, and descends below the snow-line, however, that it becomes compacted, deprived of its air, and diminished in volume, so as to constitute a veritable glacier. A glacial area may accordingly be divided into two distinct regions on this basis alone;—the névé, the locality of no melting but of constant addition; and the glacier proper, the locality of constant decrease. In polar regions the glacial phenomena are more varied. Thus, in Greenland, the transition may be observed from glaciers of the characteristic alpine type to those of the characteristic polar type, in which the snow-line is at the sea level and the ice is essentially identical with the Swiss névé, though of vastly greater thickness. It is only slow-moving glaciers of the polar type that give origin to ice-bergs—the terminal portion extending into the sea "until the buoyancy of the ice causes a mass to break away from its attachments, rise to the surface, and float away, (p. 28,) scattering the debris frozen to its base over the sea-bottom as it gradually melts; for the bergs, as the névé of which they are formed, are generally destitute of superficial accumulations of earth and stones.

Since in the circumpolar regions the snow-line descends to the sea-level, the ice of winter may not be melted during the succeeding summer, but may remain *in situ* for years or ages, as in the paleocrystic sea seen by Nares. Now such a sea might be itself overspread with snow to such a depth as to depress the ice to the sea-bottom and to convert the whole mass into névé similar to that of northern Greenland, or into a true continental glacier. Indeed,—"it seems probable that the so-called antoretic continent is nothing but an immense sheet of ice such as this paleocrystic sea would become if it were to increase in depth until it fastened on the bottom of the sea." (p. 31.)

III. *Distribution of the existing glacier.*—In the Scandinavian mountains there are the large snow-field in the gostedal highland with many scattered glaciers of considerable interest, and, in lat. 70°, a vast snow-field with an immense ice-stream descending to the sea level; while on the opposite side of Russia the Ural range is without glaciers. In the Pyrenees the glaciers are much shrunken, and mainly confined to moist northern slopes, though about one hundred in number. In the Alps there are over a thousand glaciers, occupying, with the névé, about one-seventh of the mountainous alpine region. Eastward there are no glaciers until the Caucasus is reached, where a considerable snowy range, with ice-streams on both slopes, is found. A few scattered glaciers are known in Asia Minor, one in Persia (on the volcano Demarend,) and many on Hindu Kush; though these have been but imperfectly described. In the Himalayas the glaciers are of remarkable size and extent, though as yet but partially known. In the Southern Alps of New Zealand the glaciers are also of considerable extent and of great interest. On the western hemisphere glaciers occur along the western border of South America as far north as Upper Chili, where they mainly disappear, and are but meagerly represented along the Andes and Cordilleras until Oregon and Washington Territory are reached. Those occurring within the United States are of little prominence, however; but they increase in size and number northward, until at Mount St. Elias the ice reaches the sea level. In both Arctic and Antarctic regions there are also immense bodies of moving ice or névé, constituting glaciers of the polar type.

It thus appears that glaciers are mainly confined (*a*) to regions of great cold and considerable precipitation, (*b*) to mountain ranges along western coasts outside of the trade-wind zones in regions of heavy and frequent precipitation, and (*c*) to interior ranges of great height and considerable snow-fall; while (*a*) broad arid areas—even though "the ground is frozen to the depth of several hundred feet" (p. 36),—(*b*) interior ranges of limited snow-fall, and (*c*) regions having a hot and dry summer, are generally free from glaciers. The essential conditions for glaciation are hence, 1st., cold of considerable intensity; 2nd., considerable snow-fall; and 3rd., the absence of a dry season of sufficient length to melt the winters' snow.

IV. *Distribution of ancient glaciers.*—"The most remarkable fact that has been discovered by geologists during this century is, that at various times in the earth's history the glaciers, which now cover but a very small space on the earth's surface, certainly not over about one hundreth of its area of land, have been extended until they occupied a very large part of land and sea" (p. 38)." The glacial records are, however, so ephemeral that none save the last ice-period can ever be well known to us. During this period the accumulation of ice was most extensive in regions where glaciers yet prevail, or where the various meteorological conditions at least approach those which existing ice-fields indicate to be essential for glaciation, as in the Alps, the Pyrenees, and Scandinavia, over northern Europe, and in the Himalayas and New Zealand, on the eastern hemisphere; and over much of the northern portion of North America and a lesser area in the southern extremity of South America as well as isolated localities along the Andes and Cordilleras, in the western hemisphere. Over the plains of Switzerland an ice-sheet more than 4,000 feet thick swept its debris to the flanks of the Jura, a hundred miles away; but on the northern slope of the Alps the extension was less. Here the direction of motion was everywhere determined or at least modified by local topographical features. In the Pyrenees, the Appenines, the volcanic mountains of central France, and the Jura, in the Vosges, and in Corsica, the accumulation of ice was little more than the development of an extensive system of local glaciers; and north of the Alps there is little evidence of glaciation within inland Europe. The most complete testimony concerning European glaciation in the Quaternary, is furnished by Scandinavia and Great Britain. "Stretching from Scandinavia across the North

Sea, which it must have nearly closed, the North Europe glaciers extended over Scotland, all the north of England, and probably all of Ireland. On the north its limits were perhaps the polar ice itself, and in the west the deeper waters of the Atlantic. The southern limit of this ice-sheet was in the south-central part of England" (p. 40). This was probably "the southern edge of the polar ice tops [ice cap?] rather than a local system of glacial sheets" (p. 40). In North America the accumulation of ice was still more extensive, and of somewhat different character; "here the ice lay as a continuous mass, stretching down from the polar regions to the central parts of the continent, overlapping the shores for a great distance to the south along the Atlantic and Pacific coasts, and giving a continuous though irregular ice front across the land from sea to sea" (p. 41). The terminus of this sheet is yet marked by moraines as constituting the Banks of Newfoundland, George's Banks, Cape Cod, Martha's Vineyard, and Block and Long Islands, and extending thence across central New Jersey, and south as far as Washington. The attenuated margin left less distinct traces of its existence in the hills of southern Virginia, and thence into the higher Appalachians in North Carolina, whence it returned hugging the western mountain slope, and extending through West Virginia, crossing the Ohio river near the mouth of the Kanawha. Thence the southern edge of the ice skirted the north shore of the Ohio to Cincinnati, near which place it sent a lobe across the river a few miles into Kentucky. "West of Cincinnati the front of the ice sheet inclined rapidly to the north-west, and becomes hard to trace. It probably passed somewhat south of Chicago, through Iowa, and thence through Minnesota, following near the line of the Missouri to the Rocky Mountains" (p, 42). In the Cordilleras the ice was mainly confined to the higher mountains, and probably partook of the character of local or alpine glaciers within the limits of the United States; while north of our domain "we know little of its distribution" (p. 42). "There can be little doubt that the ice sheet was continuous from its southern face to the poles during the depths of the last ice time. * * * This glaciated region of North America includes more than half the continent; in fact over two thirds of its surface felt the weight of the ice during the last geological period, and works its work in the existing geography" (p. 44). The thickness of the ice is not definitely known except in the vicinity of Mt. Washington, where it exceeded a mile. In South America it is probable that continental ice never extended north of the Rio de la Plata over the plains, nor beyond the Chilian coast on the Andes.

V. *The work of the glacial time.*—Water, whether liquid or solid, is a most efficient agent of erosion; but the mode of action of the two forms is quite different. Liquid water itself operates in a two-fold manner: 1st, as a chemical agent, penetrating the earth and disorganizing its constituents, forming caverns, mineral veins, and residuary products; and 2nd, as a mechanical agent, loosening, removing, and comminuting the rocky particles, and finally bearing them to the sea to form new lands; but in the solid form only mechanical activity is manifested. There is, first, the enormous weight of the glacier (more than a ton per square inch beneath a glacier a mile in thickness), enough in itself to comminute rocks not strongly coherent and well supported laterally; there is then the abrading action of this tremendous weight dragged slowly forward—the ice being armed with fragments of rock frozen into its mass; and there is finally the corroding action of the sub-glacial streams (sometimes, perhaps, under great hydrostatic pressure) which constantly bear away the finer detritus and prevent the clogging of the grinding faces of the glacial mill. The rapidity of operation of these forces must be almost beyond conception. Even in the diminutive Alpine glaciers the sub-glacial streamlets are so fully charged with impalpable mud as to carry away more material in a few days than is moved by a sub-ærial stream of like size in a year. Now, since the erosive action of the ice is proportional to its thickness, and since, moreover, this action is most effectively supplemented by sub-glacial streams in valleys, it is manifest that the tendency of glaciation is to increase the depth of existing depressions, and thus intensify topographical irregularities. Accordingly, glaciated regions are characterized by deep bays and fords along the coast line, V shaped valleys intersecting mountainous areas, and elongated basin-like ponds and lakes dotting more uniform surfaces—the longer axes coinciding with the direction of ice-motion; while at the same time abrupt peaks and irregular knobs are replaced by gracefully rounded swells with trains of fragments to the leeward. Since the average rate of glacial erosion is so high (it was a foot in a thousand years, or more than seven times as rapid as sub-ærial erosion in New England) it would appear that important geographical changes ought to follow the visitation of an ice-sheet, not only by the carrying out of a new series of hills and dales, but by heaping up of piles of earth and stones of such magnitude as to necessitate the development of a new drainage-system; and accordingly just such geographical vicissitudes are abundantly attested in north-eastern United States and elsewhere.

The most conspicous evidence of glacial action is the mantle of *drift* occupying areas formerly overspread by ice. This drift consists of the materials torn up and indiscriminately intermingled by the glacier, and is generally a confused, unstratified mass of stones of all sizes and shapes, generally much worn, cemented together by sand and clay. It is sometimes heaped up in irregular moraines; some of which doubtless mark the lines of greatest extension of the ice, while others probably indicate temporary pauses or re-advances in its secular retreat. Along the coast this deposit has been re-arranged superficially by wave and tide, and has afforded material for immense accumulations of *terrace drift*; the unmodified basal portion being sometimes left in the form of gracefully arched *lenticular hills* of elliptical outline, the longer axis extending in the direction of motion of the ice. In regions not submerged at the close of the ice-period the upper portion of the drift has been modified by the action of running water and of vegetal growth. The moving water was rendered effective during the retreat of the ice, not so much by the increased volume to be borne sea-ward as by the imperfection of the nascent drainage system. The valleys were clogged with glacial waste, forming hosts of pools and lakelets which burst from time to time and shifted the hetrogeneous mass here and there in a series of pygmy debacles. The terraces of this period along the Connecticut river and its tributaries contain scores of cubic miles of drift thus re-arranged, and indicate by their altitude that much more material than that now remaining has been removed. Among the minor drift phenomena are the isolated hills and greatly elongated ridges of sand, gravel, or stratified clay, denominated *aasar, kames,* or *eskers.* "No sufficient explanation has yet been given of their origin" (p. 66). In the best instance known the deposit is probably a central terminal moraine, deposited in a valley of uniform slope, by a retreating local glacier. Other examples, however, appear to be not morainal; and it may be long before we understand the method of their formation" (p. 68).

VI. *The origin and nature of glacial periods.*—The earliest of the several hypotheses which have been put forth to explain the cause of the glacial period referred the phenomenon to the secular refrigeration of the globe; but the hypothesis is untenable, since it does not contemplate the several successive transitions from warmth to cold. A second hypothesis is that of Poisson, who suggested that in the proper motion of the solar system it might from time to time come into such proximity to, or recede to such a distance from, neighboring stellar bodies

as to materially affect the temperature of the planets. "This seemed a very reasonable view, and, indeed, it cannot well be questioned that if one-half of the heat that reaches the earth's surface comes from the stars, it is likely to be warmer near an aggregation of three suns than it is where we are now" (p. 70); but astronomical considerations show that the hypothesis as a whole is untenable. Next is the view of Lyell, who attributed climatal oscillations to changes to the relative position of sea and land; but the view is open to the sweeping objection that the formulated cause would produce opposite effects from those which the hypothesis attempts to explain. The effect of minor geographical alterations on climate cannot, however be denied. Tyndall and others have shown that slight variations in the quantity of aqueous vapor, carbonic acid, or some other substances contained in the atmosphere must materially effect terrestrial temperature; but any such variations which we are justified in assuming would probably be inadequate to alone explain the phenomena of the glacial period. The next hypothesis is that of Croll, who, recognizing the fact that the "orbit of the earth around the sun is not circular, as it might be if the earth were the only companion of the sun in the solar system" (p. 73), points out (1) that during periods of high eccentricity in the terrestrial orbit the precession of the equinoxes may lead to a considerable variation in the length of the seasons, and hence to an accumulation of snow and ice in the hemisphere having the long winter and the short summer; and (2) that when such accumulation was in the northern hemisphere the effect upon the trade winds would be such as to deflect the Gulf Stream feeders to the south of Cape St. Roque and thence into the Antarctic regions, and thus further refrigerate the northern hemisphere. The hypothesis is the most important yet enunciated, though it presents certain difficulties. Other views are that changes in the earth's axis of rotation, or in the obliquity of the ecliptic may materially affect the temperature of the globe; but these views can be mathematically proven to be inadequate. Yet another hypothesis is that which attributes the phenomenon to variations in solar emission, and which "seems a most likely cause of glacial conditions" (p. 90). Less important hypothetical causes are minor geographical changes affecting aërial or marine currents—for instance, the comparatively recent elevation of Sahara, and the probable late Quaternary depression and subsequent re-elevation of Alaska and Kamchatka; but it is clear that no conceivable array of geographical changes can explain the origin of the last glacial epoch.

(To be continued.)

THE HIPPOPOTAMUS.—Dr. Henry C. Chapman, of Philadelphia, has recently devoted much attention to the anatomy of the Hippopotamus, and has read an elaborate paper before the Academy of Natural Sciences, of Philadelphia. We notice that he draws the following conclusions: "beginning with the pig, we pass by an easy transition to the Piccary, which leads to the Hippopotamus, and thence in diversing lines to the Ruminantia on the one hand and the Manatee on the other. Paleontologists have not discovered a form which bridges over the gap between the Hippopotamus and the Manatee, but it will be remembered that certain fossil bones, considered by Cuvier to have belonged to an extinct species of Hippopotamus, *H. Medius*, are regarded by Gervais as the remains of the *Halithorerium fossile*, an extinct Sirenean of which order the Manatee is a living representative." Dr. Chapman adds further on, "I do not mean to imply that the Manatee has necessarily descended from the Hippopotamus," but he considers that "there is some generic connection between them."

PROF. C. V. RILEY believes that the diminished virulency of Phylloxera in sandy soils is due to its mechanical action on the insect, his own experiments showing the difficulty such insects meet with in soils of a sandy nature.

SECTION OF BIOLOGY.

The President, DR. J. S. NEWBERRY, in the Chair.

Thirty one persons present.

The following paper was read by Prof. LOUIS ELSBERG, M. D.

ON THE CELL-DOCTRINE AND THE BIOPLASSON-DOCTRINE.

Mr. President and Fellows of the Academy, Ladies and Gentlemen.—Last May, at the meeting of the American Laryngological Association, I rendered account of some histological investigations of the cartilages of the larynx, a report of which is published in the October Number of the *Archives of Laryngology*. As the structure of hyaline cartilage has an important bearing on my subject of this evening, I crave your attention for a few minutes for a brief review of those investigations.

You know the larynx or voice-box consists of a framework of cartilage or gristle. This cartilage is called hyaline or glasslike, because it is opalescent and looks like milk-glass. Having frequently been examined under the microscope, it has always been looked upon as one of the simplest tissues, namely, as being composed of a hard matrix or basis-substance, in which are imbedded a number of small softer bodies. These softer bodies, the cartilage corpuscles, have since the establishment of the cell-doctrine been called cartilage cells. As these cells were known to be alive, the question which scientific men have had to try to answer was: how can they obtain nutrition, being isolated and enclosed in the firm, unyielding cartilage basis-substance?

Without going too much into details, I may say that it was assumed that nourishing liquid reaches the corpuscle either by imbibition and diffusion or else through canals or fissures in the homogeneous basis-substance. The idea of the existence of "juice-channels" originates with VON RECKLINGHAUSEN, although others before him had spoken of "pores" through which nutrient juices might pass. BUDGE and others believe in the presence of regular canals for this purpose, while TILLMANNS and many with him believe that hyaline basis-substance consists of fine fibrils so closely held together by a cement-substance that the mass appears to be homogeneous; it is supposed by some that this inter-fibrillar cement-substance is a viscous, soft material which permits the imbibition of nutrient liquid; by some that there are clefts or fissures, and by others that there are regular channels tunnelled in this cement-substance. On the other hand, HEITZMANN, SPINA, FLESCH and others have found that there are cilia-like offshoots or prolongations of the substance of the corpuscle penetrating into the basis-substance. Such prolongations might carry on nutrition. I have had the opportunity 6 or 7 years ago to repeat Heitzmann's observations under his own eyes and with his assistance; but the results as to their correctness at which I arrived, were to the best of my belief uninfluenced by him.

My own recent investigations have not only confirmed the existence of such offshoots and shown that they form an inter-connected reticulum or network throughout the basis-substance, but I have discovered in several specimens, small lumps in this network which, by all the tests applied to them, were proved to be lumps of living matter in various stages of existence! These investigations are illustated by the accompanying drawings viz.

Fig. 1. exhibits the appearance of a longitudinal section of the plate of the thyroid cartilage with an amplification of 100 diam.

Fig. 2. shows offshoots from the cartilage corpuscles and the network in the basis-substance with more or less large granules interwoven, as it were, in the network.

Fig. 3. shows granules of various sizes in the basis-substance with lower power of the microscope, which granules are seen with higher powers to be connected with the network of living matter, as shown by fig. 4.

Doubt as to the interpretation is impossible: instead of being a mass of basis-substance in which a number of cartilage corpuscles are imbedded, hyaline cartilage is a filigree of living matter, in the meshes of which a number of blocks of basis-substance are imbedded.

Now, for our subject proper.

The founder of the Cell-Doctrine, Schwann, has recorded in the Introduction to his great work published in 1839 that the doctrine was based to a large extent upon investigation of the constitution of cartilage. After Johannes Müller had described cartilage-corpuscles that were hollow, and Gurlt had spoken of some as vesicles,—when Schwann had succeeded, as he thought, "in actually

observing the proper wall of the cartilage corpuscles, first in the branchial cartilages of the frog's larvæ and subsequently also in the fish," he was led by these and other researches to conjecture "that the cellular formation might be a widely extended, perhaps a universal, principle for the formation of organic substances." And just as the study of cartilages has led to the cell-doctrine, which at the time of its establishment was a great advance in biological science, so the further study of cartilage has supplied the basis for a generalization which is a further development, and must take the place of the cell-doctrine. This is Heitzmann's doctrine of living matter, or, as I have named it, the *bioplasson-doctrine.*

When the term "cell" was introduced in 1838 and 1839, by Schleiden and Schwann, it was believed that on ultimate morphological analysis every plant and every animal would be found to consist of a number of minute vesicles or sacs, enclosing liquid contents in which is suspended a more solid body, the nucleus. For fully twenty years this idea has been known to be erroneous. In fact, *Goodsir*, nearly *forty* years ago—only a few years that is, after Schwann had established the cell-doctrine and attributed the vital power to the cell-membrane, I say,

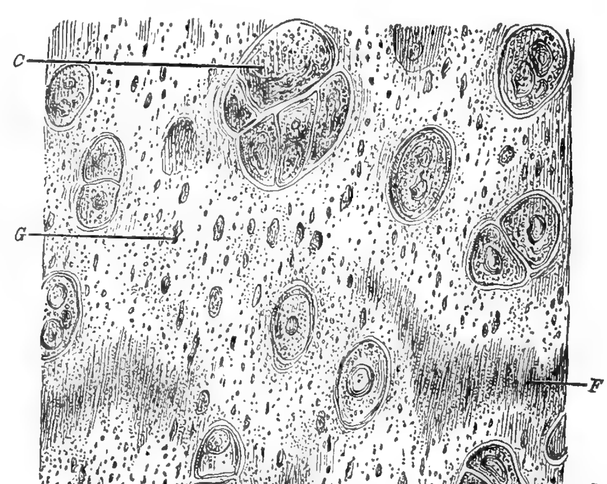

FIGURE 3.—Thyroid Cartilage of Adult. Horizontal Section x 600.

C. Cartilage corpuscle.
F. Fibrous portion of cartilage.
G. Granules of living matter.

nearly forty years ago Goodsir had experimentally determined that the seat of the vital process of secretion is ***not*** in the vesicle as such, but in the so-called cell contents; Naegeli, in 1845, and Alexander Braun, in 1851, had also shown the cell-wall to be comparatively unimportant; and in 1857 Leydig had declared the "cell" to consist only of a soft substance enclosing a nucleus. Certainly, twenty years ago it was proved beyond dispute by Max

Schultze, Beale, Hæckel, and others, that what was called a "cell" was not a vesicle, but essentially a jelly-like lump of living matter characterized by the presence of a nucleus; soon after, Robin, Brücke, Kühne, Stricker, and others, conclusively showed that not even a nucleus is an essential constituent of an elementary organism; and, biologists were compelled to transfer the power of manifesting vital properties to "living matter" instead of restricting this power to any definite form-element. As long ago as in 1861, Brücke proposed to discontinue the use of the word "cell" as being a misnomer and misleading, and offered as a substitute the expression "elementary organism." Beale proposed, instead, the term "bioplast" to designate any definite mass of living matter, and Hæckel the term "plastid." From the latter I devised the word "plastidule" as synonymous with ultimate molecule of the substance of living matter. Elementary living matter is called with Dujardin "sarcode," or with Von Mohl "protoplasm," or with Beale "bioplasm," or, still better (because it is a designation etymologically more nearly meaning living, forming matter), "bioplasson." Of these four synonymous terms "protoplasm" is the one best known; but has been used in other senses, as well as to designate, merely, elementary living matter. I therefore think that "bioplasson" is to be preferred. Of course, *dead* bioplasson is a contradiction in terms: bioplasson deprived of vitality is no longer bioplasson at all, but merely the chemical remains of what *once was* bioplasson. If this be remembered, there will be no confusion, even if the word be used in describing tissues, etc., after death. According to Drysdale, Dr. John Fletcher of Edinburgh was the first, who clearly arrived at the conclusion that "it is only in virtue of a specially living matter, universally diffused and intimately interwoven with its texture, that any tissue or part possesses vitality."

As Fletcher's work was published in 1835, several years before even the establishment of the cell-doctrine, we cannot but agree so far with Drysdale as to say that Fletcher has framed a "hypothesis of the anatomical nature of the living matter which anticipates in a remarkable manner" its discovery! In 1850, Cohn[1] recognized the protoplasm "as the contractile element, and as what gives to the zoöspore the faculty of altering its figure, without any corresponding change in volume." He concludes that protoplasm "must be regarded as the prime seat of almost all vital activity, but especially of all the motile phenomena in the interior of the cell." In 1853 Huxley[2] said "vitality, (the faculty, that is, of exhibiting definite cycles of change in form and composition), is a property inherent in certain kinds of matter." In 1856 Lord Osborne discovered carmine staining, and distinguished by means of coloring it the living formative matter from the formed material, a means which has borne important fruits in the discovery of Cohnheim's staining of living matter by gold chloride, and in that of Recklinghausen's staining all except living matter by silver nitrate.

In 1858, and in a number of later articles,[3] Max Schultze, by showing that, as had been hypothetically supposed by Unger, the movements of the pseudopodia and the granules are really produced by active contractile movements of the protoplasm, as well as by other observations, contributed much to the establishment of the theory of living matter. Hæckel has also for many years, and in various publications,[4] labored to maintain and extend the same theory, of which he thus expresses himself.[5] "The protoplasm or sarcode theory, that is the theory that this albuminous material is the original active substratum of all vital phenomena may, perhaps, be considered one of the greatest achievements of modern biology, and one of the richest in results." And says Drysdale[6]: "if the grand theory of the one true living matter was, as we have seen, hypothetically advanced by Fletcher, yet the merit of the discovery of the actual anatomical representation of it belongs to ***Beale***, in accordance with the usual and right award of the title of discoverer to him alone who demonstrates truths by proof and fact. * * * The cardinal point in the theory of Dr. Beale is not the destruction of the completeness of the cell of Schwann as the elementary unit, for that was already accomplished by others. * * * But that, from the earliest visible speck of germ, up to the last moment of life, in every living thing, plant, animal, and protist, the attribute of life is restricted to one anatomical element alone, and this homogeneous and structureless; while all the rest of the infinite variety of structure and composition, solid and fluid, which make up living beings, is merely passive and lifeless formed material. This distinction into only two

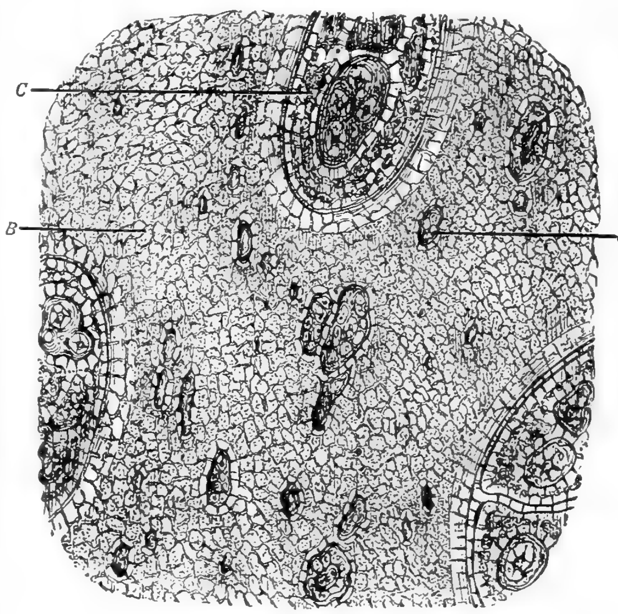

FIGURE 4.—Thyroid Cartilage of Adult. Horizontal Section x 1200.
C. Cartilage corpuscle.
B. Hyaline basis-substance.
G. Granules of living matter.

radically different kinds of matter, viz., the living or germinal matter and the formed or lifeless material, gives the *clue* whereby he clears up the confusion into which the cell-doctrine had fallen, and gives the point of departure for the theory of innate independent life of each part, which the cell-theory had aimed at, but failed to make good. The one true and only living matter—called by Beale germinal matter, or bioplasm—is described as 'always transparent and colorless, and as far as can be ascertained by examination with the highest powers, perfectly structureless; and it exhibits those same characters at every period of its existence.' * * *

The name of bioplasm, continues Drysdale, given by Beale, or protoplasm, as indicating the ideal living matter, cannot be given to any substance displaying rigidity in any degree, nor to anything exhibiting a trace of structure to the finest microscope: nor to any liquid; nor to

[6] *Loc. cit.*, 42, *et seq.*

any substance capable of true solution. Thus, 'nothing that lives is alive in every part,' but as long as any individual part or tissue is properly called living it is only so in virtue of particles of the above-described protoplasm freely distributed among, or interwoven with the textures so closely that there is scarcely any part -1- of an inch in size but contains its portion of protoplasm. Thus we see realized the hypothesis of Fletcher, that all *living action* is performed *solely* by virtue of portions of irritable or living matter *interwoven* with the *otherwise dead* textures." The objection, however, urged by *Bastian* to Beale is so very pertinent, that it must also find a place here, but I shall not dwell upon other points on which Beale differs from the bioplasson doctrine; such as, that living matter exhibits the same characters at every period of its existence; and that it is always perfectly structureless. "It has always appeared to me," says Bastian,[1] "to be a very fundamental objection to Beale's theory, that so many of the most characteristically vital phenomena of the higher animals should take place through the agency of tissues—muscle and nerve, for instance—by far the greater part of the bulk of which would, in accordance with Dr. Beale's view, have to be considered as *dead* and inert."

In 1873, the morphological knowledge of living matter became exact. In that year, Heitzmann discovered the manner in which bioplasson is arranged throughout the body, and announced the fact that what had until then been regarded as *separate form-elements* in a tissue are really *interconnected portions* of living matter; that not only are there contained *no* isolated unit-masses in any *one* tissue, but *no tissue* in the *whole body* is isolated from the *other* tissues; and that the only unconnected particles of living matter are the corpuscular elements of liquids, such as blood, sperm, saliva, pus, etc., and so-called wandering corpuscles; so that, to use his own words: "the animal body as a whole is a connected mass of protoplasma in which, in some part, are imbedded isolated protoplasma-corpuscles and various not-living substances (glue-giving and mucin-containing substances in the widest sense, also fat, pigment-granules, etc.)." This announcement marked the commencement of a new era in biology.

Heitzmann discovered that the living matter as seen in an amœba is *not without structure*, as had, before his accurate investigations, been supposed; and that its structure, in all cases when developed, is that of a network, in the meshes of which the bioplasson fluid, or the not-contractile, not-living portion of the organism, exists. When there is a nucleus, it is connected by delicate threads with the extranuclear network; nucleoli and nucleolini inside of the nucleus, as well as granules outside, are portions of living matter: sometimes in lump, sometimes mere points of intersection of the threads constituting the intranuclear and extranuclear living networks, sometimes terminals of section of such threads, as first explained by Eimer,[1] and after him by Klein.[2]

Heitzmann discovered that what is true of the structure of bioplasson in the amœba, where a single small unit-mass of living matter constitutes the entire individual, is true also of the structure of bioplasson of all, even the highest, living organisms.

To be sure much had been previously known regarding protoplasm or living matter, but the knowledge was fragmentary, until Heitzmann demonstrated *not only*, that membrane, nucleus, nucleolus, granules, and threads *are really* the living contractile matter, but also, 1st, that this matter is arranged in a network, containing in its meshes the non-contractile matter, which is transformed into the various kinds of basis-substance, characterizing the different tissues of the body; and 2d, that the tissue-masses of bioplasson throughout the whole body are *interconnected* by means of fine threads of the *same* living matter.

The Beginnings of Life: being some account of the nature, modes of origin, and transformations of lower organisms. London, 1872, vol. i., p. 155.

[1] "Weitere Nachrichten über den Bau des Zellkerns." *Archiv f. mikrosk. Anatomie*, XIV, 1877, p. 103.

[2] "Observations on the Structure of Cells and Nuclei," *Quarterly Journal of Microscopical Science*, Jan., 1879, p. 128. "The intranuclear as well as the intracellular network having, of course three dimensions, includes fibrils that lie in the two dimensions of the plane of the field of the microscope, as well as fibrils placed vertically to it. The former appear, of course, as fibrils; but, I should like to ask, as what do the latter appear, *i. e.*, those situated vertically. Clearly as dots, because they are seen endwise; and for obvious reasons most of them lie in the nodes of the network."

Unless these two facts of Heitzmann's discovery are accepted, there cannot be urged much against the continued use of the word "cell," misnomer though it be. Ranke,[1] after speaking of the "cell-wall," "cell-nucleus," etc., says: "of these component parts of the cell, one or other may be wanting without the totality ceasing to be a cell. The nucleoli, the cell-wall, or the nucleus may be wanting, and yet we must designate the microscopic form a cell, or elementary organism." Drysdale thus comments upon this quotation, viz.: "if any one choose to describe a gun-barrel as a stockless gun without a lock, he is free to do so; but what good purpose can it serve? Or is there even any fun in it? The truth is, this clinging to the mere name of the cell-theory by the Germans seems to arise from a kind of perverted idea of patriotism and of *pietas* toward Schwann and Schleiden." But, I think Tyson[2] has the better of the argument, in saying: "the word "cell" has become so intimately associated with histology, that it is doubtful whether it will ever fall into disuse, nor does it much matter, so long as correct notions of the elementary part are obtained." Now, if *there were any* separate and distinct "elementary part," it certainly would matter little or nothing whether it were called "cell" or by any other name, provided the name be properly defined and agreed upon. It is not against the name but against the idea of any *isolated individualized form-element* that the objection lies. Virchow maintains[1] "that the cell is really the ultimate morphological unit in which there is any manifestation of life, and that we must not transfer the seat of real action to any point beyond the cell." Against this statement nearly every author nowadays protests, and insists that vital power must be transferred from the "cell" to "living matter"; yet, after all, the disagreement, though ever so strenuously declared, is a mere verbal one: so long as both parties hold that "every higher animal presents itself as a sum of vital unities"—no matter what these unities are called or how defined. Hæckel, one of the most avowed advocates of "the protoplasm or sarcode theory," clings to Virchow's politico-physiological comparison, that every higher organism is like an organized social community or state, in which the individual citizens are represented by the "cells" [no matter how he may define these], each having a certain morphological and physiological autonomy, although on the other hand interdependent and subject to the laws of the whole. Heitzmann's views necessitate the comparison of the body to a machine, such as a watch or a steam-engine, in which, though there are single parts, no part is at all autonomous, but all combine to make up one individual. Even Huxley, the popular champion of protoplasm as the physical basis of life, quite recently delivered an address, before the International Medical Congress in London, August 9, 1881, in which he used the following language: "in fact, the body is a machine of the nature of an army, not of that of a watch, or of a hydraulic apparatus. Of this army, each cell is a soldier," etc., etc. According to Hæckel and Huxley, the body is composed of *colonies* of amœbæ; according to Heitzmann the body *is one com-*

[1] The Cell-Doctrine; its history and present state. Philadelphia, 1878, p. 128.

[1] Die Cellularpathologie in ihrer Begründung auf physiologische und pathologische Gewebelehre, Berlin, 1858, p. 3. (Translation by Chance, London, 1859, p. 3.)

plex amœba. I am very anxious to really make the difference between the cell theory and the bioplasson theory clear to every one of you. The essential point of the cell theory is, the idea that the body and each tissue of the body, every plant, and every animal, is made up of a number of distinct units, and the essential point of the bioplasson theory is, the idea that all the masses of living matter of each tissue of plants and animals are uninterruptedly connected, and that every tissue is connected with every other tissue by filaments of living matter. To accept Mr. Huxley's comparison, we must imagine that every soldier is indissolubly connected, hand and foot with every neighboring soldier of the solid army!

There is no *better test* of the TRUTH of the bioplasson doctrine than the structure of hyaline cartilage. If hyaline cartilage consisted, as "is generally believed," of "a homogeneous ground substance, in which are closed cavities harboring the corpuscles," [1] the bioplasson doctrine would certainly be erroneous. If it merely contained lymph, or juice-channels, no matter what their character, whether open or closed, whether lined or unlined, whether in "homogeneous basis-substance,' or "between layers of cells," or "in cement-substance," then, too, the bioplasson doctrine would be erroneous.

But the result of my observations, especially those illustrated in figs. 2, 3, and 4, admit of but one interpretation, and that an interpretation favorable to the bioplasson doctrine. It is unnecessary to more than mention that although I have placed on record so few, I have made many different examinations, under many different circumstances, and with varying powers of amplification. I need occupy myself here with only the two fields drawn in figs. 3 and 4, with an amplification of 600 and 1200 respectively. The remarkable specimens from which they are taken show more conclusively than it was ever before shown *what* the structure or constitution of hyaline cartilage *really* IS. I think I have *explained* this sufficiently, but its full significance appears in its *corroboration* of the *bioplasson* doctrine.

To be able to uphold the cell-doctrine, cartilage would have to be, using a homely comparison, like a cake composed of hard dough with raisins. No matter how widely we may extend the definition, to remain within the boundary of the cell-doctrine this metaphor must be applicable. Innumerable painstaking researches have led to various modifications of notions entertained regarding the structure of the two constituents of the cake and their relation to each other. It may be seen by the most recent publications on the subject, that the acceptation of the existence in the dough of cleavage in certain directions, of interlaminary and interfibrillar spaces, and of offshoots, even ramifying prolongations of the raisin-substance, or, at all events, of an ingredient of the raisins, is held to be not incompatible with the cell-doctrine. If, however, we can represent cartilage as a filigree or framework of raisin-substance, in the meshes or interspaces of which framework blocks of dough are imbedded, certainly the fundamental view of the ultimate construction of the tissue is changed, and we are no longer in accord with the cell-doctrine, even though we be inclined to use that term in the widest possible sense. Look for a moment at the two illustrations on the blackboard, as well as at figs. 2, 3, and 4. The upper figure represents a section of cartilage stained with gold chloride. This, as I have already alluded to, stains the living matter and leaves the basis-substance unstained. High powers exhibit the appearance, etc., etc. In regard to a NAME as a *substitute* for the term "*cell*," I would say that all corpuscular masses may be called, simply, corpuscles—thus we may speak of blood-corpuscles, pus-corpuscles, etc. For all the accumulations of living matter within the ordinary fields of basis-substance, but more especially for those smaller masses which, having as yet developed neither a network structure nor much vacuolation, are still homogeneous, or nearly so—I am quite willing to adopt either the designation of "plastids," proposed by Hæckel, or that of "bioplasts," proposed by Beale. Perhaps it would be well to restrict the word "bioplast" to a small mass of living matter exhibiting no differentiation, and distinguish from it as "plastid" the larger mass showing an interior structure more or less like the fully developed corpuscle. Thus, I would always use the term "plastid" in the place of "cell."

The result of my investigations as to the structure of cartilage is that in this tissue, beyond the possibility of a doubt, the living matter is arranged in the form of a network containing in its meshes the non-contractile matter. How is it with regard to the other proposition of the bioplasson doctrine, viz., that the living matter of the different tissues is interconnected? Examinations with high powers of such a specimen as that represented in fig. 1, showing the perichondrium, of horizontal sections through the larynx, or the neck, with skin and more or less of other tissues included, enable me to answer this question to the effect that fine filaments of living matter pass from one tissue to another in connection with the network of living matter in each. The details of these examinations are reserved for another time! But it has been suggested to me that I ought not to conclude without saying a few words as to the *practical* advantages of the Bioplasson Doctrine over the Cell-Doctrine. Well, *every exact* scientific investigation, even though at first of *theoretical value* only, sooner or later brings with it some practical benefit; and this doctrine of living matter, aside from the satisfaction which the perception of ABSTRACT *truth* grants—lying as it does at the foundation of our knowledge of living things—has advanced their physiology, and pathology at every point! In *Practical Medicine* it has already aided us in so many ways that their merest enumeration would require another hour's lecture. We know that the disposition of living matter is different in different persons, and that in the case of increased supply of food the *reaction* is different in strong and healthy people from that in the sick and weak. Upon this knowledge rests, to-day, the *whole doctrine of pulmonary consumption.* Now, the *amount of living matter* within the same bulk *varies greatly*, both in normal and morbid conditions. A small lump of bioplasson in the urine or expectoration, taken from an individual of *good* constitution, will show a *close* network with coarse granulations, or perhaps be almost *homogeneous*-looking under the microscope—owing to the *large amount* of living matter in the small bulk: while a plastid from a weak, broken down or phthisical person will be finely granular and exhibit a *network with large meshes* on account of the *relatively small amount of living matter* in it. Sometimes we thus from the examination of a *drop of blood* gain an insight into the condition and vital power of the whole individual; sometimes, recognize a disease before it is sufficiently developed to do much harm, and thus come a step nearer to the *highest aim* of the physician:—the *prevention* of disease.

DISCUSSION.

Dr. B. N. Martin remarked on the great value and important bearing of this investigation.

Mr. A. C. Elliot enquired whether the blocks of non-living matter in the cartilage were entirely separated.

Dr. Elsberg explained that the blocks were separate, their only connection being the interposed threads of the *reticulum* of living matter, and to the former is due the opalescent character of hyaline cartilage. He further stated that the condition of health of an individual might be inferred in a degree from a study of the character of the

[1] This statement of the general belief is quoted from the introductory paragraph of Thin's memoir "On the Structure of Hyaline Cartilage" (*Quarterly Journal of Microscopical Science*, xvi, 1876) in which Thin's own views are laid down to the effect "that layers of cells epithelial in arrangement exist in the substance of cartilage," "that both the stellate and the parallel systems of lymph-channels exist," etc.

network, a thin section of a very minute portion of the body often showing a difference of network in different persons, *e. g.*, in the thickness of the threads, the size of the meshes, the character of the points of intersection, etc. From the uniformity in the size of the meshes, etc., or from their variability, or from the proportion of corpuscles presenting a normal and abnormal character in their network, a good or bad prognosis was deduced by the physician, and even an indication of the progress of disease.

Prof. E. H. Day remarked on the wonderful character of protoplasm in its wide results in the construction of the most varying textures in the vegetable and animal kingdoms. The speaker's observations have brought the protoplasm of cartilage tissue into correspondence with that in the tissues of the sponge, of the plant, and all the lower forms of life. In protoplasm we are brought face to face with the most astonishing substance in nature.

Mr. J. D. Warner offered objections to the vague views of Virchow on the soul of the cell and its relation to the soul of the individual.

Dr. Newberry said that, having been educated as a physician, and having studied microscopic anatomy under Dr. Charles Robin, he had followed with great interest the progress of modern research into the ultimate structure of organic tissue, and the discussions of the origin and seat of vitality to which it has given rise; and he regarded such investigations as those of Dr. Elsberg as of the highest scientific interest and practical value. If we ever learn the causes of malarial and infectious diseases, or the cure of the morbid growths which are the scourges of humanity, cancer and tubercle, it will be through such researches. But he thought that much of the discussion which had been excited by these investigations had been irrelevant and confusing, especially that in regard to the seat and nature of life, into which microscopists and chemists had entered with great earnestness and some acrimony, but with no satisfactory result. In this discussion some writers had made the ultimate cell the seat of life, and had glorified and almost deified it. Others claimed that the cells were only portions of a general vitalized and automatic tissue; while others still contended that the phenomena of vitality were the mere manifestations of chemical changes taking place in structure otherwise lifeless.

With none of these views could he sympathize as there had really been no approach to an end in the effort to localize or analyze life. Unless we accept the materialistic theory of spontaneous generation advocated by Dr. Bastian, but rejected by most biologists, we must confess that no more is now known of the origin, nature and seat of life than was known to Aristotle. All we have done is to acquire a better knowledge of the *machinery* by which the functions of life are accomplished; most important knowledge truly since it enables us to distinguish between normal and morbid life action in the tissues where this action begins, and promises to point the way for promoting the one, and preventing the other—but limited to the methods in which the life force acts, not reaching the inscrutable and intangible force itself.

The work done by a microscopic cell is wonderful and incomprehensible to us, yet all cells work not as independent individuals, but as members of a community, and for a common end. For example, the terminal cell of the fibril of a plant root is a delicate vesicle—the cell in its simplest form, and yet when new born, and having existed but the fraction of a minute, it begins its special work of supplying certain food elements to the plant above; and this it does with a discrimination which is infallible. Water it absorbs by endosmosis, and when deficient begets progeny to send for it. It also appropriates other things that are necessary to the growth of the plant to which it belongs, whatever that be; if tobacco, an unusual quantity of potash; if grass, of silica. It always works to a pattern determined by the character of the plant whose general economy it serves, and is controlled by the influence which gives to that plant its special and recognizable leaf, flower and fruit, its noxious or alimentary qualities. So in all other parts of the structure the cell is doing its allotted work in a community of which it forms an integral part. It is therefore in no sense an independent individual. Our notions of what constitutes an individual or a community may seem to us quite clear, but they are in fact likely to be somewhat confused. Every man recognizes and asserts his own individuality, but we all know that men who live in communities often think and feel as one though many. A great grief crushes all alike, a great danger rallies all in defence. The social insects, ants and bees, retain their corporeal individuality, but are curiously linked together in a common life that makes each but a part of a whole. A tree is universally accepted as an individual, but as all know it may be divided to form an unlimited number of perfect trees which expand this individual into a forest and prolong its life indefinitely. The sponge is said to be a community of amœboid individuals, but these share a common skeleton, fashioned for the wants of all, and all unite in the general function by which the inhalent and exhalent currents are maintained, a function on which the life of all depends. In the corals which live in communities we find the common skeleton covered with a vitalized gelatinous integument on which are set here and there the individual polyps. These live to a great degree each for itself; each throws out its tentacles and forages for its own support, but at the same time it shares a life with its neighbors; an injury done to one affects those about it, and a misfortune involving a sufficient number destroys the life of the colony.

The elusive and intangible nature of the life which pervades plant tissue is well shown in the growth and decay of a tree. From a microscopic germ a young *Sequoia* springs into existence, and for a thousand years or more lives its life. All this time it is inspired by a power which acts in antagonism to the affinities of inorganic chemistry, in opposition to the force of gravitation, and which builds up a mass hundreds of tons in weight, mostly obtained by the breaking up of one of the strongest bonds in chemistry, that of carbonic acid, appropriating the carbon and setting the oxygen free. Every part of the huge structure is pervaded by this peculiar creative and conservative influence; and every cell of root or stem or leaf contributes its part to the harmonious whole. At length the time arrives when this peculiar influence which we call life deserts the structure it has created. The affinities of inorganic chemistry now assert themselves, all the ephemeral fabric is rapidly disorganized, and soon a heap of ashes—the inorganic matter woven into its composition—alone remains to tell of its existence. Who can tell us what was the nature of the enchantment which created this Aladdin's palace—whence it came, where it dwelt during its sojourn, and whither it has gone? We may say it resided in the terminal root cells; but these are inseparably connected with the leaves hundreds of feet above. The tie that binds them is a vital one; neither could live without the other, nor without the intervening chain which connects them.

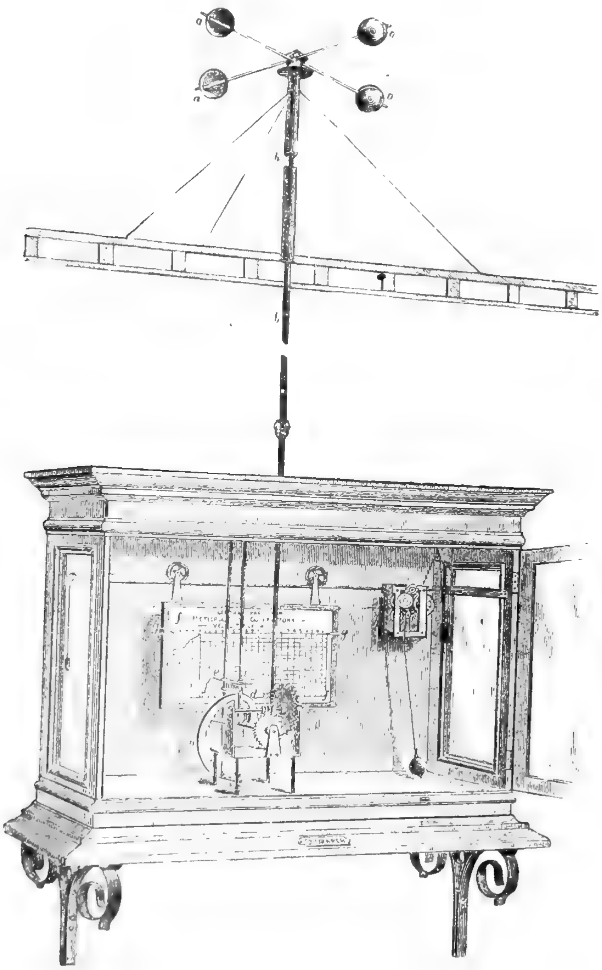
By studying the anatomy of plants and animals, we obtain a knowledge of the organs and laws, as we call them, of animal and plant life; that is, we get a knowledge of the machinery with which the functions of life are accomplished, a knowledge of the order and manner in which these functions are performed; but the *primum mobile*, the real "power behind the throne," remains as yet unseen and unknown to us.

SLIDES OF MARINE ALGÆ.—The Rev. A. B. Hervey, of Taunton, Mass., author of the very beautiful work on "Sea Mosses," will mail to any address for two dollars, a set of six slides showing the characteristic fruit of the six great groups into which Professor Agardh divides the Red Algæ.

DR. D. DRAPER'S INSTRUMENT FOR RECORDING THE VELOCITY OF THE WIND.

On the ends of a cross supported by a vertical shaft several feet above the roof of the building, are four hemispherical copper cups. These, whatever may be the direction of the winds, are caused to turn round with a speed, as has been determined by experiment, of about one-third the velocity of the wind. This portion of the contrivance was the invention of Dr. Robinson, of Ireland. It is used in the foreign observatories, and is known as Robinson's cups.

To the lower end of the shaft thus made to revolve by the cups is attached an endless screw connecting with a train of wheels, which move a cam. The wheels are so arranged that one turn of the cam answers to 15 miles in the movement of the wind. A pencil which rests on the edge of the cam, and bears lightly against a surface, is carried from the bottom to the top of the paper by each revolution of the cam. It should be understood that the paper is attached to a board drawn aside by a clock at the rate of half an inch an hour. The number of times that the pencil moves from the bottom to the top of the paper, multiplied by 15, gives the number of miles that the wind has moved in an hour or day.



The four hemispherical cups, *a a a a*, turned round by the wind, impart their motion to a vertical shaft, *b b*, at the bottom of which is the endless screw, *c*, its lower end resting in a small agate cup filled with oil, connected with the train of wheelwork turning the cam, *d d*. At *e*, is the pencil resting on the edge of the cam ; *f f* is a sheet of ruled paper attached to the board, *g g*, by means of small brass clamps, which is drawn aside at the above mentioned rate by the clock, *h*.

STATISTICS OF THE SUN.

The following *Statistics* of the Sun, comprising facts which can be stated in numbers, are selected from Professor C. A. Young's recent work "The Sun," being one of the last additions to Messrs. Appleton's International scientific series.

Solar Parallax(equatorial horizontal), 8.80″ ± 0.02″

Mean distance of the sun from the earth, 92,885,000 miles, 149,480,000 kilometres.

Variation of the distance of the sun from the earth between January and June, 3,100,000 miles, 4,950,000 kilometres.

Linear value of 1″ on the sun's surface, 450.3 miles; 724.7 kilometres.

Mean angular semi-diameter of the sun, 16′ 02.0″ ± 1.0″.

Sun's linear diameter, 866,400 miles; 1,394,300 kilometres. (This may, perhaps, be variable to the extent of several hundred miles.)

Ratio of the sun's diameter to the earth's, 109.3.

Surface of the sun compared with the earth, 11,940.

Volume or cubic contents, of the sun compared with the earth, 1,305,000.

Mass, or quantity of matter, of the sun compared with the earth, 330,000 ± 3000.

Mean density of the sun compared with the earth, 0.253.

Mean density of the sun compared with water, 1.406.

Force of gravity on the sun's surface compared with that on the earth, 27.6.

Distance a body would fall in one second, 444.4 feet; 135.5 metres.

Inclination of the sun's axis to the ecliptic, 7° 15′

Longitude of its ascending node, 74.°

Date when the sun is at node, June 4–5.

Mean time of the sun's rotation (Carrington), 25.38 days.

Time of rotation of the sun's equator, 25 days,

Time of rotation at latitude, 20,° 25.75 days.

Time of rotation at latitude, 30,° 26.5 days.

Time of rotation at latitude, 45,° 27.5 days.

(These last four numbers are somewhat doubtful, the formulæ of various authorities giving results differing by several hours in some cases).

Linear velocity of the sun's rotation at his equator, 2.261 miles per second; 2.028 kilometres per second.

Total quantity of sunlight, 6,300,000,000,000,000,000,000,000,000 candles.

Intensity of the sunlight at the surface of the sun, 190,000 times that of a candle flame ; 5300 times that of a metal in a Bessemer converter ; 146 times that of a calcium light, 3.4 times that of an electric arc.

Brightness of a point on the sun's limb compared with that of a point near the centre of the disk, 25 per cent.

Heat received per minute from the sun upon a square metre, perpendicularly exposed to the solar radiation at the upper surface of the earth's atmosphere (the solar constant), 25 calories.

Heat-radiation at the surface of the sun, per square metre per minute, 1,117,000 calories.

Thickness of a shell of ice which would be melted from the surface of the sun per minute, 48½ feet; or 14¾ metres.

Mechanical equivalent of the solar radiation at the sun's surface, continuously acting, 109,000 horse-power per square metre ; 10,000 (nearly) per square foot.

Effective temperature of the solar surface (according to Rosetti), about 10,000° Cent.; or 18,000° Fahr.

WE have to thank our English contemporary the London "*Lancet*" for its acknowledgement of the interesting nature of the articles published in "SCIENCE."

THE Governor of Texas has taken steps to form a permanent organization preparatory to the establishment of a State University.

FRENCH ACADEMY OF SCIENCES.

Nov. 7, 1881.

Action of cold on the voltaic arc.—According to M. D. Tommasi, the voltaic arc is considerably enfeebled if, by means of a current of water, the electrodes between which it is produced, are cooled. Its brilliancy is then not intense and the least breath extinguishes it. Its temperature also is relatively but little elevated. These facts are evident *à priori*. The magnet displaces and extinguishes it. It is the same on the approach of an inflamable body.

Molecular Physics.—M. Fizeau sent a communication relative to the variation in length of a bar of zinc brought to an even temperature after having undergone different actions. The application which these facts will receive is immediately seen in point of view of the construction of metallic measures.

The accents of the deaf and dumb.—It is known that the deaf and dumb can be taught to speak so that we can converse with them very nearly as well as with men who have possession of both of these senses. M. Félix Hément announces the fact that the individuals who can thus speak, are affected by the particular accent of their native province. As they have not acquired this accent by imitation, since they are deaf, the author thinks that the reason must be sought in the arrangement of the phonetic apparatus, special to each race.

Mechanics.—It is in a special way that M. Bertrand announces a memoire by M. Lévy, relative to the transportation of force to a distance by electricity. It is known that calculus demonstrates that a 16 horse-power engine can transmit force to a distance of 10 to 50 kilometres. M. Lévy states that a much superior result can be obtained.

INFECTED PORK.

It is not only Trichinæ which is to be dreaded in the hams exported by the United States; in one of the recent meetings of the Medical Congress, Dr. E. Ballard and Mr. E. Klein called the attention of the public to another still more dangerous parasite in the same meat. The *Journal of Hygiene* makes the following remarks on this subject:

In 1880, on the estates of the Duke of Portland, at Welbeck, twenty persons were taken seriously ill, after a dinner in which boiled ham had been served, with pork imported from America. Four persons died; others felt no evil effect. The morbid symptoms showed nothing very characteristic (choleric diarrhœa, vomiting, pains in the muscles, great prostration); the autopsy only revealed pulmonary congestion. In a piece of kidney, examined under the microscope, there were found traces of inflammation of the parenchyma, and in the capillaries of the Malpighian tufts, incrustations formed by masses of Bacilli.

In passing over the field of the microscope, particles of the raw ham and of the boiled ham which was infected, a species of Bacillus with its spores was found; the bacillian threads and the spores adhered closely to the muscular fibres and to the intermuscular tissue.

Experiments were made on animals: 1. By feeding and by inoculation, or by the two methods combined. 2. By inoculation after cultivation of the bacillary matter in the incubator. In every case sickness was caused, and at the autopsy, lesions of pneumonia or pulmonary hemorrhage were established.

A second series of observations was made on fifteen persons who felt serious symptoms after having eaten a leg of pork, roasted in the oven, bought at a second-class cookshop. One of them having died, Bacilli were found, at the autopsy, in the blood of the heart, in the blood pressed out of the pulmonary tissue, and in the blood extravasated around the pulmonary alveoli. The tissues of the stomach, the ileum, the spleen, and the kidneys, also contained Bacilli.

Experiment by inoculation with different liquids, on animals, caused morbid and often mortal symptoms. Bacilli were also found in the blood, and in the different tissues of the animals. Unfortunately, in this case, the suspected food could not be examined.

In the face of these facts, Messrs. Ballard and Klein do not hesitate to admit an acute specific affection, not to this day defined, and presenting marked characteristics, in point of view of the morbid phenomena, with the known cases of poisoning by damaged or trichinated meat.

Dr. Tripe, of London, recalled two febrile maladies which he had observed in his medical circumscription. In the first, sixty-six persons showed alarming morbid symptoms, after a dinner in which sausage containing a mixture of beef and pork fat, had been served. In the second it was pork fat alone which was the immediate cause of the sickness. Dr. Buchanan mentions cases of diseases, in which beef and mutton constituted the infected substances.—*La Nature*.

THE COMPARATIVE ACTION OF DRY HEAT AND SULPHUROUS ACID UPON PUTREFACTIVE BACTERIA.*

Pieces of woolen and cotton cloths and wadding were dipped in a solution of putrefying flesh and slightly dried; and after being shown to be infected by causing discoloration and development of bacteria in a Pateur solution, one portion was subjected to dry heat, and the other to the influence of a definite quantity of sulphurous acid. When these agents had operated for a certain time, the substances were brought into a developing liquid and again observed.

These experiments, which were conducted by Dr. Wermch, were as follows:

First. Fragments of the materials above referred to, treated as mentioned and dried, produced in sixteen experiments an exceptionably rapid disturbance of the test liquid. In four experiments with wadding this was somewhat retarded. It took place most rapidly in tubes which had been inoculated with woolen thread.

Second. After inoculation with the material which had been exposed one or two minutes to a dry heat of 284° to 300° F., clouding took place in four of eight experiments; but only after from two to three days. With material which had been exposed from ten to sixty minutes to a heat of 230°–244° F., in five out of six experiments a development of bacteria took place after the end of twenty-four hours.

Third. Substances which were exposed five minutes to a heat of 257° to 302° F. produced no infection whatever in ten experiments. The test liquid remained clear for eleven days from the time of inoculation.

Fourth. When the objects were exposed under a bell glass to the action of a percentage, by volume, of 1.5, 2.2, and 3.3 of sulphurous acid, in eight out of nine experiments a bacterial clouding was developed in the sulphurized material, whether the application had continued for one hour or twenty-two.

Fifth. In fifteen experiments, in which sulphurous acid constituted 4.6 and 7.15 per cent. by volume, of the contents of the bell glass, the introduction of the sulphurized material produced no cloudiness, when the experiment continued six hours and more. On the other hand an exposure of 20, 40, 60, and 200 minutes was followed by the development of bacteria.

In conclusion, the fact was considered especially interesting that the different fabrics gave up the infection concealed in them with different degrees of rapidity, the woolen fiber the quickest, the linen less easily, and the wadding with the greatest difficulty of all.

* From the proceedings of United States National Museum.

NOTES ON THE MORTALITY AMONG FISHES OF THE GULF OF MEXICO.

Prof. SPENCER F. BAIRD, *U. S. Commissioner of Fish and Fisheries, Washington, D, C.:*

SIR: Noticing in the Forest and Stream of 9th instant some answers to queries as to the cause of mortality among fishes in the Gulf of Mexico, I make bold to present the result of my observations.

After very heavy rains and overflowing of rivers, the inner bays on the Texas coast suffer a loss of from one-half to three-fourths of their stock of salt water fish, not including mullet, which live as well in fresh as salt water. In fact land-locked mullet in a fresh water pond or tank grow to a weight of nine or ten pounds.

Last winter, after a heavy rain and a freeze, *all* the salt water fish in the *Laguna del Madre* (a large sheet of water lying between Padre Island and the mainland) were found dead on the banks.

We have two causes for the destruction of fish here, vis., too much fresh water and too cold weather.

In the lagoon above spoken of, in a long drought, the water gets too salty for the fish, and they become covered with sores, and unless relieved by a rain they die from too much salt.

I have never known any serious mortality among fish on the Gulf coast where there was a free flow of water, except during violent storms, when many fish both small and large were beached and killed.

Very respectfully,

S. H. JOHNSON.

CORPUS CHRISTI, Texas, *June* 17, 1881.

ANGLO-AMERICAN ARCTIC EXPEDITION.

Commander Cheyne's paper, describing his proposed Arctic expedition in conjunction with Lieut. Schwatka, read before the N. Y. Academy of Sciences, on the 28th ultimo, will be printed in our next issue, with the regular proceedings of the Academy. We understand that Commander Cheyne is receiving a strong support from those interested in the subject, and that there is an early prospect of his plans taking a definite form.

The English Arctic Council for the organization of this expedition, meet on the 13th instant, and are awaiting a cablegram, informing them of the prospects of success, for international co-operation.

ADVICE TO ASTRONOMERS.—In Sir William Herschel's work "*On the Construction of the Heavens,*" the following line of conduct for astronomers is indicated: "in an investigation of this delicate nature we ought to avoid two opposite extremes. If we indulge a fanciful imagination and build worlds of our own, we must not wonder at our going wide from the path of truth and nature. On the other hand, if we add observation to observation, without attempting to draw not only certain conclusions but also conjectural views from them, we offend against the very end for which only observations ought to be made. I will endeavor to keep a proper medium, but if I should deviate from that I could trust not to fall into the latter error.—*See Holden's and Hasting's Synopsis.*

METEOROLOGICAL REPORT FOR NEW YORK CITY FOR THE WEEK ENDING DEC. 3, 1881.

Latitude 40° 45′ 58″ N.; Longitude 73° 57′ 58″ W.; height of instruments above the ground, 53 feet; above the sea, 97 feet; by self-recording instruments.

LONDON, ENGLAND, - - - - 150 LEADENHALL ST.

SATURDAY, DECEMBER 24, 1881.

THE glad tidings of the safety of a large proportion of the crew of the *Jeannette*, and the probability that the missing members of the company will probably be soon heard from, will be a relief to many aching hearts, and welcome to the general public who have taken a great interest in this expedition.

As the success of the expedition has not been referred to in the despatches, the probability is great, that the discovery of the North Pole is still a problem to be solved, but the experience of Captain De Long will doubtless prove very valuable in making future plans for Arctic explorations, and we trust that no time will be lost in obtaining authentic details of the expedition.

From what we know respecting the voyage of the *Jeannette*, and from other information to date, our opinion is that the route by Smith's Sound, is the most practicable for all who attempt to reach the North Pole, and we still maintain that the plans of Commander Cheyne present a higher prospect for success, than any other scheme which has been announced.

The first step which we advise, is to establish firmly a small colony at St. Patrick's Bay, where coal exists in abundance, and ample protection can be found for stores and shelter for men. This spot is less than 500 miles from the North Pole, and, with such a base of operations firmly established, the coveted prize can surely be won by continued and persistent efforts.

We approve of Commander Cheyne's proposal to utilize balloons, on the ground that no facilities which can be devised by practical scientific men should be neglected, and it is far from impossible that some means of aerial navigation may be invented, which may be at least sufficient for this purpose.

The establishment of the colony at St. Patrick's Bay, should be the immediate plan which should claim attention, without desiring by a rush to accomplish the remaining distance. Time should be given for traversing the 500 miles which intervene before reaching the Pole, and all the devices which science can suggest should in turn be put to the test.

We cannot conclude these remarks without giving a due acknowledgement to Mr. James Gordon Bennett for his liberal outlay in the cause of geographical exploration. Inspired by his generous hand, Stanley braved the horrors of tropical climates and penetrated to the unknown recesses of Africa, and by Mr. Bennett's aid De Long has added new laurels to the American flag, and increased our knowledge of the Arctic regions.

THE presence of fossil organisms in meteorites alleged to have been discovered by Dr. Hahn, was fully explained in "SCIENCE" (No. 50, June 11, 1881) by Dr. Rachael. Since the appearance of this article I have discussed the subject with many specialists, with the result of finding a general distrust of Dr. Hahn's discovery.

I, therefore, endeavored to obtain a portion of the Knyahinya meteorite which fell in Hungary on the 9th of June, 1866, as many of the most convincing specimens were obtained by Dr. Hahn from it, and by the aid of Messrs Ward and Howell of the Natural History Museum, Rochester, N. Y., a small fragment of this meteorite recently reached my hands. From this specimen two sections were cut, and ground down to a condition of transparency by a gentleman skilled in such preparations, and are now mounted as microscopical objects.

An examination which I have since made confirms in every respect the correctness of Dr. Hahn's statement, as to what he saw, and it therefore remains only to decide whether the deductions he made were correct. The doubtful forms are very clearly defined and sufficiently large to be examined with precision by a 1-inch objective; one prominent object, which to the uninitiated might be taken for a diminutive clam shell, is found to measure 1-25 by 1-20 of an inch. I was disappointed to find that high powers failed to develop structure which indicated decisively the nature of these forms, and to show the difficulty of arriving at a correct solution, I may state that the two persons to whom I have so far shown the specimens, differed entirely as to their interpretation; the one pronounced them veritable fossils, and the second was equally sure that they were merely interesting forms of crystallization.

I reserve an opinion until the section has been studied with more attention, and comparison made with other specimens now being prepared; in the mean time I shall be pleased to show the section to any person who is interested in this subject, or able by previous study to throw any light on the subject.

JOHN MICHELS.

THE AMERICAN CHEMICAL SOCIETY.

The annual meeting of the American Chemical Society was held on Friday evening, December 2nd, with Vice President Leeds in the chair.

After the reports from the various officers were read, the society proceeded to the election of officers to serve during the coming year.

The results were as follows:

President: J. W. Mallett.

Vice Presidents: A. R. Leeds, W. M. Habirshaw, E. Waller, L. A. Goessman, A. B. Prescott, N. P. Lupton.

Treasurer: T. O'C. Sloane.

The remainder of the ticket, as announced in the previous notice, were all elected with the single exception of the treasurer, whose name was substituted by that of Dr. Sloane, whose name on the nominating committee was replaced by that of Mr. A. P. Hallock.

The board of directors will be as follows:

P. Casamajor, Jas. H. Stebbins, Geo. A. Prochazka, H. Endeman, H. Morton, P. de P. Ricketts, T. O'C. Sloane, A. R. Leeds, W. M. Habirshaw, E. Waller, C. F. Chandler, J. B. F. Hernshoff, W. E. Geyer.

The reading of the papers announced for the evening was postponed until the conversazione, which will take place on the evening of the 16th inst.

"J. W. Mallett," says Prof. Silliman, "has for many years been an industrious worker, publishing original researches in chemical subjects, which form important contributions to our science."

Among the very first to work in the then newly isolated element, Tellurium, was Prof. Mallett. Under the direction of the celebrated Woehler these researches were made, and, in recognition of their merit, the university at Gottingen conferred the doctorate on the youthful scientist. Coming to this country, for Prof. Mallett is an Englishman by birth, he located himself at Philadelphia with Mr. J. C. Booth who, at that time, had among his students and assistants T. H. Garrett, the two Morfits, McCulloh and others whose names have since become distinguished.

Later on, in the records of American chemistry, the subject of our sketch was appointed Professor of Chemistry at the University of Alabama, and at present he fills the same position at the University of Virginia; he also lectures in applied chemistry before the students at the Johns Hopkins University. His printed papers are very numerous, most of the earlier ones may be found in *Silliman's Journal*, while those of a more recent date have been published in the *American Chemical Journal*. To this latter periodical he has been a faithful contributor since its commencement, and its columns have been enriched by his very interesting review "Of the Progress of Science Among the Industrial Arts During the Last Ten Years." Prof. Mallett served as one of the judges in Group III at the Centennial Exhibition, and furnished for the governmental reports a very satisfactory resumé of the sugar industry of the United States.

He is a member of the Royal Society of Great Britain, of the Chemical Societies of London, Berlin and Paris, as well as many other learned bodies both at home and abroad. The American Chemical Society have made a wise selection, and it is to be hoped that its new president will resume that desirable custom of presidential addresses, which unfortunately has been omitted during the past few years.

M. B.

COMMANDER CHEYNE has started on his trip to Canada, and will return to New York about the 20th of January; in the interval Mr. Henry Walton Grinnell, who has consented to become Secretary of the committee to be formed to promote this expedition, will attend to matters requiring early attention.

THE NEW YORK ACADEMY OF SCIENCES.

Dec. 5. 1881.

REGULAR BUSINESS MEETING.

The President Dr. J. S. NEWBERRY, in the Chair.

Twenty six persons present.

Dr. NEWBERRY exhibited an ancient perforated stone axe from Europe, consisting of dioryte, and remarked that the aboriginal tribes of America never attained to the degree of skill required in the perforation of stone implements for the insertion of wooden handles.

The following paper was read by Dr. ALEXIS A. JULIEN.

THE VOLCANIC TUFFS OF CHALLIS, IDAHO, AND OTHER WESTERN LOCALITIES.

(*Abstract*).

In a paper recently read before the Academy it was shown that a certain compact white almost structureless rock, often porcellanous in texture, occuring abundantly in the Western Territories and variously styled "trachyte," "rhyolyte," "porphyry," etc., (*e. g.*, at Leadville, Colorado, in the Black Hills of Dakota, etc.), is a sedimentary form of a highly silicious volcanic tuff, probably derived from the finest detritus of trachytes, rhyolytes, and quartz-porphyries. A series of specimens collected by Prof. NEWBERRY, during the last and previous summers, and kindly put in the author's hands for lithological examination, has furnished the material for the following additional notes on this interesting but neglected group of wide-spread American rocks.

1. *Coarse pumice-tuff of Challis, Idaho.*

The rock is quite compact, chistose, of a gray color with dull white spots. The latter consists of pumice in finely fibrous grains, from 1 to 5 mm. in length. Quartz and feldspar are seen in small angular flakes, sometimes reaching 0.5 mm. in length: hornblende commonly in fibrous black fragments, about 1 mm. in diameter: and much biotite, brownish-green, sometimes brownish-black, with greasy lustre, in hexagonal scales, often up to 2 to 3 mm. in size.

The thin sections present under the microscope numerous grains, generally angular, of several minerals, varying in size up to 3 or 4 mm.: pumice in rounded to sub-angular fawn-colored fragments lying at all angles, commonly made up of straight or curved fibres, and often including glass lenses filled with crystallites: a trichinic feldspar, in clear grains, sometimes including minute globules of glass, and possessing fine lamellation, beautifully striated in polarized light, the remaining traces of crystalline outlines indicating that these grains are all of fragmentary, never of indigenous formation: quartz, in water-clear angular grains, 0.2 to 1. 6mm. long, retaining more frequent and perfect traces of their crystalline forms, their sides being often very ragged, curiously and deeply eroded into rounded indentations, while within occur numerous inclusions of the ground mass and of scales of biotite, long greenish needles of hornblende, and sub-angular drops of a brownish-violet glass with one or several fixed bubbles of gas: biotite in abundant irregular scales, 0.2 to 1.3 mm. long, brown inclining to maroon or brownish-yellow, cloudy to opaque, with some dichroism remaining in the striated sections; hornblende in brownish-green, strongly dichroic, fibrous crystalline flakes: opacite, probably magnetite, and ferrite or iron-oxide, in dusty particles or groups in the biotite scales and among the pumice fibres. The fine groundmass is mainly composed of minute fragments, fibres, scales, etc., of all these minerals: also in large part of solid globules of fawn-colored glass, or of thin and apparently hollow shells, or of fragments of quartz or feldspar coated with a glass crust. Many of

these forms are found adhering in curious aggregations or with their sides crushed in.

The general constitution of this rock is similar to that of the volcanic tuff of the El Dorado Cañon, Cal.

2. *Fine green volcanic tuff, of Challis, Idaho.*

A very fine compact rock, with almost the texture of stoneware, with a pale, greenish-gray color, and a very thin parallel lamination. A few minute scales of biotite can be distinguished by the loup. The surfaces of fissures are mottled and spotted with bluish-green and ochreous, brownish-gray films.

The thin sections present the same constitution as that of the coarse variety of the rock, without the presence of pumice, the particles of quartz and feldspar varying in size from 0.06 to 0.25 mm. Biotite is abundant in scales 0.1 to 0.2 mm. in diameter, often of ochreous shades of brownish-yellow and maroon, through partial decomposition, and with curved fibres or wrinkles as if crushed in by pressure. To its abundance are due the fine lamination of the rock and, in part, its greenish color. The ground mass largely consists of globules of colorless glass, but in less degree than in the preceding variety, their size varying from 0.006 to 0.01 mm.

3. *Fine white pumice-tuff, of Challis, Idaho.*

A very fine compact rock, grayish, with a bronze shade, with a lamination so decided that it inclines to slaty. Under the loup the same constituents are visible as in No. 1.

The thin sections show a close relationship to those of No. 2. A little hornblende is present. Biotite occurs in distinct scales, sometimes hexagonal, not so minutely dispersed as in No. 2, generally 0.01 to 0.1 mm. in diameter. The fragments of quartz and feldspar, as a rule, present their longer axes in the schist plane, varying from 0.03 to 0.22 mm. in length. The glass inclusions in the quartz, ranging from 0.002 to 0.037 mm. The ground mass appears to be mainly composed of pumice, more or less altered, in very minute fibres and particles.

This rock strongly resembles the tufa of the lignite beds near Osarisawa, Akita, Japan.

4. *Pumice-tuff, Moore Station, Pancake Range, Moray, Nevada.*

This rock is decidedly ochistose, cream colored, nearly white, of a fine grain, intermediate between Nos. 1 and 2, most of the constituents being the same as in No. 1 and less than 0.5 mm. in diameter, though occasional grains of pumice, gray and red obsidian, and perfect crystals of quartz may reach from 2 to 8 mm. in length.

In the thin section the constituents are found disposed with great regularity: pumice, with its fibres often curved, as if crushed while still soft and plastic: quartz: trichinic feldspar: possibly sanidine: magnetite: ferrite: biotite, salmon colored, sometimes very cloudy: and volcanic glass in cellular network, often full of gas bubbles, elongated and distorted. In the ground mass, globules of glass and fibres and threads of pumice largely predominate.

The pumice in all these tuffs is not perfectly isotrope between the crossed nicols, but presents innumerable, though exceedingly minute glittering points, apparently crystallites formed by incipient devitrification. A few minute sphercelites were also detected.

5. *Stratified Rhyolye-tuff, Tempiute, Nevada.*

A snow-white Kaolinic variety, related to the preceding, which appears to consist principally of pumice. A few grains of black obsidian and red quartzite occur, the latter also as a somewhat rounded pebble, 34 mm. in length.

The thin section, transverse to the schist-plane, presents an interesting structure, made up of granular layers alternating with others possessing strong fibration.

The material of the former is mostly like that of No. 4: feldspar is sparsely scattered: quartz fragments abound, with the usual glass inclusions, and with sides deeply eroded and indented: also magnetite, ferrite, and minute colorless particles of a polarising mineral, perhaps Augite, in a predominant groundmass of particles and fibres of pumice and glass, rich in dark gas-bubbles.

The alternating fibrous laminæ consist of a true rhyolyte material, salmon-brown, with a marked fluidal structure around the few quartz-grains, and displaying in spots, and especially next the junction, with granular material, the constituent pumice-fibres whose partial interfusion or cohesion seems ordinarily to have produced the solid laminæ.

The arrangement of the glass fibres in parallel planes may have been produced by sorting in the air during their fall, by later superincumbent pressure while still hot and plastic, or it may be in some instances by the influence of overflowing lava-sheets. The cohesion produced by such downward pressure and interfusion has produced a structure which can hardly be distinguished from that of many obsidians and rhyolytes.

6. *Fine white pumice-tuff, from mouth of Bill Williams fork of Colorado River, Arizona.*

A compact white schist, with almost the fine texture of No. 3, traversed in places by brown curved impressions, apparently produced by rootlets.

The thin section mainly exhibits a very finely felted mass of short, straight fibres of pale brownish pumice. Besides these only a very few black particles of magnetite, feldspar, etc., were distinguished.

7. *Fine brownish pumice-tuff, from last locality.*

A brownish variety of the preceding, with abundant minute black particles. The slaty lamination is decidedly marked, with slight adherence over many planes at which the rock breaks easily, presenting remarkably flat surfaces.

The constitution displayed in the thin section is similar to that of the preceding specimen. Minute glass globules are abundant, and also more numerous angular particles of other minerals: colorless feldspar (sanidine?) showing cleavage: brownish and greenish augite: brownish and dichroic fibres of hornblende, and black particles of magnetite.

8. *Stratified pumice-tuff, from Black Mountains, Colorado river, Arizona.*

A coarser stratified tuff with brown and white layers, in which grains of pumice, obsidian, glassy feldspar, and quartz reach a diameter of 1 to 5 mm.

The thin section is rich in pumice in all its fibrous, curving, and reticulated forms, and in minute globules, threads, and shreds of volcanic glass: angular grains of finely lamellated plagioclase, water-clear quartz, and sanidine with well marked cleavage and often zonal stricture: particles of biotite, hornblende, magnetite and ferrite: abundant grains of augite, angular to rounded, sometimes retaining its optical characteristics in spots, but mostly decomposed and isotrope, colorless, brownish-yellow, light to deep maroon, etc., finely granular, thready, or fibrous, and more or less darkened by opacite even to complete opacity.

9. *Basalt-tuff, or peperino, Chenniti Mts., Texas.*

A fine-grained olive-green rock, with white streak, friable to arenaceous, with barely perceptible schist structure in the specimen. Under the loup, minute granules of feldspar, quartz, etc., are distinguishable, rarely 1 mm. in diameter, embedded in a grayish-green cement.

In the thin section the constituents are very much the same as in No. 8, with the exception of hornblende, and all the grains are in large part rounded. A few elongated rounded grains of a basaltic lava are also included, highly micro-crystalline with minute ledge of plagioclase scattered through a reddish-brown opaque base.

This specimen, and perhaps the preceding, represent the basic division of the tuffs, being ejections from an eruption of basaltic lava, though naturally composed of its more fluid, glassy, and acid scoria.

From these facts it may be concluded that enormous

masses of volcanic tuffs of widely varying character are dispersed throughout these regions in the West to an extent which could hardly be appreciated from the meagre references in our present petrographical literature.

In his discussion of the rhyolytes of the fortieth parallel, Zirkel remarks :*

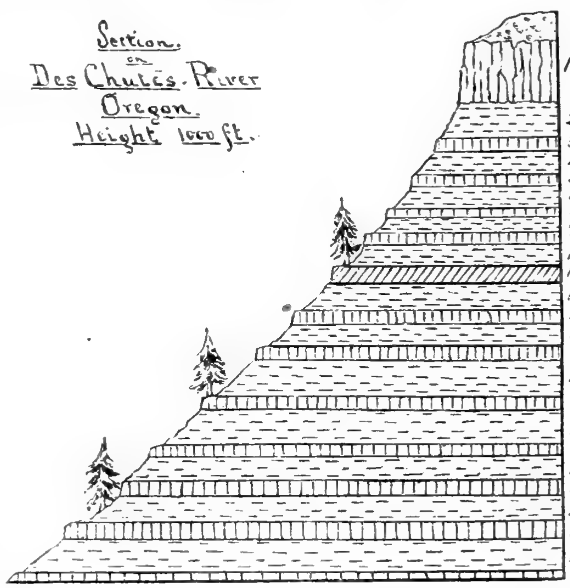
"The foregoing descriptions show in what abundance those fibrous bodies in which the fibres are not grouped radially around a centre, as in sphœrolites, but arranged axially along a longitudinal line, are disseminated through these rhyolites.... These axiolites usually consist of distinct, uniformly thin fibres, or of wedge-like particles.... We see in the arrangement of the fibres in these rhyolites four different types: *a*, centrally radial: *b*, longitudinally axial: *c*, parallel: *d*, confused and orderless. The development of fibres is, indeed, a phenomenon very characteristic of rhyolites, etc., etc.'

A comparison of these facts with those presented in my examination of these tuffs appear to me significant, not of the development of fibration, etc., in a fused mass, but of the fragmental origin of at least many rhyolytes, obsidians, etc., as suggested in the study of No. 5. The evidences of the hot and plastic condition of the fibres and drops of volcanic glass, with the occasional exception of a cooled outer shell, for a long time after their fall, and of a tendency to the growth of microliths, sphœrolites, etc., within them, may offer another mode of origin for the formation of axiolites and sphœrolites. The anomalous presence of augite in a quartzose rock like rhyolyte, to which Zirkel calls attention in the same passage, may also find explanation in the varied intermixture of minerals which prevails in many tufts, rather than to indigenous development within an acid lava.

Dr. NEWBERRY said that he had no doubt that Mr. Julien was quite correct in regard to the genesis of the peculiar rocks which he had described. He had collected the specimens and was able to supply some facts in regard to their mode of occurrence. They belong to a series of rocks, plainly volcanic, but of which the history has not been given by those who have studied the volcanic rocks of the West. The circumstances of their occurrence are briefly these: over a great belt not less than one thousand miles wide in some places, viz., from the crest of the Sierra Nevada to the eastern foothills of the Rocky Mts., and with a north and south extension of thousands of miles in British Columbia, the United States and Mexico, we have an extraordinary display of the products of volcanic action. This is the great silver belt of the world, and is also rich in mines of gold, copper, lead, etc. Throughout all the Paleozoic and Mesozoic ages this country was an unbroken though not entirely unwarped sub-marine or sub-aerial plateau, where the most continuous and extensive series of sedimentary rocks was deposited of which we have any knowledge. At the close of the Jurassic age the western portion of this region was folded up, to form the great chain of the Sierra Nevada and Cascade Mts., and along this line of fracture numerous volcanic vents were established, Lassen's Butte, Mt. Shasta, Mt. Hood, Mt. Baker, etc., which have continued in intermittent activity to the present day. In Tertiary times the plateau east of the Sierra Nevada was broken up by a series of north and south fractures resulting in the formation of the remarkable system of meridional mountain ranges which constitute the chief topographical features of the district. These mountain ranges are composed of blocks of Paleozoic limestones and sandstones --now converted into marbles and quartzites—set up on edge or at a high angle, or of volcanic materials which have welled up through some of the fissures. Along the lines of fractures are great numbers of hot springs, the representatives of thousands more which existed in former days, and to which we owe the great system of fissure veins of this country:—hot water charged with mineral matter gradually depositing this and filling the channels through which it flowed.

The volcanic rocks which have been poured out in so many places exhibit a great variety of physical and chemical characters, but have been grouped by RICHTHOFEN and ZIRKEL into five species—propylite, rhyolite, trachyte, andesite and basalt. Capt. DUTTON who has given great attention to the volcanic rocks of the West, has distinguished a larger number of kinds and has adopted a different classification. Aside from these massive rocks there is another group which constitutes a marked feature both in the topography and geology, and these are those which have been made the subject of Mr. JULIEN'S paper. They are generally soft in composition, often highly colored,—white, red, blue, green, gray or yellow—more commonly white, red or gray. They are often quite local and usually occupy the lowlands, frequently underlying much of the level surface between the mountain ranges; and their best exposures are seen in the banks of streams which have cut these lowlands. There they are shown to be often horizontally bedded and sometimes interstratified with lacustrine sediments and sheets of basalt. Typical exposures of these rocks may be seen at Eureka, Nevada, where houses and cellars are excavated in the soft material which forms the sides of the valley; at Challis, in the banks of Salmon River and Garden Creek, whence the specimens described by Mr. JULIEN came, and in the cañons of the Des Chutes and its tributaries in Oregon.

Economically these rocks have considerable inportance as they are extensively used in place of fire brick for lining lead smelting furnaces, being very refractory, and easily dressed into shape with an old axe.



The above section represents the filling of some of the fresh water lakes which formerly existed in Oregon just east of the great volcanic cones of the Cascade Mountains. Numbers 1 and 11 represent sheets of basalt, the even number softer tuffs and bed of diatomaceous earth, the odd numbers consolidated conglomerates of volcanic materials called "concrete" in my notes.

The study of a large number of outcrops of this series of rocks from Southern Arizona to the Columbia River has convinced me that they are generally volcanic ashes which have been washed down and more or less perfectly stratified in bodies of water which formerly occupied the intervals between the mountain ranges of the great basin. On the Des Chutes a section of more than 1000 feet shows 25 alternations of strata, many of which are examples of the rocks in question. Here they are interstratified with beds of tripoli, composed of fresh water diatoms, and layers of basalt. Some of the ash beds are almost entirely composed of lapillae of soft cottony pumice, others are finer, grey, red, white, etc., and contain the trunks of coniferous trees, and in some instances

* U. S. Geol. Expl. 40th Par., VI, Microsc. Petrog., pp. 201-205.

are pierced with holes which represent the stems of upright plants, thickets of which were buried by the descending showers or rapidly accumulating sediment of volcanic ash. Here the source of the materials is to be sought in the line of great volcanic vents which crown the summit of the Cascade Mountains, and from which, at intervals, were emitted either floods of lava, poured down on to the plain along the eastern border of the range, or showers of ashes which, borne inland by the prevailing westerly winds, fell on forest, savannah and lake, temporarily destroying animal and vegetable life and forming, when falling or washed into water basins, strata which alternate with fossil beds, the accumulations of quieter times. In other places these tufaceous deposits were washed from all the highlands into the valleys, forming local masses of considerable thickness without the intercalated beds mentioned above.

The accompanying section, copied from my report on the Geology of Northern California and Oregon (Pacific R. R. Report, Vol VI, Geology, p. 47), will illustrate the deposition of these tufaceous rocks in the lake basins where they are interstratified with the fossiliferous beds.

THE SCIENTIFIC SOCIETIES OF WASHINGTON, D. C.

THE PHILOSOPHICAL SOCIETY.—During the month of November three very important papers were read: on the Anomalies of Sound Signals, by President James C. Welling; on the Storage of Electric Energy, by Mr. J. C. Koyl; and on Barometric Hypsometry, by Mr. G. K. Gilbert.

The first named paper was a comprehensive review of the vexed discussion concerning the anomalies observed in the transmission of sound, and the summation of the result in a series of twelve aphorisms. The second paper was by a fellow of Johns Hopkins College, with reference to a series of experiments lately made by him in company with some Washington gentlemen upon an invention for the storage of electricity. Mr. Gilbert's communication had reference to a scheme of measuring altitudes by means of two barometric stations in the same vicinity, the one quite elevated, the other as low as convenient. By this means the influence of the thousand and one local causes affecting the barometer would be more thoroughly brought under the knowledge of the observer.

THE BIOLOGICAL SOCIETY.—The following communications have been made during the past month: on the Philosophy of the Retardation of Development Among the Lower Animals, by Prof. C. V. Riley; Antiquity of Certain Types of North American Non-Marine Mollusca, and the Extinction of Others, by Dr. C. A. White; Recent Explorations of the U. S. Fish Commission, by Mr. Richard Rathbun.

Professor Riley drew the attention of the society to a number of instances where the development of insects had been retarded in the embryo stage for a very long time. This did not refer to the well known retardations of whole broods, but to wholly exceptional cases. The speaker attributed the phenomena to evolutionary causes, and showed how a species might be saved from the wholesale destruction of a very severe winter or other disaster by this means.

Professor White's paper had reference to the survival from very high antiquity of many of the fresh water and brackish water forms, and to the total disappearance of others, for which events no adequate causes can be assigned.

Mr. Rathbun's communication was a review of the work of the Fish Commission from its foundation, illustrated by a map locating every dredging station; by a papier maché model of the Atlantic bottom as far out as the deep soundings, from the mouth of the St. Lawrence southward, and by specimens of the apparatus employed as well as the fauna discovered. The address was necessarily very comprehensive, but exceedingly interesting. At the same time the attention of the society was called to a pamphlet by Prof. G. Brown Goode, entitled "The First Decade of the United States Fish Commission, its Plan of Work and Accomplished Results, Scientific and Economical, Salem, Mass.: Salem Press, 1881."

THE ANTHROPOLOGICAL SOCIETY.—Three papers were also read before this society in November, to wit: How Shall the Deaf be Educated? by President E. M. Gallaudet; a Navajo Myth, by Mr. R. L. Packard; the Regulative System of the Zunis, by Prof. J. Howard Gore. The education of the deaf must be preceded by a proper classification of the heterogeneous group commonly called deaf mutes. The question of the relative superiority of the sign language and of visible speech was discussed with great minuteness. The author also treated the problem of heredity, of relative intelligence, and of the power of abstraction, with great ability.

Mr. Packard's myth was one taken by him last summer from one of the Navajo tribe and related to the origin of the Navajos.

Mr. Gore has spent some years upon the evolution of deliberative assemblies and the conduct of such bodies. Last summer, being in charge of a surveying party in New Mexico for the government, he availed himself of his opportunities to become familiar with the customs of the Pueblo Indians in such matters. These papers will be published in the proceedings of the Society.

DIAGRAMMATIC REPRESENTATION OF STEREOSCOPIC PHENOMENA.

(Continued from p. 548, Nov. 19th, 1881, in Transactions of N. Y. Academy of Sciences).

In a previous article (8) it has been shown that no reliance can be placed upon the theory of apparent distance in the stereoscope, elaborated by Wheatstone and Brewster, and applied in the diagrammatic explanation of stereoscopic phenomena in all our text books on Physics. We may well ask, therefore, to what extent it is possible, by any diagram, to represent the position of objects as they should appear in the stereoscopic field of view. So far as this is determined by the relation between the visual lines we may secure an approximation only by the following method, in which it must be assumed that we know also the relation between the camera axes at the time the photograph was taken. Since the visual lines may be practically regarded as special secondary axes to the crystalline lenses, it will be found convenient to call them visual axes, and their possible relations, axial convergence, parallelism, and divergence. It may be well also to restate two principles that have been sufficiently demonstrated elsewhere.

I. A point farther or nearer than the point of sight is necessarily seen double (9) and with imperfect focalization. If farther, the internal rectus muscles of the eyeballs must be slightly relaxed to make it the point of sight; if nearer, they must be contracted. Such relaxation is habitually associated with remoteness, such contraction with nearness, of the point fixed.

II. If an external point is imaged upon corresponding retinal points, the subjective effect is that of union of the two eyes into a central binocular eye, the nodal point of which is the point of origin in all estimates of direction and distance. (10)

A brief preliminary proof of a geometrical principle to be applied is also necessary. Let C and C′, fig. 1, be two fixed points, and E midpoint between them on a horizontal plane. Let this plane be cut by four vertical planes, parallel to each other, their traces being marked I, II, III, and IV. Let B and Q be any points of plane I, from which straight lines are drawn to E, piercing plane II at A and P respectively. Through C and C′ let pro-

jecting lines be drawn from A, B, P and Q to plane IV. It is required to find what relation exists between the horizontal displacements of the projections, a from b, p from q, a′ from b′, p′ from q′.

Since CC′ is horizontal, the projected horizontal displacements will be the same for all elevations of B and Q; these may hence be taken as points on the horizontal trace of plane I.

Since EC=EC′, we have

$Pq_2 = Pq'_2 = Ab_2 = Ab'_2$

$\therefore\ pq = p'q' = ab = a'b'$.

This equality will not exist if E be not midpoint between C and C′. It is true for all points in planes I and II respectively, through which straight lines can be drawn to E.

Let now C C′, fig. 2, be the distance between two camera lenses, for example 10cm; A and B, objects in the foreground and background of a landscape, on the median line from E; Aa, Aa′, Bb, Bb′ secondary axes extending to the sensitized plate. The stereoscopic displacements on the photographic negative, a b and a′ b′, are equal to each other and to those of any other points, P and Q, related to the midpoint E, as they are in Fig. 1.

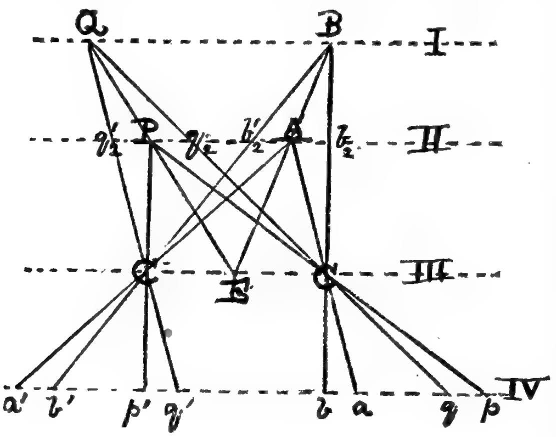


Fig 1.

The camera axes to A make a known angle, θ, with each other. Let E be midpoint also between a pair of eyes, R and L. If proofs from the negative be inverted and placed in front of R and L in such manner that the visual axes through a_1 and a'_1 shall form with each other an angle, α, equal to θ, then A_1 and B_1 are, as nearly as possible, the apparent positions of foreground and background respectively. If α exceed θ, A_1 will be nearer, if α be less than θ, A_1 will be farther; and this will be true if $\alpha = 0$, or $\alpha < 0$. Either of these last conditions is attained by simply increasing the distance $a_1a'_1$. Whether the visual axes are convergent, parallel, or divergent, the *subjective* effect is that of the union of R and L into a binocular eye which, for the geometrical reasons just given, can be nowhere else than at the midpoint, E. In this the dissimilar retinal images are superposed. If those of the points a_1 and a'_1 coincide, b_1 appears to the right eye projected outward on the right, to the left eye an equal distance outward on the left; to the combined eye it is a homonymous double image. Let A_2 be the external projection of the combined images of a_1 and a'_1, as seen by the binocular eye at E_2; if $\alpha = \theta$, the distance E_2A_2 is equal to RA_1 or LA_1, which differs but little from EA_1 unless α be large; it has been drawn equal to EA_1. Then B_2 and B'_2 will be the external projections of the uncombined images of b_2 and b'_2. If the attention be transferred to the background, the angle between the visual axes must be diminished by relaxing the internal rectus muscles, and this instantly suggests greater remoteness of the point of sight. The retinal images of b_2 and b'_2 coalesce and are projected to the more distant external point between B_2 and B'_2, while those of a_2 and a'_2 cross slightly to opposite sides and are projected as a heteronymous double image at its proper distance. The ratio of E_2A_2 to EA_1 must depend upon the variation in muscular tension due to the difference between the angles θ and α. The duplication of the images of the background points when the foreground is regarded, and *vice versa*, is easily perceived if a properly constructed diagram is viewed in the stereoscope, provided the observer be attentive to his own sensations, examining each point of the combined picture separately instead of regarding

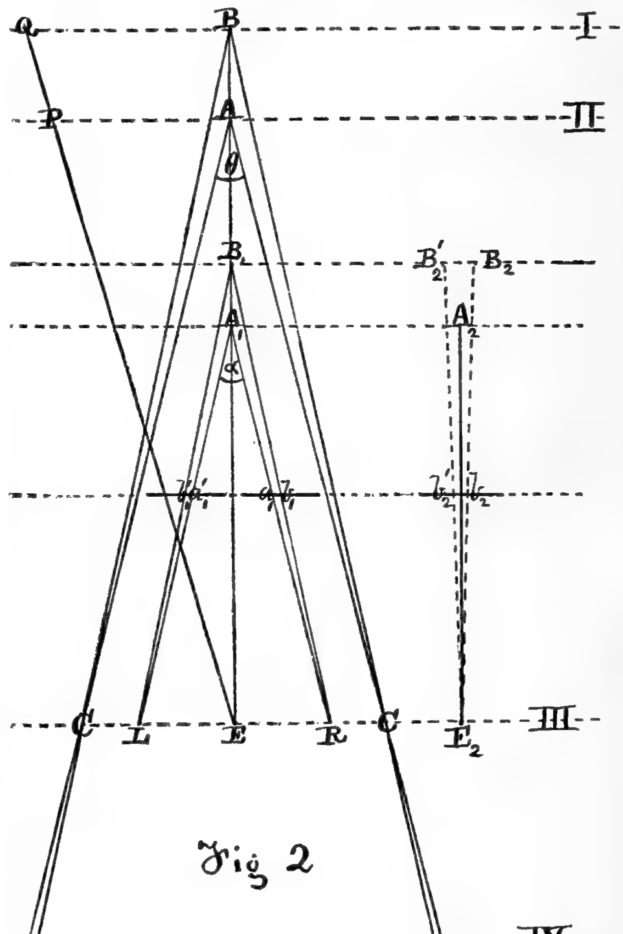

Fig 2

the total effect at once. Let Figures 3 and 4 be examined in the stereoscope, by resting the edge of the page on the cross-bar of the instrument at the proper distance in front of the semi-lenses. In each case, when the foreground circle is seen single, the background dot is seen double, and *vice versa*. When the background circles of one figure are combined binocularly, those of the other are seen separately by monocular vision. Axial convergence is necessary to combine the circles of Fig. 4. The combined image appears nearer, smaller, and less tall in proportion to its base than the combined image of Fig. 3, which requires axial divergence. The stereoscopic displacement is the same in both figures, and is measured by the distance between the centre of the large circle and that of the small one within it. The stereographic interval for the background is 90 mm. in

Fig. 3, and 50 mm. in Fig. 4. An average lenticular stereoscope will fail to produce axial convergence when Fig. 3 is viewed by a pair of eyes whose centres are 64 mm. apart. These variations in visual effect can be rendered still more striking by using the reflecting stereoscope, after cutting apart the right and left halves of the stereograph.

It must be remarked that although the perception of binocular relief is intensified by alternate examination of foreground, and background it is quite possible to attain it by momentary illumination with the electric spark, at least with convergence of visual axes, as has been done by Dove [11] and others. During such brief illumination, no variation of convergence is possible, and, if the foreground be distinctly focalized, the background must be slightly doubled homonymously. The position of the point of sight is found thus to be almost as nearly determinate as when the illumination is prolonged. Whether binocular relief, and the position of the binocular image, be perceptible with equal distinctness when the visual lines diverge, has not thus far been ascertained by experiment, so far as I am aware. I hope to test this, and to study certain other points of interest connected with it, at some future time.

Since the apparent distance of the point of sight continues to increase in a positive direction after axial parallelism passes into divergence, it becomes necessary to investigate the physiological conditions that interfere with the results of the mathematical theory hitherto generally applied.

In looking at any picture constructed in accordance with the rules of perspective applied by all artists, the illusion of distance is quickly attained by forming a conception of the reality in space to which the different parts of the picture are supposed to correspond, or of the object as the observer has been accustomed to view things of its kind. With the same degree of axial convergence a mountain and a piece of statuary will never be judged equally distant. It is unnecessary here to enumerate the elements that combine to produce the illusion. If these be excluded to the utmost, as in mere skeleton diagrams, there will still be left three to consider in judging the distance, size, and form of what is represented. These are—

I. The optic angle between the observer's visual axes.
II. The focal adjustment of the crystalline lens.
III. The visual angle subtended by the picture.

Of these the first is the only one usually considered as *distinctive* of binocular vision. It can never be dissociated entirely from the others, and its effect may be so overpowered by them, when distance is to be estimated, that calculations based upon its value, like those of Brewster, lose all claim even as approximations to the truth. Its true importance is dependent upon the extent to which the individual, in natural binocular vision, has been accustomed to associate the sensation of muscular contraction in the rectus muscles of the eyeballs with the true distance of objects as learned by other means. Doubtless this varies with different individuals. For distances of more than 240 m. the optic angle becomes inappreciable, and hence theoretically valueless; its importance is greatest near the lower limit of distinct vision. In every case its effect is appreciated mainly through the muscular sense and through the retinal perception of double images from objects farther or nearer than the point upon which attention is fixed. We are safe in disregarding the mere fact that a pair of imaginary lines *would* make a measurable angle with each other *if constructed*, though the use of this angle may be convenient in analyzing the phenomena of vision. It is well to remember, however, that its variations imply simply changes of muscular tension, and these constitute the most appreciable effects that influence the estimate of limited distance.

The judgment due to focal adjustment is also an interpretation, based upon personal experience, and suggested by the sense of contraction in the ciliary muscle, while adapting the crystalline lens to produce a distinct image. Variations in this are hence inappreciable for distances of more than 6 m., and are most noticeable near the lower limit of distinct vision. It is near this limit that the stereograph is held in most cases when regarded.

The visual angle is important as chiefly determining the size of the binocular retinal image. Since two eyes receive more of the light reflected from a given surface than either eye alone, the binocular image appears brighter than one that is monocular; and this is apt to produce the illusion of slight decrease of distance, if the focalization is perfect. But variation due to this cause is not important in comparison with that due to change in the visual angle.

The relative importance attached to the separate elements enumerated depends most frequently upon the unconscious experience of the individual. The results which they combine to produce cannot be referred to any one mathematical formula until the physiology of sensation is completely brought within the domain of mathematical law.

In testing the effects of these elements it will be best to apply a formula for the distance of the optic vertex from each eye, in terms of the interocular distance, i, and optic angle, α. Assuming the optic triangle to be isosceles, and calling D the required distance, we have, as the formula to be tested by experiment,

$$D = \tfrac{1}{2}\, i \ \text{cosec.}\ \tfrac{1}{2}\alpha.$$

Considering angles of convergence positive, the possible values of α, between which I find myself limited, are $+ 80°$

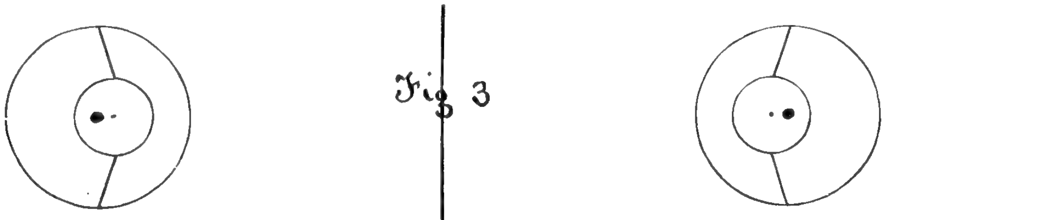

Fig 3

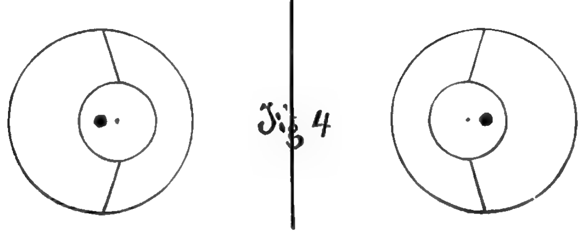

Fig 4

and $-7\frac{1}{2}°$, my eyes being perfectly healthy. If a curve be constructed from the formula, the values of a being taken as abscissas and those of D as ordinates, for parallelism of visual lines we have $a = 0$, $D = \infty$, and the axis of ordinates is hence an asymptote. A vanishing point should therefore be reached by the external binocular image. Its apparent distance, however, is still finite, and vision very easy. In passing to negative values of a by increasing the stereographic interval, the distance estimated continues to grow in a positive direction. This is undoubtedly due to the sense of increasing relaxation of the internal rectus muscles and contraction of the external rectus; but the rate of growth bears no recognizable relation to any succession of values given by the formula.

The explanation just given is based upon experiments, the description and discussion of which must be withheld for the present. It may be simply stated that with binocular fusion of images from the same pair of conjugate pictures, I have tested the visual effect of varying the optic angle from $-5°$ to $+45°$, vision becoming indistinct after the last named limit is passed. The value of the optic angle has been found to be largely, but by no means exclusively, effective in determining apparent distance in the stereoscope, especially for convergence of visual axes. Its effect is antagonized by the difficulty of focal adjustment and by the constancy of the visual angle, the latter element being particularly important when the axes diverge.

The variation in apparent magnitude of the combined image, dependent upon the value of the optic angle, has been noticed by Wheatstone ([12]), Helmholtz ([13]), and Meyer ([14]). Helmholtz constructed his telestereoscope ([15]) for producing exaggeration of perspective when distant objects are viewed, but no reference is made, in this connection, to divergence of visual lines. The possibility of fusion by optic divergence seems to have been first noticed about 1860, by Burckhardt ([16]); and Helmholtz notices the exaggeration of apparent distance thus produced, but explains it by saying ([13]), "Infinity does not, in our visual conceptions, present an impassable limit. When our eyes occupy a position which is never presented in the normal observation of real objects, all that we can do, conforming ourselves to the rule which we ordinarily follow for the interpretation of abnormal sensations, is to compare the sensation produced with that which resembles it most, and which is distinguished from it only by more feeble convergence, that is, with what is given us by real objects very remote." Vision in the stereoscope is always to some extent abnormal. The error into which Brewster fell, and in which he has been generally followed, was in supposing that under such conditions no modifications would be imposed upon the mathematical law found applicable to normal vision, in which there is perfect coincidence between the impressions traceable to the optic angle, focal adjustment, and visual angle respectively.

W. LE CONTE STEVENS.

THE German government is considering the participation of German men of science in the plan of International Polar Research. The Reichstag has been asked to grant the necessary funds $75,000.

FOREIGN NOTES ON THE SOURCE OF COMETS' LIGHT.

Numerous observations have been made abroad upon comet *b*, 1881, to settle the question as to the origin of the light of these bodies. Messrs. Thury and Mayer at Geneva compared the brightness of the comet's head, as ascertained by photometric measurements, with the brightness it would have had if its light had been derived solely from the sun, by reflection. It was found that the intensity of the light of the nucleus, as it withdrew from the sun, diminished at first faster, and after a time slower than would have been the case, had it shone solely by reflected light. The decrease in intensity took place, in fact, as if the nucleus, during its approach to perihelion, had acquired through the force of the sun's rays an intrinsic light, which accompanied violent action of some character; this violent action ceasing after the comet had measured some distance on its return track, its light decreased speedily in conformity therewith, but the nucleus continued to glow as if in a state of incandescence, and remained visible, according to the above observers, longer than could have been expected.

This method seems to be well adapted to an independent determination of this interesting question. In the data it is a question, not of absolute, but of relative quantities. Ignorance of the physical condition and nature of a comet's reflecting surface renders it impossible to compute the intensity of its light under reflection alone, with any degree of certainty. As not the absolute light, however, but the increase or decrease under the circumstances, is required, the necessity for such knowledge is eliminated.

Another conclusion as to the origin of the comet's light has been reached by Respighi, from spectroscopic evidence. According to him there is no doubt that the light in part is reflected, as is proved by the appearance of the Fraunhofer lines in the photographs of the comet's spectrum. As to the bright lines or bands, they also may be caused by reflected light, as will be seen when it is taken into consideration what changes this light must have undergone after it has passed through the gases and vapors which form the whole mass of the comet. "It is certain," he continues, "that the largest part of the light emitted by the comet comes from its interior, and that it has passed through thick strata of gases and vapors. It is there subject to the selective absorption which is peculiar to these vapors and their combinations. It is accordingly natural that dark lines and bands should thence arise, which are different from the Fraunhofer lines; and with the weak, but complete, spectrum of the light that is reflected from the exterior substance of the comet, another spectrum must appear, which is considerably modified through powerful absorption."

"The limits of a simple notice do not permit me to enter in detail into my numerous spectroscopic observations of the Comet *b*, 1881. But I can affirm that it does not require the supposition of an intrinsic light to explain the phenomena which they exhibit. For the discontinuity of the spectrum might arise from the same cause as the broad, dark bands in the spectrum of the sun near the horizon, or in those of the planets. In the case of comets, however, the phenomenon is greatly exaggerated by the immense thickness of the absorbing strata, the rich character of their chemical constitution and the weakness of the light which they reflect to us. One must therefore proceed as in the case of the spectrum of our atmosphere, and not consider so much the bright bands as those dark through absorption."

A COMMITTEE has been formed at Reggio, (Emilia) to collect funds for establishing a fitting monument to the memory of the Padre Secchi, in the form of a fine refractor, of which the objective is to have 70 centimetres diameter. Reggio thus follows the example of Arcetri, where a fitting scientific monument has been erected to the memory of Galileo.

The Editor does not hold himself responsible for opinions expressed by his correspondents. No notice is taken of anonymous communications.]

LOUDNESS *vs.* INTENSITY OF SOUND.

To the Editor of "SCIENCE."

Will it seem like firing a blank cartridge at Copenhagen to urge that writers on acoustics ought more carefully to distinguish between the words loudness and intensity as applied to sound? We think not, so long as statements like the following are found in elementary manuals of physics; or so long as the language of even distinguished lecturers on Sound is not wholly free from similar indefinite expressions.

For instance, the law of variation in intensity of a sound free to move in a homogeneous medium is often stated in substance thus: the intensity *or loudness* of sound decreases as the square of the distance. As an illustration it is sometimes added, a sound at the distance two will be only one fourth as loud as at the distance one. While as a triumphant proof or verification of this law, it is often said: a single bell at the distance of ten yards will sound as loud as four similar bells at twenty yards.

It is well known that the word sound and several of the terms used in describing sound have two meanings. The word loudness primarily refers to the sensation of hearing. In order to avoid confusion of thought, I esteem it important that the use of this word be restricted to the sensation, and that the word intensity (or volume) shall refer solely to the external vibrations which are the cause of the sensation. In other words, loudness ought always to be used in a subjective, intensity in an objective, sense.

What is meant by such expressions as those above quoted? Perhaps they are simply examples of a loose use of language, but it will certainly be natural for the unwary reader to infer from them that loudness and intensity vary according to the same laws, and also that we can by the ear verify those laws. I have no hesitation in affirming that this use either purposely or otherwise, of the word loudness as synonymous with the word intensity, has been the cause of great confusion of thought, and has often loaded down the undulatory theory of sound with that which is really foreign to it. The time has come when we ought to regard that treatise on sound as a failure in one important respect which does not leave the reader thoroughly imbued with the idea that the law of variation in the intensity of a sound refers to sound vibrations and not to the intensity of the sensation of hearing.

But if those who use such expressions as have been quoted, really mean to claim that loudness, i. e., relative intensity of sensation, varies according to the same laws as the energy of the moving molecules of the sound wave, or if it is claimed that by the ear we can accurately and validly verify the law, then it will be in order to demand the proof.

In order that such physiological laws may be proved true it must be shown, either, 1, that we can accurately know when one of our sensations is a multiple of another (as when one sound is four times as loud to the ear as another), or, 2, that we can recognize sensations of equal intensity; and, 3, it must also be proved that the intensity of the sensation is proportional to the energy of the blow causing the sensation. These assumptions cannot be proved.

1. It goes without saying that any one having normal senses can tell a heavy blow from a light one, and can recognize degrees of intensity among sounds, lights, heats, tastes, and smells. But if it is claimed that there are quantitative relations between sensations of different intensity, and that we can by consciousness recognize these ratios, we at once become committed to a remarkable system of mathematics. Since experience shows that the senses are easily deceived and that different persons disagree as to their estimates, who shall decide what are the true ratios? But we can only compare the relative intensities of two sensations by memory. Here is a fruitful source of uncertainty, for before we can be sure that one sound is to our ears four times as loud as another, we must be certain that we can by memory reproduce the first sensation and place it beside the second in exactly its true intensity. No one can be sure of this. This reasoning applies to those who have perfect senses, if there are such. When we consider the myriad degrees of nerve sensitiveness, partly congenital, partly the result of habit, and partly the result of disease, the problem becomes still more difficult, ludicrously so.

2. Can we recognize sensations of equal intensity? No doubt we can do so much more exactly than we can estimate the relation between sensations varying greatly in intensity. Yet here we meet the same cause of doubt as before,—the uncertainty of memory. The less is the time intervening between two distinct and independent sensations, the more nearly we can estimate their true intensities. In comparing sounds, somewhat more than one sixteenth of a second must elapse between them. In the photometer the lights or shadows are shown in contrast and are thrown side by side upon the screen, where we can see them simultaneously or pass from one to the other very quickly. Probably there is no way whereby we can compare two sensations more accurately than by the photometer, yet no one will claim that he can move the lights so that their intensities shall be exactly equal on the screen. All he can say is: to the eye they are equal. If then under the most favorable conditions, there is a residuum of doubt, the sense of hearing will be still more untrustworthy; I regard it, therefore, as a fallacious method of research to bring physical laws to be tested by the uncertainties of sensation. Can feeling demonstrate the accuracy of a thermometer, or can the laws of energy be verified by striking ourselves blows with moving bodies? All that we can say is that within certain limits the testimony of our senses approximately conforms to the laws which have been deduced from more accurate observations and reasoning.

3. Are sensations proportional to the energy of the impacts producing them? They must be, if loudness and intensity vary according to the same laws, or if equal sensations are caused by equal blows. The hypothesis is manifestly absurd as a general law, for we are unconscious of very weak blows, and very violent ones either destroy the nerves or paralyze them by what is known as shock. Even within the most favorable limits the rule can only be approximately true, and if it were true, could not be proved, for the nerves retain their impressions for a variable length of time, and this marks a limit to the intervals at which we can repeat impressions of normal intensity free from the residual effect of previous impressions. Hence if impressions be repeated too soon they will generally cause a progressive deadening of the nerve sensitiveness, or sometimes an increased sensitiveness, as in the case of the punishment of the bastinado. Even if there were nervous conditions such that the sensation was proportional to the energy of the impact, it would be difficult if not impossible to prove that the nerves were in the proper condition at any given time. Into such a tangled maze of uncertainties are we led when we try to pervert our senses, admirable in their proper sphere, into mechanisms for the quantitative estimation of energy!

If it be said that a single bell at the distance one will sound as loud as four bells at the distance two, it must be assumed that the ear is equally well adapted for receiving and transmitting all sounds, irrespective of the shape of their wave front. I will omit from the following discussion all the complications which spring from differences in the pitch and timbre of sounds and will premise a perfect ear and nerves.

According to the undulatory theory of sound, the wave

front in a homogeneous medium is a spherical surface, and the rays of sound proceed outwards in all directions and in straight lines ; hence the nearer is the source of sound, the more convex is the wave front and the more diverging are the rays. When the nearly parallel rays of sound proceeding from a distant point, strike the cup-shaped outer ear, a part is reflected toward the centre and thus reinforce the rays which directly enter the external opening of the ear. If a sound proceed from a point very near the ear the rays will be so diverging that all, except such as directly enter the opening, will be reflected outwards and will be lost. Hence it is evident that a far sound will seem louder than a near one, if their vibrations are of equal intensity as they come to the outer ear. This will at once upset the theory that loudness and intensity vary according to the same laws, unless in some way the far sound shall lose its advantage after entering the external meatus; but, as they enter the tube, the diverging rays of the near sound will strike obliquely outwards against the walls and will be reflected. Thus a part of their energy will be lost, a much larger proportionate loss than will come to the more parallel rays of the far sound. When at length after various reflections from the walls of the crooked meatus, the waves are wedged between one wall and the membrane of the tympanum which is placed obliquely across the inner end of the tube, the rays will fall upon the concave outer surface of the membrane, and a part will be converged. The more parallel rays of the distant sound will be more converged than those of the near sound, and hence will reinforce the impulse at the center of the membrane more than the other ; but the center is the point of greatest leverage against the hammer bone which is fastened to the back of the membrane ; hence nearly parallel rays of sound would more violently agitate the tympan of the inner ear than more diverging rays, even though both were of the same intensity before striking the concave membrane of the tympanum. The comparison by the ear of the intensities of two sounds would be still more untrustworthy if one of the sources of sound were within the outer tube of the ear.

Loudness, that is, the intensity of sound sensations, does not, then, depend upon the energy of the external sound vibrations, but upon the proportion of the energy which the mechanism of the ear is able to transmit to the auditory nerves, which amount is variable. The ear is so made as to relatively strengthen distant sounds and to weaken near ones, and it is so much the better an instrument because of this, for we are thereby saved from too violent shocks of the nerves, which are most likely to come from near sounds, while at the same time we retain a wide range of hearing. Such illustrations as that of the bells would not be chargeable with setting up a false test for the verification of physical laws, if it was not at the same time explained that the intensity of the sensation of hearing does not, and in consequence of the peculiar construction of the ear, cannot vary as the energy of the moving particles of the sound wave; also that at certain distances the testimony of the ear will approximately coincide, at other distances it will not coincide with the laws of intensity of sound which have been established by mathematical reasoning. The errors involved in the argument from the bells are very commonly held; it is not evident that all such arguments ought to be eliminated from treatises on sound, or at least that their true significance ought to be explained, and that the distinction should be more clearly defined between the subjective word loudness and objective word intensity.

GEORGE H. STONE.

COLORADO SPRINGS, *December 1st.*, 1881.

NEW YORK, *Dec. 19th.*

To the Editor of "SCIENCE."

In the official report of my paper read before the N. Y. Academy of Sciences, published in your last issue (Dec. 16th), I notice the cost of the balloon is given at about £12,000, whereas the amount should have been £4,000. The report also states, "the great body of warm water that flows northward by the peninsula of Norway and Sweden strikes the lighter currents near the Pole and goes on as a submarine current, sweeping around the Pole till it goes out again through Smith's Sound." I desire to say that it is obvious that only a part of the current passes through Smith's Sound.

Respectfully,

JOHN P. CHEYNE, R.N., F.R.G.S.

To the Editor of "SCIENCE."

Sir,—In No. 12 of this year's *American Naturalist* I notice a short paragraph on 'fossil organisms in meteorites.' The subject certainly is interesting and it seems perfectly proper that the '*A. N.*' should at last take notice of it.

The only objection that I may be allowed to raise on behalf of "SCIENCE" and perhaps of myself is that the *American Naturalist* did not duly give credit for what had been reprinted from your columns.* I cannot conceive any plausible reason—unless it be an oversight—why this simple duty of editorial courtesy should be neglected by an American contemporary, while every English scientific journal takes pains to give due credit to "SCIENCE" for all the various data and notes which are gleaned from its columns (*e. g.* Jour. Microsc. Soc., *Lancet, Crookes' Journal, Journal of Science.*)

As to the sceptical remarks with which the *A. N.'s* paragraph concludes, to the effect that "a great deal more evidence will be required by biologists before crediting these alleged discoveries," I may refer all sceptics to Mr. Darwin's opinion, as reported in No. 61 of your valuable journal and to any (silicious) meteorite on which they can lay their hands and grind transparent sections from. This will go far to supply the wanted evidence.

Very respectfully,

GEO. W. RACHEL, M. D.

To the Editor of "SCIENCE."

NASHVILLE, TENN., *Nov.* 30, 1811,

Dear Sir,—I have to-day received from Mr. H. H. Warner, of Rochester, N. Y., $200 (two hundred dollars), the "Warner Comet Prize" for the discovery of Comet E, 1881, on Sept. 17.

Respectfully,

E. E. BARNARD.

MUSICAL FENCES.

In the abstract of an interesting paper by Prof. S. W. Robinson, in a recent number of "SCIENCE," the author begins with the statement that "this sketch is mainly of a simple fact of observation." He gives then a clear exposition of the acoustic phenomena observed by him in walking past picket fences, and the mathematical formula expressing the law of retrogression of pitch.

The observation is by no means new. I am unable to say at what time it was first published, if at all, but am sure that it was made nearly as far back as twenty years ago. On the crisp, cold morning of December 31st, 1861, while taking a walk with Prof. Joseph Le Conte, myself being innocent of mathematics on account of my youth, we noticed the whistling sound returned by a picket fence past which we were moving, our feet striking sharply against the frozen earth. My fondness for music made me particularly appreciative of a musical fence, and I have noticed the phenomenon hundreds of times since that date, knowing its explanation qualitatively, though I did not deduce the formula. If the fence be long, and the distance between the wickets considerable, the returning whistle may be much longer in duration than a quarter of a second. The stroke of a hammer on a board

*S. my paper on the subject in SCIENCE No. 50.

is a convenient substitute for that of the foot against the ground. I recently had a beautiful illustration while riding slowly on the horse-cars in New York. A vehicle passed rapidly between me and a picket fence, every stroke of its wheels against each stone of the pavement being returned as a whistle from the opposite fence. The acoustic effect was much like that of the trilling of a canary bird.

I cheerfully accord to Prof. Robinson the credit of giving mathematical expression to this truth. His observation is none the less original even if others have preceded him, and I am by no means sure that any one has preceded him in giving it publication.

W. Le Conte Stevens.
40 W. 40th St., New York.

Dec. 17th, 1881.

NOTES FROM OUR FOREIGN EXCHANGES.

Phosphorescent Fungi—At the present day, several inferior species of fungi are known, which have the power of throwing out a phosphorescent light. M. Crié, Professor of the Faculty of Sciences at Caen, has noticed new species which spring up on old stumps or between the bark and the wood of the elder-tree.

Rectification of Inferior Alcohol.—Electricity is now employed in the rectification of inferior alcohol. The electricity generated by a voltaic battery and a dynamo-electric machine is passed through the alcohol so as to disengage the superfluous hydrogen. By this means, beet-root alcohol, which is usually very poor, can be made to yield eighty per cent. of spirits, equal to that obtained from the best malt.

A Japanese Antelope.—Several interesting acquisitions have recently been made by the Zoological Garden of London. Among other rare animals, it has obtained a Japanese antelope which has never before been in any collection in Europe. The antelope of Japan (*Capricornus Crispus*) is found only in the highest mountains of the Niphon and Shikoku islands. Very little is known of its habits and it has been but incompletely described by Siebold in his Fauna of Japan.

Phosphorescent Ice —Mr. J. Allen has written to "Nature" an interesting letter, in which he describes a curious phenomenon of phosphorescence of floating ice, observed in the Polar regions. Every time that the bow of the ship, where the observer placed himself, shattered the ice during the night, the ice suddenly shone with a very perceptible light. It is a light similar to that which is produced on the breaking of sugar, the cleavage of sheets of mica, or the striking together of pieces of flint in the dark.

Electric Fusion of Metals—M. Siemens, in the presence of the members of the Congress of Electricians, performed the following curious experiment: in a crucible conveniently arranged, furnished with a perforated cover, fragments of steel were placed; the two currents of an electro-motor apparatus entered the lower and the upper part of the crucible. In 14 minutes the metallic mass became hot, reddened and melted. The mass showed no inflation. The expense of the combustile consumed by the electric apparatus is much less than that which fusion by direct application of heat would necessitate.

Electricity produced by Light.—While traveling in Mexico, M. L'ur, mining engineer, was struck by the fact that the *amalgamation* of silver ore, by what is called the *American* method, only operates well under the influence of light. According to him, the action does not take place in the darkness. He sought the cause of this unexpected effect and his experiments seemed to him, to show that light, by acting upon the mixture of sulphide of silver, sulphate of copper, salt and mercury, develops electricity without which the amalgamation cannot take place.

M. Boussingault, however, expressed an objection to this conclusion, which appears decisive; that in Mexico, the operation is not confined to small quantities, but whole mountains of ore are acted upon. Now light is only able to act upon the periphery of the latter, and the largest part of their mass remains in permanent darkness.

The Telephone in a Storm.—A very curious experiment was made and announced by M. René Thury, of Geneva. He stretched a metal wire from one roof to another. One extremity of the wire was in connection with a telephone, the opposite extremity with the earth. During a storm, every time there was a lightning stroke, even at a distance of 20, 30, and even 40 kilometres, the telephone gave a very characteristic sound. This noise, according to M. Fleury, was due to the peculiar electric currents, called currents of induction, produced under the influence of the atmospheric electric discharge. It was a sort of return impact.

The Sulphate of Alumina of Commerce.—For a long time there has been a tendency to substitute sulphate of alumina for potash or ammonia alum, since it is richer in alumina. But the manufacture of pure sulphate of alumina, that is to say, free from iron, is not easy, at least in an economical point of view.

During the last twenty years, pure hydrated alumina has been prepared at a low cost, and by saturating this alumina by sulphuric acid, a warm liquid is obtained which congeals into a dry and easily transportable mass of sulphate of alumina containing about 15 per cent. of alumina.

The products obtained in this manner are relatively expensive, and it would be a great advantage to purify the ferruginous sulphate of alumina furnished by the action of sulphuric acid upon common clay, if this purification could be accomplished by an easy and less costly method.

Extraction of Magnesia from Sea Water.—*The Moniteur des produits chimiques* contains the following method of abstracting magnesia from sea water: "magnesia can be precipitated from sea water by means of calcium, just as from other more concentrated solutions. After precipitation and rest for a day, a cubic metre of sea water gives a precipitate of gelatinous magnesia, about 80 litres in volume. The treatment on a large scale of water whose magnesia is to be deposited in large basins, can easily be accomplished, speaking in an industrial point of view; the calcium will be the greatest expense.

If the magnesian sediment thus obtained is treated with phosphoric acid, a precipitate of tribassic phosphate is obtained, which, filtered, becomes an excellent chemical agent for the precipitation of ammonia from excrements in the form of ammoniac-magnesian sulphate, which is a powerful manure.

Spontaneous Combustion of Carbon.—Spontaneous combustion in colliers is a very important question, for, in 1874, 70 cases of this kind occurred. The recent investigations of M. Haedicke have thrown light upon this subject. These experiments were conclusive in proving that this combustion is due to the influence of iron pyrites. This substance becomes oxidized when submitted to moisture and is changed into ferrous sulphate. During this decomposition, the carbon bursts and offers a larger surface to the action of the air. The ferrous salt is then transformed into a ferric salt which yields up its oxygen to the carbon. In order to prevent spontaneous ignition, all currents of air should be excluded, unless they should be allowed to enter from the beginning in great quantities, so that the air acts as a cooling agent. As moisture prevents ignition and the accumulation of oxygen, the introduction of a jet of steam, where the temperature of the carbon has been raised to a high degree, will also act as a preventive.

Sea-sickness.—A correspondent of the "Paris Medical" has sent a communication to the editor, which will prove interesting to many persons who suffer sea-sickness in their travels.

"In a recent voyage from Algeria to France," he writes, "the sea being very rough, and almost all the passengers being sick, the officers of the ship could offer but insufficient means of relief. Among the passengers there was one, about thirty years old, who suffered cruelly. He vomited continually for thirty hours, and his sufferings became so severe that the surgeon had to be called. After hearing him prescribe lemon juice, I asked him if he had not morphine or chloral. To my astonishment he replied that he had none. I then offered him one centigram of morphine and my syringe. This was accepted. A solution was made in 20 drops of water, was injected into the epigastrium, and, a half hour afterwards the sickness was allayed. He ceased

vomiting and remained unmolested during the rest of the journey. This fact appeared remarkable to me. The benefit had been immediate." If this observation can be confirmed by other similar cases, it would be very fortunate, for then the surgeons of the maritime and transatlantic companies would be able to relieve passengers who suffer seasickness.

THE SEPARATION OF WOOL AND SILK IN WOVEN GOODS.—A. Rémont.—The following method is sufficiently exact for commercial purposes: the sample is kept for a quarter of an hour in boiling water containing 5 per cent. of hydrochloric acid, and is then washed and dried. The threads of the warp are then separated, if possible, from those of the weft, and examined separately as follows: a thread is burnt. There is given off a smell like burning horn, and a thread heated with a fragment of caustic soda evolves ammonia. In this case some threads are plunged in basic zinc chloride at a boil. If they dissolve completely the threads are *silk*. If on adding hydrochloric acid there is a plentiful flocculent precipitation, the threads are silk mixed with wool or with vegetal fibres. If nothing dissolves in zinc chloride, the threads are plunged in a boiling solution of soda, not too concentrated. If they dissolve completely, *wool*. If partially, *wool* and *cotton*. If no odor of burnt horn is given off, the threads consist entirely of vegetal fibres. These results may be confirmed by means of the microscope. For the quantative examination, if the preliminary tests show silk, wool, and cotton, four swatches weighing each 4 grms. are cut; one is laid aside and the three others are boiled.—*Journal de Pharmacie et de Chimie.*

THE REDUCTION of COPPER SOLUTION BY GLUCOSE* appears first to have been utilized by Trömmer. Frommherz suggested the employment of a citrate to keep the cupric oxide in solution. Modifications of the ordinary alkaline tartrate solution have been devised by Barreswil, Poggiale, Rosenthal, Chevalier, Boussingault, Reveil, Fehling Strohl, Viollette, Magneshahens, Lowenthal, Joulie, Pos soz, etc. Loewe employed glycerin instead of a tartrate. Various treatments of the precipitated cuprous oxide have been proposed by the following chemists: Mohr dissolves the oxide in hydrochloric acid, and titrates with permanganate. Brunner dissolves in an acid solution of ferric chloride, and estimates the reduced iron by bichromate or permanganate. Champion and Pellet dissolve the precipitate in hydrochloric acid and chlorate of potassium, boil off free chlorine, and titrate the liquid with stannous chloride. Girard and Soxhlet reduce the cuprous oxide in hydrogen, and weigh the metallic copper. Muter dries the cuprous oxide at 100° C., and weighs it as Cu_2O. O'Sullivan and other operators ignite the precipitate strongly, and weigh as CuO. Ferdinand-Jean dissolves the cuprous oxide in hydrochloric acid, and weighs the metallic silver precipitated on adding ammoniacal silver nitrate. Maumené uses an excess of copper solution, filters, adds ammonia to the filtrate, and estimates the residual copper by titration with sodium sulphide, for which Perrot substitutes potassium cyanide. Lastly, Pavy adds ammonia to the alkaline cupric solution, and runs in the sugar solution till the hot liquid is decolorized.

SATURDAY, DECEMBER 31, 1881.

As the present number of this journal concludes the second volume of "Science," the moment appears opportune for us to acknowledge our obligations to the many friends of the journal, who, by their contributions of valuable papers, have assisted in placing it in the distinguished position which it now occupies.

The expression of good will and satisfaction which we have received from so many of our subscribers, is encouraging for the future of the journal, for we must confess that our plans for the editorial management have been but partly developed; if we have deserved such recognition in the past, we look forward for a wide extension of our circulation in the future, when the improvements and additions which we contemplate shall be carried out. Arrangements are in progress to increase the number of pages of "Science" from twelve to sixteen, the four extra pages to be devoted to applied and practical science; in this division the most recent application of scientific principles to the arts and manufactures will find a place, and novel inventions of real scientific merit will be fully described.

Suggestions from our readers respecting any improvement or addition which will increase the efficiency of the journal, will be always welcome, and receive consideration, and we ask our subscribers to introduce "Science" to their friends, and to forward us names of those who in their opinion would desire to receive a sample copy.

We are gratified to find that heads of schools and other representatives of the intelligent classes are sending in their subscriptions, and recognizing "Science" as one of the highest educational journals in this country. The United States Commissioner of Education at Washington has expressed his high approval of the journal in this respect, and we hope to find it in the hands of all men interested in the education of others.

Our subscription list now includes Principals of Schools, Professors in Colleges and Universities, Pastors, Physicians, Manufacturing Houses; and we claim that no person of average intelligence should fail to read "Science," for he will find it a valuable and useful weekly journal, and when bound, a standard work of reference for all time.

An esteemed contemporary calls for a scientific journal, "such as the great body of intelligent people will admit with confidence to their homes." "Science" certainly fills this *role*. The editorial conduct of this journal has been based on a policy to admit the widest discussion of all current scientific subjects, but no editorial bias has been given to any particular set of views. The editor has not himself indulged in polemics, nor permitted the discussion of religious questions, believing that the ground covered by investigations of all branches of the sciences, is sufficient for one journal to cultivate, and that aimless attacks on religious belief are foreign to the purpose of a scientific journal, and inconsistent in a country where religious liberty is guaranteed to all.

At the moment of going to press, a copy of Mr. S. E. Cassino's International Scientists' Directory came to hand. We have, therefore, only time to take a glance at the book, which is a handsome work of 400 pages, containing the names, addresses, special department of study, etc., of those engaged in scientific investigations in America, Europe, Asia, Africa and Oceanica.

About 18,000 names and addresses are given, and the general arrangement of the work is all that can be desired. The Directory will be welcome to all engaged in scientific work, and we trust that it will be strongly patronized, and thus enable Mr. Cassino to continue his good work, which is still far from complete; although so many names are given in this directory, it clearly represents only a fraction of the whole list of scientists, as such well known names as Professor R. O. Doremus and Professor J. W. Draper, are omitted.

We have no doubt that Mr. Cassino has done his best to make his Directory complete, and we congratulate him upon his success, and it simply rests with scientific men to aid him in making future editions perfect.

On receipt of two dollars we will mail a copy of the International Scientists' Directory to any address in the United States or within the postal union.

THE DEVELOPMENT OF HEAT BY MUSCULAR ACTIVITY.

By Professor A. Fick, of Würzburg.

It is the object of physical science in the proper sense of the word, to perceive in all the phenomena of nature the operations of the *same* forces, with which any two material particles always act upon each other, when they come in contact with each other in the same relations. This object has never been so clearly seen by the majority of naturalists, as during the last decade. Since that time a law already proved in mechanics has been recognized as one applicable to all the events of nature. It is called by Helmholtz, who in a treatise which appeared thirty-one years ago, first demonstrated its universal importance, the "law of the preservation of power"; recently the designation "law of the preservation of energy" has also been brought into use by English men of science. The amazing productiveness of this fundamental law of the operation of all natural forces essentially consists in the fact that from it may easily be derived experiments for testing results even in natural phenomena, in which in detail the nature of the acting forces is wholly concealed.

Therefore it could not fail to happen, that since this time individual investigations in the most varied departments of physical science have principally turned upon this fundamental principle. It now seems to me that the results of such individual investigations, which are connected with the most universal points of view, might be best adapted to secure interest even outside the circle of the scientists. In this opinion I will venture to claim the attention of the readers of this publication for some general observations connected with an experiment made by me a short time ago, and elsewhere communicated to persons familiar with such matters.

Each individual can experience in his own body at any moment, that with the aid of his muscles he can conquer opposing forces and set masses in motion. The former happens, for instance, when we lift a burden or throw the whole weight of the person upward in climbing a mountain; the latter occurs when we hurl a stone or swing a hammer. The principle of the preservation of power now demands that, where we see forces conquered or masses moved, necessarily powers on the other side have "acted" or performed labor, that is, that the points of assault of forces have been displaced. This, for instance, is clearly apparent in the voluntary fall of a heavy body. It is the point of attack of a power directed downward, namely weight, and as under the influence of this power it moves downward, its velocity increases; or when in a wavering balance one scale with its burden ascends—its weight is conquered—but the other sinks and its weight performs a certain amount of work. So if by the mediation of muscular action we see forces conquered or masses moved, it must be asked: what powers have acted or performed the labor here, that is, have changed their points of attack in their action.

Forces which, for instance, like weight, act upon larger bodies in a similar manner, will not of course be alluded to here. The point in question can only concern powers that operate even among the smallest particles of muscular substance, that is chemical powers of attraction. Something must take place in the muscle similar to what occurs in the steam-engine, when in the act of combustion under the boiler the particles of carbon and oxygen, obeying their strong reciprocal power of attraction, rush towards each other, makng violent little movements, and a portion of this energy, by means of a series of shocks, is applied to the conquest of opposing forces, or to accelerating the speed of bodies. So in the muscle, during its activity, chemical processes evidently take place, with which powerful kindred forces come into action. That this is really the case can be shown by experiments. Singularly enough, it is not only an analogous, but for the most part at any rate precisely the same chemical power of attraction which performs the work in the active muscle and in the steam-engine, namely the power of attraction between the particles of carbon and the particles of oxygen. The product of the operation of this power of attraction, carbonic acid, appears in a certain quantity at every act of muscular motion.

In all the examples, in which, by the mediation of any arrangements, through whose operation the action of chemical powers of attraction, taking place even in extraordinarily small distances, accelerates the movement of bodies, or overcomes mechanical forces, like weight, a general remark may be made, which has hitherto been everywhere confirmed by experience. The lines of communication between the particles undergoing a change by means of a chemical process are usually irregularly distributed in every part of the space. The movements arising from the individual processes of change are, therefore, also irregularly driven in all directions, and thus can never be applied in their full strength to overcome an opposing force acting in a fixed direction, or to accelerate the speed of a body, whose particles are all moving in the same direction. Only a portion of this collected energy of motion can appear in such a form. A fraction, greater or less, according to circumstances, of the sum of the individual processes of change must retain its original form of the irregularly whirling movement of the tiniest particles. This conclusion may, therefore, be briefly expressed thus: wherever in a chemical process the power of attraction of the smallest particles of different substances performs labor—no matter under what circumstances this may occur—a portion of the labor will always be employed in the development of *heat*.

The *heat* contained in a body is, therefore, nothing else than the energy of slight invisible irregular whirling movements, in which the tiniest particles of the body are included. To increase the temperature of a body, therefore, is merely to increase the energy of these irregular molecular movements of the smallest portions. This view instantly finds support in the common phenomenon, that at the increase of the temperature of a body above a certain degree its particles in consequence of the colossal energy of motion really pulverize each other—"the body evaporates."

If this view of heat is correct, a certain degree of heat can be produced by a certain amount of work. The proportion of work, or the operation of a power is, as is well known, the product of the intensity of the power and the distance through which it has acted. Therefore the product of the unit of the intensity of the power, the *kilogram*, and the unit of the distance, the *meter*, is chosen as the unit of this power. This unit of the value of the work is called the *kilogrammeter*. As the unit of the quantity of heat the same degree has been fixed that is required to be supplied to a kilogram of water, when its temperature is to be raised from 0° to 1° of the Centigrade.

Natural philosophy has now succeeded—and it is one of its most important achievements—in showing, that for the production of a unit of heat an expenditure of work of 425 kilogrammeters is requisite. This number is called the *mechanical equivalent* of *heat*, because it is thereby possible to calculate each quantity of heat in a certain number of mechanical units of work, which is requisite for its production.

The knowledge of the mechanical equivalent of heat enables us to measure exactly the work performed by any chemical process of kindred forces operating even at immeasurably little distances, although we know nothing at all of the laws of action of these forces in detail. In fact, we need only direct the process, so that no effect is produced except the development of heat. If we then measure the heat developed and multiply the number of units found by 425, we shall have the labor which the chemical powers of attraction have performed in the process, expressed in kilogrammeters, since according to the

supposition the whole operation of this labor consisted exclusively in the development of heat. The burning of one kg. of coal may serve as an example; if no other effects are accomplished, about 8000 units of heat will be released. The work which the kindred powers between the atoms in one kg. of coal and the two-fold number of atoms of oxygen accomplish in their union into carbonic acid, thus amounts to 8000 x 425 or 3,400,000 kilogram-meters. From this an idea may be formed of the prodigious intensity of the chemical power of attraction between an atom of carbon and an atom of oxygen. The force with which the particles of carbon, amounting only to one kg., rush from a very little distance to the corresponding particles of oxygen in burning, is precisely as great as when a body weighing 3,400,000 kilograms falls from a height of 1 m.

Let us go back with these axioms from natural philosophy in general to muscular action. If, as was shown, there are chemical powers of attraction, whose operation or performance of labor produces mechanical effects which are externally perceptible, besides these, heat must also proceed from every muscular action. This proposition, which we here bring forward as a conclusion from the most universal lessons of the action of powers, has already long been acknowledged as a principle derived from experience.

It was by no means easy to prove this proposition. To be sure, it is rendered extremely probable by the daily experience, that our bodies are perceptibly heated by great muscular exertion, and give off more heat than during the same time with the muscles at rest. But this does not afford an accurate proof. It might be represented that the excessive activity of the muscles only afforded increased opportunity for heat-producing combustion in other constituent parts of the body, for instance in the blood. An exact proof can, therefore, only be given by putting in action a muscle severed from connection with the rest of the body, and proving that heat is developed therein. Such experiments can, of course, only be made on the muscles of cold-blooded animals, because those of the warm-blooded, when separated from the body, lose their vital properties too quickly.

The first person who made such experiments and has shown an increase of temperature, that is a development of heat in *isolated* muscles by action, was *Helmholtz*. This fundamental fact could not fail to attract great attention, and make people endeavor to ascertain what circumstances had an influence on the greater or less development of heat by muscular action. The most important labors in this direction proceeded from *Heidenhain's* laboratory. He has especially much improved the thermo-electric system, which alone can be used to ascertain the increase of temperature of the muscles. With the aid of this system one can distinctly perceive even the extraordinarily slight increase of temperature, which a little frog muscle undergoes at a single, by no means energetic, movement, that scarcely amounts to $\frac{1}{1000}$ of a Centigrade. In successive experiments it can even be determined, in which *more*, and in which *less*, heat was developed, but until now the system has not been thoroughly adapted to fix the absolute value of the increase of temperature.

Some time ago I succeeded in so changing the thermo-electric apparatus, that it is possible, by its means, to fix with some degree of accuracy, the increase of temperature a muscle experiences in its action. Thereby the possibility was instantly afforded, of stating in the usual units the quantity of heat developed by the muscular action. This quantity of heat is namely, evidently, the increase of temperature multiplied by the capacity for heat of the proportion of muscle used, which latter is assumed to be about equal to $\frac{9}{10}$ of the capacity for heat of a body of water of equal size.

According to a general observation previously made, the whole labor performed in the muscular act by chemical powers of attraction can now be definitely determined. For this purpose it is only necessary to allow the muscular action to pass away, so that finally no sort of mechanical effect remains; then, since every labor of forces must leave an effect, a quota of heat will exist that will be the exact equivalent of the work performed by the chemical powers. The condition just expressed may be fulfilled by simply letting the muscle, in its action, raise a weight; but allowing this to fall again, so that it pulls the muscle which meantime has relapsed into a state of rest. In so doing the work performed by the weight of the falling body will evidently be used for the development of heat in the apparatus. To be sure, it might now be asked, in what portions of the whole machinery used, this amount of heat is developed. Theoretically it is beyond doubt, that a portion of it is set free in the intermediate pieces, which connect the weight with the muscle, especially by the friction at the points of union, but since these intermediate pieces are practically non-ductile, and the friction at their points of union can only be very slight, it may be assumed from the beginning, that the quota of heat in question is almost entirely released in the body of the muscle itself, which, by its extreme ductility, receives, so to speak, almost entirely the shock of the falling burden. This supposition is so probable, that in the exact scientific publication of the result of my experiments, I have pre-supposed it as a matter of course. Meantime I have made experiments in my laboratory, which render this supposition one empirically shown.

The experiments have been made in the following manner. A body of known weight fastened to the muscle was raised, not by its own action, but by other labor to a measured height and then allowed to fall. The increase of temperature experienced by the muscle in consequence of the jerk was now measured, and by multiplication with the capacity for heat of the muscle, the quantity of heat developed in the muscle was ascertained. It usually corresponded in a really surprising manner with the thermic equivalent of the mechanical labor, which was applied to raise the appended burden. This affords the proof, that the heat produced by such a jerk is liberated almost entirely in the *muscle*, and only very inconsiderable fractions are developed in the other portions of the machinery used. Every such experiment can thus be looked upon as fixing the mechanical equivalent of heat, which, of course, in point of accuracy, falls far behind the purely physical tests, but is worthy of notice because a living tissue is the means of ascertaining it. To us, however, the interest of these experiments consists in the fact that they prove the reliability of the system used to fix the heat of the muscles.

Let us now return to the development of heat by *active* muscular action, and consider more closely the numerical product of an accurate experiment. That in the estimates of the quantities of heat, and afterwards the value of labor too, many ciphers may not appear immediately behind the comma, we will base them upon units a million times smaller. So, for the unit of heat, we will take the quantity of heat necessary to raise the temperature of 1 mgr. of water from 0° to 1°. As the unit of labor we will choose instead of the kilogrammeter the grammillimeter. The equivalent proportion, therefore, remains unchanged—425. For an experiment a body of muscle weighing 3114 mgr. had lifted in ten pulls, rapidly succeeding each other, a burden of 500 gr. 10 times, and the latter had fallen again as many times, so that at last it hung no higher than at first. The temperature of the mass of muscle was increased 0,0195° by this act. Now, since 3114 mgr. of muscular substance possesses exactly as much capacity for heat as 2803 mgr. of water, the increase of temperature which followed, required $2803 \times 0{,}0195 = 54{,}6$ units of heat. But in our experiment the production of this quantity of heat is the *only* effect of the work accomplished by the chemical powers of attraction in the muscular action. It must, therefore, ex-

pressed in the measure of labor, have amounted to 54.6×425, that is 23205 grammillimeters.

The chemical process, which takes place in muscular action is, it is true, by no means accurately known in the individual stages of its course; but as a whole, it undoubtedly consists in the combustion of a body free from nitrogen, whether fatty or saccharine, to carbonic acid and water. The numbers obtained, therefore, afford us a point, by which to determine what quantities of the above mentioned materials must be consumed in a muscular contraction. We know, through *Frankland's* researches, that in the consumption of 1 mgr. of sugar the chemical powers of attraction perform as much work a is necessary to produce 3800 units of heat. Now, since in the ten contractions of our experiment, 54,6 units of heat were produced, an expenditure of material of $5{,}46 \div 3800 = 0{,}014$ mgr. would have been necessary, under the supposition, that the combustible material was a saccharine body. Let us suppose that the combustible material is a fatty body, then a still smaller expenditure would be sufficient, to produce the effect observed, namely, $54{,}6 \div 9000 = 0{,}0067$ mgr., because 1 mgr. of fat, according to the estimates of the investigator just mentioned, supplied in its combustion, 9000 units of heat. So, for one contraction the combustion of 0,0014 mgr. of sugar, or of 0,00067 mgr. of fat, would have been requisite. If we divide this number by 3.1 (the weight of the quantity of muscle used in grams) the result will show how much material must be consumed at *one* energetic contraction in a gram of muscular substance, that is 0,00045 mgr. of a saccharine, or 0,00022 of a fatty combination. So it appears, that for 1000 energetic contractions not quite 1 mgr. of combustible material in each gram of muscle is requisite, and, therefore, it can no longer surprise us, that only very small quantities of the actual combustible material are ever found in the muscular substance, the greater portion of which, as is well known, really consists of very different materials, principally of substances like the white of an egg.

The results obtained with the new systems can be applied to the decision of the question, what portion of the work performed by chemical powers in the active muscle, can, in the most favorable cases, produce mechanical outward effects. The closest interest in this question might be designated as an "economical" one. In fact, the real object of the animal subject in muscular activity is the production of mechanical effects in the surrounding universe, and one might denote the portion of the work accomplished by chemical powers, which is applied to the mere production of heat, as an inevitable loss from the point of view of animal economy. At any rate, one will have the more reason to admire the judicious arrangement of the muscular substance, which can apply a larger portion of the chemical labor performed in it to external mechanical results.

It is precisely the same as in the steam-engine, whose construction we also call the more perfect, according to the larger portion of the work performed by the chemical powers of attraction in the burning of the coal it allows to be used to produce mechanical effects. In spite of the most eager efforts of technics hitherto no attempt has been successful in making more than $\frac{1}{10}$ of this labor mechanically effectual. Fully $\frac{9}{10}$ are lost to the objects of the machine, by being inevitably employed in the production of heat, which at the utmost can only be used for minor purposes, such as the heating of rooms and similar objects.

If it must now be ascertained, how the muscle is situated in this respect, it is only necessary to fix, by experiment like the one above described, what mechanical effect has been accomplished in a given time, and compare this measured in the proportion of work, with the chemical labor calculated by the heat produced. It will be advisable to pay special attention to the fact, that the heat finally developed would be less by a corresponding amount, if the experiment had been so arranged, that the mechanical effect, that is the raising of the weight, had been maintained. The quantity of heat corresponding with this effect was first released in the muscle by the falling of the burden again.

By the 10 contractions of the foregoing experiment 500 gr. were raised on an average about 1.3 mm. high. Thus the mechanical result amounted in the whole to 6,670 grammillimeters. The work performed by chemical powers of attraction in the 10 contractions we have found above—23,205 grammillimeters. This number is about $3\frac{1}{2}$ times 6,670. Thus, by these contractions, somewhat over $\frac{1}{4}$ of the whole chemical labor was applied externally and not quite $\frac{3}{4}$ to the direct production of heat. That in the actual experiment this quarter was also finally converted into heat, depended merely on the external arrangements, which permitted the burden raised to fall again each time.

We see by this, that—as was to be expected—the muscle machine is very superior to even the most perfect steam-engine, in so far that it *can* employ the combustible material twice as frugally for the same main object.

Besides, this relation between mechanical action and development of heat is by no means obtained at *every* muscular contraction. I have intentionally selected from my experiments as an example, the one in which the mechanical labor amounts to the largest fraction of the whole chemical labor. To obtain this most favorable proportion, the burden must stand in a certain relation to the thickness of the muscle. If the burden is larger or smaller, a smaller portion of the chemical work will be used for mechanical action, or—as it might be expressed—the combustible material will be less economically used. This proposition may be demonstrated *a priori*, for it is easily seen, that in the two extreme cases, where the burden is a cypher or infinitely great, chemical work is performed and heat developed, but no external mechanical action is obtained.

The solution of the question, in what relation the mechanical action for the development of heat can stand, under the most favorable circumstances, towards the muscular contraction, enables an observation to be made which throws new light upon the change of substance in animal bodies. As is well known, the change of substance in animal forms may be designated in general as a process of combustion. In reality, a certain quantity of combustible nutritious matter daily enters into the fluids, and a corresponding quantity of oxygen is taken in with the breath. On the other hand, every day on an average, a precisely similar quantity of substances is withdrawn, whose combination is to be regarded as the product of an almost total combustion of the nutritious matter. The condition of the body with this equal balance between receipts and expenditures, remains for a long time apparently unchanged.

With the formation of the product of combustion from the assimilated nutritious matter and the inhaled oxygen, the colossal power of attraction of this element for the elements of the nutritious matter, especially for the carbon and hydrogen gas, now performs a fixed amount of labor, which is independent of where the combustion takes place, and whether it occurs at once or in various stages at various places.

People were formerly inclined to suppose, that the greater portion of the combustion in question occurs either in the fluids themselves or in special organs, such as the liver, the kidneys, etc.

Since the changes occurring in animal bodies have begun to be viewed from the standpoint of the principle of the preservation of power, it must be looked upon as a self-evident truth, that at least a certain portion of the assimilated nutritious matter passes into the muscles, to be first consumed here, since from the point of view of that principle, the mechanical performance of the muscles can only be understood as the action of the labor of the

chemical powers of attraction, as we have done in the preceding discussions. The question may now be raised, how large a fraction of the whole combustion takes place in the muscles, and how large a fraction in the other parts of the body? The distribution of the process of combustion in the different places might, therefore, be accomplished in two ways. One part of the material might be consumed entirely in the muscles, the other entirely elsewhere, or certain stages of the combustion of the whole material might take place in the muscles, and other stages in other places. However this may be, as it is supposed that a considerable portion of the combustion takes place outside of the muscular substance, it must be expected that, under all the circumstances, far more than $\frac{3}{4}$ of the whole heat of the combustion of the assimilated nutritious matter in animal bodies appears as heat, and only the equivalent of far less than $\frac{1}{4}$ is available for mechanical labor. For, as we saw, even under the *most favorable* circumstances, about $\frac{3}{4}$ of the chemical work performed in the muscle itself is inevitably used for the production of heat. But under these most favorable circumstances, however, probably *all* the muscles do not take part in the labor of the whole body. Therefore, in the acts of living beings we must assume that more than $\frac{3}{4}$, probably $\frac{4}{5}$ of the result of the work performed in the muscles by chemical powers, finally appears as heat. Now, if the material coming into the muscles for combustion should be even a moderate portion, for instance $\frac{1}{3}$ of the whole assimilated nutritious matter, while $\frac{2}{3}$ was consumed elsewhere, then $\frac{14}{15}$ of the chemical work performed by the whole combustion is used for the mere production of heat, since $\frac{2}{3}$ of the labor accomplished outside of the muscles can have only the result of producing heat, and of the third coming from the muscle, $\frac{4}{5}$ will also produce mere heat. So, under this supposition, it must be expected, that at the utmost the equivalent of $\frac{1}{15}$ of the heat proceeding from the combustion of the nutritious matter would be available for the mechanical effects of the organism, externally.

It is already more than twenty years since Hemholtz, by very convincing arguments, proved from facts known at that time, that in seasons of extreme muscular labor, for instance, climbing a mountain, the measureable mechanical performances of the whole organism are proportionally considerably greater. They are equal to the equivalent of about $\frac{1}{5}$ of the heat of the consumption of the material that burns during the time of these performances, in the whole body. Unless the supposition is now made, that the muscles of mammalia can work incomparably more economically than the muscles of the frog—a supposition wholly unjustified by our knowledge of the properties of the muscular substance in the different bodies of animals—we must conclude that, in times of extreme muscular activity, the whole process of combustion takes place in the muscles and the chemical processes going on in other parts can only be those in which the chemical powers of attraction accomplish no considerable labor. In fact, from the results of our experiments concerning the heat of the muscles we have inferred, that by the chemical labor performed in the active muscles themselves in the movements of living beings, fully $\frac{4}{5}$ is employed in the production of heat; but if chemical labor was performed in other parts of the body, whose whole result could be only a purely thermal one, more than $\frac{4}{5}$ of the chemical labor performed in the whole body must go to the production of heat, and less than $\frac{1}{5}$ would remain for mechanical external actions.

If it is once proved, that in times of extreme muscular action the processes, by which the chemical powers of attraction perform labor, take place almost exclusively in the muscles, a similar performance will occur even in times of comparative muscular rest; for otherwise it must be supposed, that the change of substance during the period of rest takes a totally different direction from that during the time of muscular activity, which is scarcely conceivable. Yet it must be supposed, that in animal bodies a certain kind of combustible material is prepared for the machinery of the muscles, for which in other portions the conditions of combustion do not exist, as coke cannot be burned in a stove arranged for wood. We shall, therefore, be compelled to suppose, that the process of combustion, which renders muscular labor possible, glimmers continually in this texture even in times of rest, only with so little strength, that there is no mechanical action, and only heat is produced.

There is a very note-worthy harmony between this inference and an assertion made by Pflüger and some of his pupils on the basis of very different facts, which is, that in the muscles, even during periods of rest, processes of combustion occur, which are under the influence of the nervous system; they can be kindled to considerably higher degrees of intensity, before attaining the point requisite for the purpose of a visible mechanical action of the muscle. The increase in the department of these lower degrees of power would, therefore, lead only to an increase of the production of heat, and according to the well-founded hypothesis in question ought to explain the fact, that the development of heat in animal bodies can exist under conditions of the loss of heat externally.

From all this one would form the following idea of the course of the chemical processes, by which the assimilated nutritious matter is transformed into the rejected matter. The nutritious matter enters into the blood, the liver, and other places only during the chemical processes in which the chemical powers of attraction either perform no considerable work, or in which as many chemical powers of attraction are conquered as come into positive action. These may be partly synthetic performances, partly disunions. Above all, it must be supposed that the greater portion of the nutritious albumen undergoes, directly after its reception into the fluids, a process of this nature, in which a body containing nitrogen is separated, that soon leaves the body under the form of urine. The remnant of the nutritious albumen, free from nitrogen and the other nutritious matter rich in carbon and hydrogen, is then supplied to the muscles as combustible material, perhaps loosely united with the oxygen received by the breath. In action, however, the vast powers of attraction between the atoms of oxygen on one side and the atoms of carbon and hydrogen on the other, first enter into the muscular tissue, whereby in the formation of carbonic acid and water, partly heat and partly mechanical effects proceed.

I should consider the object of these lines attained if I succeeded in showing how a few insignificant thermometrical experiments in frogs' muscles are capable, from the point of sight of the principle of the preservation of power, of casting a new light on all the particulars of the nourishment of the human body.—*Translated from "Deutsche Rundschau," by M. J. S.*

DR. T. S. COBBOLD exhibited (at the Linnean Society's meeting, November 5) under the microscope about a hundred eggs of *Bilharzia hæmatobia*. They were taken from a gentleman who had just arrived from Egypt, and who was the victim of hæmaturia, supposed to have been contracted during a shooting expedition. By adding water nearly all the eggs were hatched during the meeting of the society, and a rare opportunity was thus afforded of witnessing the behavior of the newly-born ciliated animalcules.

DONATION TO AID SCIENCE. Mr. Charles Crocker has made the very handsome donation of $20,000 to the California Academy of Sciences, the income of which is to be devoted to aid worthy and studious investigators in any branch of science, who, by their scientific work, have excluded themselves from acquiring support through the ordinary avocations of current industrial life.

M. PAUL BERT, the new French Minister for Public Instruction, is said to be a candidate, in the section of Medicine, to fill the place vacated in the Academy of Sciences by the recent death of Dr. Bouillaud.

EXPERIMENTS OF M. BJERKNES.

"INVERSE" IMITATION OF ELECTRIC AND MAGNETIC BY HYDRO-DYNAMIC PHENOMENA.

It must be confessed that absolutely nothing is known of the real nature of electricity. The principle of the conservation of energy and that of the unity of physical forces, which tends to simplify the phenomena and embrace them under one common term, for want of a clear and precise definition lead us to consider electricity or rather electric phenomena, as a *mode of movement*. This conception removes the difficulty, simplifies the question, but does not resolve it. The mode of movement, once admitted, forcibly compels the abandonment of the idea of *fluid*, which always accompanied electric phenomena at the outset of their study.

If we are agreed to-day upon the immateriality of electricity, we are, on the other hand, far from understanding the nature of the special mode of movement which characterises electricity, the word being taken in its most general acceptation.

In his *Recherches sur l'électricité*, M. Gaston Planté expresses his ideas on this point in the following words: "Electricity can be regarded as a movement of *ponderable matter*—movement of *transportation* of a very small mass of matter incited with very great velocity, if the question is of the electric discharge, and a very rapid *vibratory* movement of the molecules of the matter, if the question is of its transmission to a distance under the dynamical form, or of its manifestation under the statical form at the surface of the body."

For some, who are much less precise in their definitions, electricity is produced by *molecular movements*, without otherwise determining its nature, characterised by form, direction, velocity, periodicity, &c.

In the experiments about to be described, M. Bjerknes proposed to throw light upon the question of the nature of molecular movements, by reproducing *mechanically*, but INVERSELY, simple and fundamental electric phenom ena

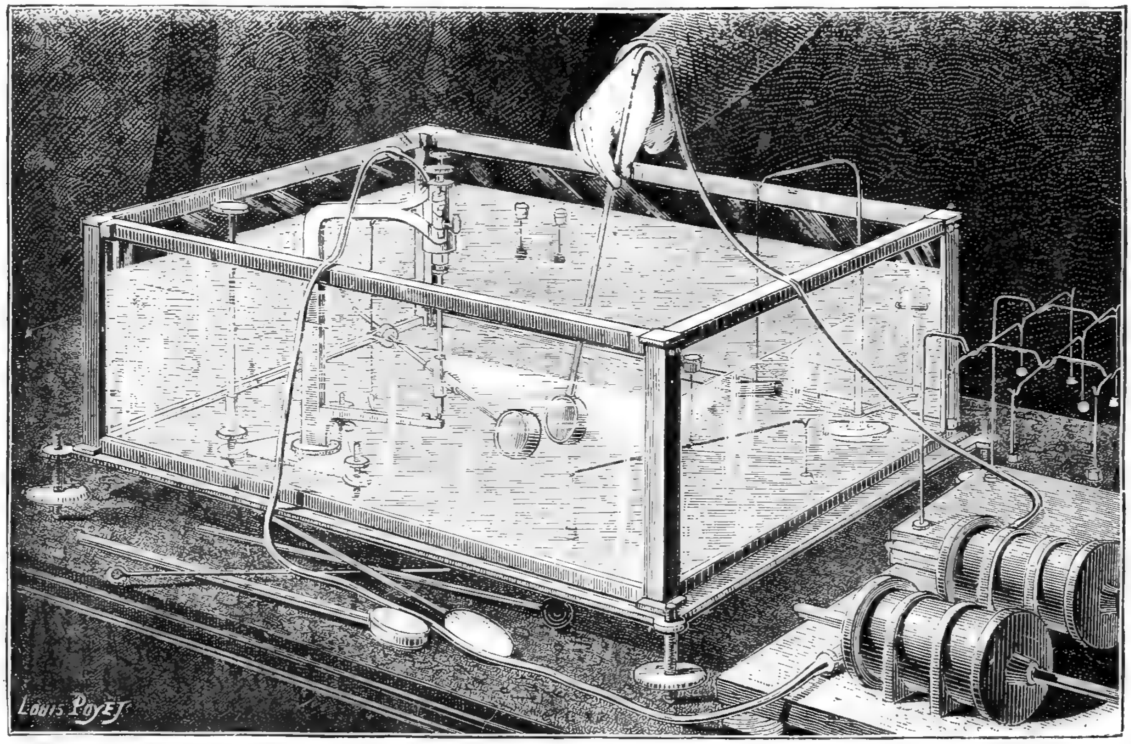

Fig. 1. Apparatus of M. Bjerknes at the Electrical Exposition.

M. Bjerknes designates under the general name of *vibration*, the movements which take, according to their nature, the name of *pulsation, oscillation*, etc.

Pulsation has reference to the change in volume. It includes two phases, one, in which the body swells, the other in which it shrinks. Pulsations are *synchronous* when the phases commence simultaneously.

Oscillation has reference to the change in place, it is an alternative displacement to the right and to the left.

M. Bjerknes mechanically obtains pulsations in water by the aid of a very ingenious apparatus.

The *pulsations* are produced by small cylinders stopped at their ends by flexible walls. A small hand pump which is partly shown on the right in fig. 1, is employed to exhaust and compress alternatively the air in the cylinders provided with flexible walls, at a great velocity.

In the simplest pulsator, the two walls dilate and contract at the same time under the action of forcing the air from the pumps, the phrases are synchronous (fig, 2. No. 1). In another arrangement, the two drums are separated by a rigid wall, which forms two chambers each in connection with a separate pipe conducting the air (fig. 2, No. 2). We have thus a most complete system, for by adjusting conveniently the tubes of the air-pump for exhausting and filling, synchronous pulsation can be produced at will, as in the first case, or pulsation in which the phases are alternate.

Oscillations are produced by means of small metallic spheres bound to supports, upon which they oscillate, under the action of compressed air, in a plane which varies with the position of the sphere.

Fig. 2 (No. 3) represents two of these oscillators, the sphere on the right oscillating vertically up and down; that on the left, on the other hand, oscillates horizontally from right to left.

This is the very simple and well constructed apparatus which M. Bjerknes employs. Now we come to the phenomena.

First two pulsators are taken and made to vibrate. The phase of dilation, according to M. Bjerknes, correspo ds

to the north pole, the phase of compressing to the south pole. Now bring to one of these pulsators which can turn freely around a vertical axis which acts as its support, while allowing the vibration to continue, a second pulsator held in the hand.

If we put in juxtaposition, in the liquid, the two pulsators whose phases are of the same kind, synchronous, poles of the same name will always be in juxtaposition, there will be *attraction*, the movable pulsator turning on its axis, will tend to approach the pulsator held in the hand by the experimenter, and it will follow it if it is moved. If the phases are changed, so that they are inverse, opposite poles will be together, and there will be *repulsion*. In the one case as in the other, the attractive or repulsive force is proportional to the intensity of the pulsations and inversely proportional to the square of the distances. In both cases, the hydro-dynamic effect is the reverse of the magnetic effect: similar phases attract (poles of the same name repel each other), different phases repel (opposite poles attract).

The same experiment is repeated with the oscillators (Fig, 2, No. 3); by presenting to a vibrating sphere, movable on an axis, a second vibrating sphere, attraction or repulsion is produced according to the synchronism or the discordance of vibration, which the parts of the sphere in juxtaposition present at each instant.

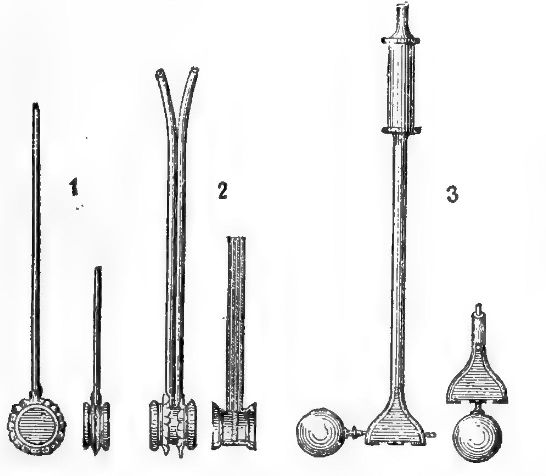

Fig. 2. Apparatus for reproducing pulsations and oscillations in a liquid.
1. Simple drum. 2. Double drum. 3. Sphe es.

For these phenomena, the arrangements for which can be varied, M. Bjerknes has a collection of apparatus almost complete, representing inverse analogies to the phenomena of the reciprocal action of two permanent magnets. A result similar to the action of a magnet on a piece of soft iron can be obtained. By presenting, in the water, a small metallic sphere to a pulsator, or to an oscillator, the small sphere will be attracted.

The effects of *diamagnetism* are shown by means of a small sphere lighter than the water, maintained at the middle of the liquid by a thread attached to a weight which ballasts it. By bringing a pulsator or an oscillator near this sphere, the latter will be repulsed.

From these experiments, and from others the details of which cannot be given, M. Bjerknes concludes that the motion in water of a vibrator (pulsator or oscillator) produces in this fluid a real magnetic field with its lines of force, presenting, *but always inversely*, phenomena similar to those of diamagnetism, paramagnetism, magnetic interference, etc.

M. Bjerknes has even succeeded in tracing the directions of the lines of force produced in the liquid, by means of the arrangement shown in fig. 3. For this a light bowl sustained by an elastic rod is placed in the middle of the liquid; this bowl having no motion of its own will take exactly the direction of the oscillation of the ambient medium. If it is surmounted by a small brush, the latter will paint faithfully and automatically on a sheet of glass the lines of force of the field under the influence of which it oscillates.

M. Bjerknes commenced by submitting all these questions to analysis, and the results of his experiments are only the rigorous confirmation of his calculations. In that which concerns the analogy between the electric currents and hydrodynamic action, M. Bjerknes recognized that the question is not as advanced as in magnetic phenomena.

In order to produce more complex movements, the vibrators are no longer suitable. M. Bjerknes attempted to realize them in a viscous liquid, and striking analogies were found between the lines produced by hydro-dynamic phenomena under these conditions and the lines obtained by real currents under corresponding conditions, but the results obtained are not accurate enough to enable one to form an opinion.

What now can be concluded from the experiments of M. Bjerknes? The fact indisputably established is as follows:

Mechanical vibrations produced in a liquid medium cause phenomena analogous, but *inverse*, to the magnetic

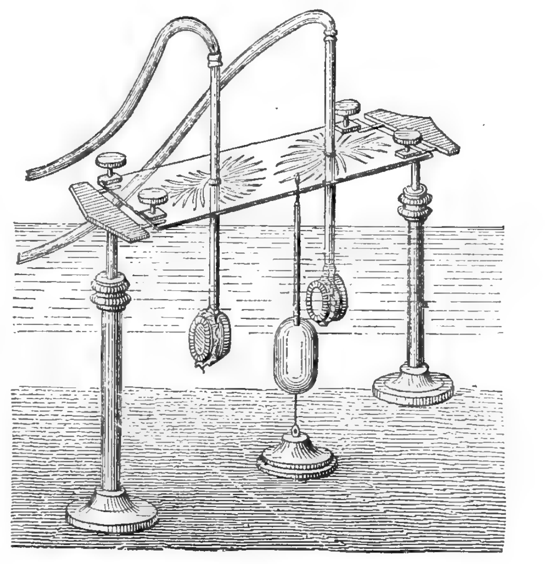

Fig. 3. Apparatus of M. Bjerknes for tracing automatically the lines of hydro-dynamic force.

phenomena produced by magnets. From this can be concluded, by *analogy*, but not *absolutely*, that molecular vibrations of a different nature can produce *direct* phenomena.

If this is not a new *proof*, in the exact meaning of the word, of the *vibratory nature* of magnetic and electric effects, it is at least a powerful argument applied to this view, accepted at the present time by most physicists.—*Translated from La Nature.*

M. PLATEAU describes as "*un petit amusement*" the following experiment:—a flower like a lily, with six petals each about an inch long, was constructed in outline in thin iron wire, the wire being first slightly peroxidised by dipping for an instant into nitric acid. This wire frame was then dipped into a glyceric-soap-solution, which, when it was withdrawn, left soap-films over the petals. The stalk was then set upright in a support, and it was covered by a bell-glass to protect it from air-currents. In a few moments the most beautiful colors made their appearance. If the solution is in good condition the films will last for hours, giving a perpetual play of color over the flower.

SHALER AND DAVIS' "GLACIERS."

By W. J. McGee.

(*Continued from page* 584).

VII. *Ancient glacial periods.*—Since the records of glacial phenomena are mainly such as are likely to be obliterated by succeeding geological mutations, it is needless to look for as unequivocal testimony of glacial periods as that attesting the occurrence of the last ice age. The principal evidences we can hope to obtain are (1) tide-washed boulders, gravel, and sand, (2) erratics dropped from icebergs in the deeper sea deposits, and (3) paucity or absence of organic remains, or possibly fossil forms suggesting low temperature; and it is to be expected that such evidence will become constantly less explicit as the geological record is traced backward.

Anterior to the Quaternary ice period, we first come upon evidence of a Miocene glacier, well marked in the hill of Superga, near Turin; from which evidence it may be inferred that the European continent underwent a very severe glaciation in Miocene times. Next follows the Eocene, in which the Flysch of Eastern Switzerland, formed of conglomerates containing immense boulders, supposed to be derived from worn-down mountains of the Vosges or Black Forest, eloquently attests vigorous ice-work; while "in North America we can almost mark the line of the ice by the limit of the destruction of the Tertiary beds" (p 95), and are hence without so characteristic ice deposits. The Cretaceous affords no evidence of glacial conditions save occasional iceberg-dropped boulders; but in the Jurassic are found the conglomerates of Northern Scotland and of the Connecticut Valley, which appear to be of glacial origin. The traces of Permian glaciers are unmistakable, and of almost world-wide extent, being found in Central England, in Scotland, in the Isle of Arron, in Ireland, in South Africa, and elsewhere. The rocks of Carboniferous age include conglomerates, probably of glacial origin, from Southern France to Scotland, from Alabama to New Brunswick, in India, and in other countries; from which it appears "that it extended ice action over a wider meridional range than any [periods] that have succeeded it" (p. 98). There are then no beds certainly attesting ice-work until the base of the Cambrian is reached, when the extensive Ocoee conglomerates and Chilhowee sandstones, and lesser deposits of like character at Roxbury, Mass., and elsewhere, are found. In many of the foregoing cases the associated beds indicate warm or subtropical climate, as should happen according to Croll's theory.

VIII. *The climatal conditions of the glacial periods.*—There is no reason to believe that ice periods were ever of particularly low temperature. On the contrary, the Quaternary fauna was characterized by the great size of its individuals, and clearly proves the contemporaneity of a luxuriant flora, such as could not exist in arctic cold. Moreover, there are abundant proofs, that this glacial period was a time of much greater rainfall than the present. Accordingly several glacial hypotheses may be summarily dismissed. That of Poisson is qute untenable. It is questionable whether that attributing climatal oscillation to variation in the constitution of the atmosphere should be admitted to have weight; though effects resulting from such a cause would be cumulative. Croll's theory is found to harmonize strikingly with the observed facts; There is the last period of high eccentricity occurring at the proper date for the Quaternary ice age; there are the numerous successive inter-glacial periods corresponding with the alternate advances and retreats of the ice; and there are the brief epochs of warm climate, represented by luxuriant floras and vigorous faunas. On the other hand, however, there are the objections that some minor factors may possibly have been overlooked in framing the theory; that there are vast ages without evidence of glacial action, as should not occur, according to the theory, since "the eccentricity of the earth's orbit is such a constantly recurring phenomena" (p. 107); that the Antarctic glaciers are not advancing, but that all observations "lead us to the conclusion that the ice there is as much in process of retreat as it is in the Northern Hemisphere" (p. 107); and that, the hypothesis assumes essentially the same outline for Cape St. Roque during the glacial periods as at present. But none of these objections are fatal to the theory; the only question is as to its being a sufficient cause of anything so wide-spread as the continental ice periods. There are also elements of probability in the hypothesis of Le Coq, that variations in solar emissivity might produce glaciation; for augmented temperature would increase precipitation and lead "to an extension of the fog envelope which in all glaciated regions does so much to protect the ice from the sun" (p. 108); but on the whole, though this hypothesis has the advantage of ndefiniteness, it is entitled to less weight than that of Croll. Neither must the hypothesis of minor geographical alterations be overlooked, since it is perhaps possible that such changes may have occurred in such manner as to facilitate glaciation. The question, however, remains an open one, "and it is unsafe for the geologist to commit himself definitely to any of the hypotheses that have been suggested" (p. 110). There are half a dozen distinct and powerful causes, together with a number of minor factors, which co-operate to produce the singular uniformity of terrestrial temperature; and the only safe conclusion is that the earth's secular winters may be due partly or wholly to any or all these agencies.

IX. *Effect of glaciers on the altitude of the lands.*—Throughout northern regions there are evidences of considerable depression of the land during the glacial period; which depression in Europe was variable, and mainly confined to the severely glaciated area. "In America this depression has not been studied except along the Atlantic shore" (p. 113), where it increases from twenty feet near the southern limit of glaciation, to over two thousand feet in Greenland. The land appears to have remained below the normal level until after the withdrawal of the ice. Two hypotheses have been framed to account for this depression:—1st. That of Adhemer, which attributes the phenomenon to the dislocation of the earth's centre of gravity by a polar ice-cap, and which is based on the assumption of a rigid terrestrial crust. The depressions at various latitudes were not, however, of the relative value demanded by this hypothesis. 2nd. That of local deformation of a flexible terrestrial crust beneath the weight of the ice. This hypothesis is supported by the greater part of the evidence thus far collected; though it is likely that both classes of agencies co-operated in producing the effect. There is reason to believe, also, that a temporary upheaval of lands south of the ice-sheet occurred during the Quaternary; which upheaval was doubtless a concomitant of the local depression beneath the ice.

X. *The effect of glaciation on the life of the earth.*—During the growth of the ice-sheets there must have been a widely extending southerly migration of animals and plants, giving rise to individual and specific variation in consequence, not only of the change of habitat, but also of the crowding of individuals over the contracted habitable area; and the converse movements following the withdrawal of the ice must have been nearly as important biologically. The development and extinction of the hairy mammoth affords an illustration of the effects of secular winter on animal life. "In the closing stages of the glacial period we find him the most widely disseminated of all the large mammals that are known to us" (p. 119); his remains occurring alike over Europe, Asia, and America. "As we go back into the glacial time, we have fewer and fewer indications of the existence of this noble beast, yet we have remains enough to make out that he or his immediate ancestors existed at the beginning of that epoch, and that in all its stages he was feeding

in the rich forests that seemed to have flourished close to the walls of ice" (p. 119). In Europe, and perhaps in Asia and America he was a contemporary of man. In Asia, he dwelt in vast numbers on the plains of Siberia. "When he abounded there, the climate was * * * as cold as it is at present. The rivers in that country have their sources farther to the south than their main streams, so that the springtime sends down a torrrent of water before the more northern channels are released from their wintry bonds; the elephants seem to have herded together along these streams for winter quarters, * * * and to have been swept away to the north by the inundations. These freshets carried their bodies to latitudes where the cold was so great that they were frozen in the mud that wrapped them round and covered them to such a depth that the brief summer-times never melted their icy casing" (pp. 119-20). Some of these bodies remained undecomposed up to the time of their discovery in recent years; and their tusks yet occur in such numbers as to be of commercial importance. The low temperature under which the mammoth existed is attested not only by his hairy covering, but by the coniferous vegetation upon which he, with his congeners, appears to have subsisted. Whether his final extinction was accomplished by human agency is a question; but it is little less than certain that he entered the glacial era with man, was hunted in Europe, Asia, and America by paleolithic savages, and survived until the amelioration of the glacial climate.

XI. *Relation of glaciation to the history of man.*—The evidence concerning man's relation to the glacial period is divisible into two categories:—(1) that which connects him with the closing stages of that epoch; (2) that which establishes his existence previous to the advent of the ice. The evidence belonging to the first category is overwhelming in quantity; it mainly consists in the finding of human bones and products of art associated with the remains of glacial animals or imbedded in later glacial deposits. That belonging to the second class is much more meagre, and has been obtained satisfactorily in only three localities, viz.; central France, California, and New Jersey. In the first of these localities a human cranium was discovered in volcanic tufa beneath a sheet of lava, associated with a fauna whose general facies is ancient, though not sufficiently definite to establish the pre-glacial existence of man paleontologically. The pre-glacial age of all these remains may be, however, inferred from the evidence furnished by the sub-ærial erosion of the valley of Le Puy and the glacial erosion of the adjacent mountains of Coutal; though the testimony can hardly be regarded as conclusive. The finding of a human cranium in auriferous gravels overlain by extensive lava-beds probably of pre-glacial age in California, associated with organic remains of rather more southern type than those of Le Puy, as attested by Whitney, affords more satisfactory evidence of the pre-glacial existence of man. Along the Delaware river in New Jersey numerous rough-stone implements have been collected by Abbott from a table drift, or mass of re-arranged glacial matter, which is destitute of organic remains. "From a rather incomplete study of the ground, the only view I could take of these remains was that they were scattered on the surface of the earth to the northward before the last glacial period; that they were thrust before the glacier during its period of greatest extension, and deposited in the beds where they now lie by the action of water, while the above underwent a slight submergence" (p. 134). These chipped flints of the Delaware, no less than the Le Puy and Calaveras eronia, indicate that even at this early day man had attained a social condition similar to that of the European stone age; and hence that during the vast intervening period, the duration of which was probably not less than 200,000 years, or forty times the term of recorded history, there was almost no progress in the latterly rapid process of intellectual development.

XII. *The movement of glaciers.*—"It is to DE SAUSSURE that we owe the first hypothesis concerning glacial motion" (p. 140); his view being embraced in the suggestion that the ice slid bodily downward in a solid mass, the sliding being facilitated by melting of the basal portion of the ice through the influence of proper terrestrial heat. The utter inadequacy of this hypothesis must, however, have been apparent to its talented author;—indeed—"we are forced to believe that this statement does not represent his conclusions" (p. 140). Charpentier subsequently suggested that the motion is due to the nightly freezing and expansion of the water taken into the interstices of the ice during the day; but this hypothesis is also inadequate. Still later the solution of the problem was undertaken by AGASSIZ, who devised a critical series of experiments to determine the empirical laws of motion of the glaciers. The plan was to plant a line of stakes across the ice-stream, and to measure their absolute and relative movement at the end of a year. During the first season the entire series was overthrown by the superficial melting of the ice; but the stakes were again more firmly planted. Among the naturalists who visited his camp on the glacier was J. D. FORBES, whose contributions to glacial physics are well known. "While the guest of Agassiz, Professor Forbes made his first acquaintance with existing glaciers. Owing to his superior training in the branches of learning that this peculiar problem called for, he soon saw that the method that Agassiz was using was, by a slight modification, capable of a more speedy solution than his Swiss host could obtain under the conditions of his experiment. Agassiz planted a row of stakes across the glacier, but proposed to wait, with the patience that characterized his mind, until after a winter, to read the answer he sought. Mr. Forbes saw that with a transit or theodolite he could, in a few days at most, see how the stakes were moved, and so anticipate the results his host was seeking. With this plan in mind he went to the Mer de Glace, set up a line of stakes in the precise position devised by Agassiz, and within a month proved that the ice moves most rapidly in its middle parts, and not, as had been supposed, more quickly upon the sides of the stream; this result he hastened to make public" (p. 142). These, as well as later observations, show the laws of motion of glaciers correspond to those of moving liquids. Somewhat previously RENDA had reached a similar conclusion. FORBES soon after enunciated the viscous theory of ice-motion, illustrating "his conception of glacial movement by frequent reference to other substances, the the viscosity of which we recognize in ordinary experience, such as tar, wax, or molasses" (pp. 143-4). "In the hands of his followers this theory has sometimes assumed a different shape * * *; it is then made to mean that the ultimate tangible elements of the glacier, the bits of ice into which it is divided, slide over each other, as, for instance a heap of peas when poured on a sloping surface" (p. 144). This captivating hypothesis has not, however, been widely adopted. Next followed the fracture-and-vegetation hypothesis of Tyndall; but neither has this view commanded general assent. Still later Croll enunciated the hypothesis of successive melting and freezing of the molecules of the ice; "each molecule, as it is melted, parting with its heat to its neighbor on the inward side of the ice, and returning to the solid state, shortly to be remelted by the heat transmitted by its outer neighbor" (p. 145). There are certain phenomena, however, which this inherently probable hypothesis fails to explain. There is then the view in which the motion is referred to momentary melting, through the influence of pressure, of the particles of ice from time to time subjected to unusual strain; but, like the last, this hypothesis is alone incompetent to explain all the phenomena of ice-motion. Finally there is the sliding theory of Hopkins, which is in conflict with all we know of glacial movement. Examples of glacier motion are furnished by the annual snows of New England hill-sides; and the energy of this motion is well illustrated by a phenomenon observed

on a terrace in a cemetery at Augusta, Me. "On this terrace snow accumulated one winter so as to fill up the re-entrant angle it formed with the hill-side. When in the spring this snow melted away, it was found that the upright tombstones and the iron fence that surrounded the graves were broken off near the surface of the ground, and moved in the direction of the general slope of the hill" (p. 148). Summing up the foregoing hypotheses in their application to glaciers of the alpine type, and viewing them in the light of the various phenomena recorded, it appears that all except the sliding and viscous theories are "true causes" of ice-motion; and though neither is alone competent to explain the various phases of the movement, all must be recognized in a satisfactory and consistent theory. As in the theory framed to account for glacial periods, so in this case also, our theory is sufficiently flexible and indefinite to be sure of coinciding with the truth in some of its aspects.

"The problem with which we have to deal when we come to the task of explaining continental glaciers is of quite a different nature" (p. 151), since in this case "we have to leave gravity, as it works in Swiss glaciers, almost out of account" (p. 154). The ice might move freely for a score of miles from its southern border; but in the interior little if any motion would probably occur, except such as might result from pressure-melting; the excess of water formed in this manner escaping in sub-glacial streams. "In this way we may conceive that the ice of British America may have been carried out, from centre to periphery, in the form of water, and the waste of its grinding borne along by the streams that were formed by the pressure-melted water" (p. 159). In other words, continental glaciers appear not to move as ice, but only as water, except along their extreme peripheries.

XIII. *Certain effects of glaciers.*—Outside of glaciated regions the soils and sub-soils are the products of simple weathering conjoined with vegetal action, and may be denominated *soils of immediate derivation*: while within such regions the superficial accumulations are made up of mechanically comminuted materials brought thither from numberless localities, some perhaps hundreds of miles distant, and may be termed *soils of remote derivation*. Since the soils of the first class vary with the character of the underlying rocks, it follows that the latter are more uniform in constitution over considerable areas; and they are at the same time more durable, for not only are the materials essentially identical in all parts of the thickness of the deposit, but they also contain desirable mineral constituents locked up in the included pebbles to be gradually liberated by atmospheric and chemico-vegetal action. The glacial clays were "laid down in a very unoxidized state. Generally they are of a bluish hue, and only attain the ordinary yellowish or reddish color of decomposed clays as the waters acidulated by vegetation slowly penetrate into them." "In North America this penetration of atmospheric decay is distinctly proportionate to the nearness of the clays to the old glacial front" (p. 165); and hence affords a rough measure of the length of post-glacial time.

The coarser moraine debris constitutes, however, but a small part of the glacial waste;—the impalpable glacial mud must have been formed in scores if not hundreds of times its volume, and swept for the most part into the sea to build up azoic shales and clay slates, perhaps intercolated with conglomerates, as in the Roxbury conglomerate series near Boston. This fine glacial detritus, whether accumulated in river-beds, lake-bottoms, or unfossiliferous marine formations of any age, may be distinguished from river salt by its unoxidized state and blue color. The distribution of both the coarser and the finer glacial products has been largely accomplished by marine forces, after they were thrust by the ice into the sea; as in the case of the Tertiary sands of the southern states, which were probably originally brought to the ocean by glaciation along the more northerly Atlantic coast.

The formation of auriferous gravels and the general accumulation of gold in drift by glacial action, was accomplished by the simple concentration of heavier materials in depressions or gentle slopes, just as occurs in miniature in a miner's pan or rocker; and the result may be brought about by local as well as general glaciation, as is well shown in the valley of the Arkansas River at Twin Lakes.

"It is a very important fact that no pre-glacial caverns have ever been discovered" (p. 170)—a fact which leads to the inference that the extent of glacial erosion was so great as to totally remove pre-existing cavern-bearing limestone strata. The excavation of fiords and lake-basins, already adverted to, is a farther illustration of the enormous extent of this erosion. A most interesting, though indirect, result of this property of glacier ice is the influence which it has exercised on the social condition of mankind; for it is only shores indented by bays, fiords, and inlets, and fringed with islands, that afford the incentives to and facilities for the development of the maritime industries which occupy so important a place in human progress. The far-seeing geologist cannot, however, avoid speculating on the possibility that a contrary effect may, in the distant future, be exerted on mankind, by the return of glacial conditions to our globe. There is every probability, indeed, that the earth will again be enfolded in an icy mouth such as crept over it during the Quaternary; though there is no reason to fear that such an untoward vicissitude is imminent.

A glossary of some fifty terms, a bibliography of nearly seven hundred entries, and a four-page index with the plates and descriptions follow.

It has been the aim to present, in the foregoing paragraphs, a full synoptical *resumé* of the work considered, without approval or comment. Several passages which are regarded as either erroneous or misleading, or open to serious objection on well-established theoretical grounds, have, however, been quoted in the words of the author. A portion of these may be noticed in their order; reference being made to the pages on which they occur.

P. 28.—Geikie[1] regards ice-bergs as the terminal portions of glaciers, broken off by their buoyancy on entering the sea; Tyndall,[2] however, supposes that the masses break downward by their own weight; while Schwatka[3] has shown that they are formed in either mode according to the temperature of the sea—and, he might have added, other circumstances.

P. 31.—"From information derived from all sources up to the present time, it may be gathered that the unpenetrated area of about 4,700,000 square miles surrounding the South Pole is by no means certainly a continuous 'Antarctic Continent,' but that it consists much more probably partly of comparatively low continental land, and partly of a congeries of continental (not oceanic) islands, bridged between and combined, and covered to a depth of about 1,400 feet, by a continuous ice-cap; with here and there somewhat elevated continental chains, such as the groups of land between 55° and 95° W., including Peter the Great Island and Alexander Land, discovered by Billingshausen in 1821, Graham Land and Adelaide Island, discovered by Biscoe in 1832, and Louis Philippe Land by D'Urville in 1838, and at least one majestic modern volcanic range discovered by Ross in 1841 and 1842, stretching from Balleny Island to a latitude of 78° S., and rising to a height of 15,000 feet."[4]

Pp. 38, 98.—Geologists generally do not consider that the correctness of the views of Ramsey and others as to the repeated recurrence of glacial periods throughout ge-

ological time, is fully established; and they certainly do not regard the covering by ice of "a very large part of land and sea" as a "fact," or indeed as more than an extremely vague hypothesis.

P. 40.—Croll long since suggested[5] that Caithness and the Orkneys were glaciated by the Scandinavian ice-sheet, and Peach and Horne have recently urged[6] that during a part of the glacial period the Shetlands were overspread by the Scandinavian *mer de glace*, while during another part they gave origin to a system of local glaciers, though Milne-Home[7] seriously questions these several conclusions; and it has also been suggested by Reid,[8] though it can hardly be regarded as established, that the contortion of the drift along the Norwich coast was effected by Scandinavian land-ice. As shown by Croll's[9] and Geikie's,[10] as well as all other reliable maps, however, all the British highlands were unquestionably independent centers of glaciation, quite distinct from the Scandinavian ice-sheet;—indeed, when Milne-Home characterized the statement that "the land-ice which glaciated Scotland could only have come from Scandinavia" as an "astounding declaration,"[11] Peach and Horne hastened to explain that the word *Scotland* was a mis-print for *Shetland*.[12] There are also grave reasons to question whether a polar ice-cap ever existed in the northern hemisphere, as the writer has endeavored to prove,[13] and it is quite certain that if such an ice-cap did exist it did not extend to the British Isles by way of Scandinavia. So long ago as 1845 Murchison showed by means of a map in his "Geology of Russia and the Ural Mountains," that the Scandinavian drift "proceeded eccentrically from a common centre;"[14] and Geikie (illustrating his remarks by a map) says: "the direction of the glaciation in the extreme north of Scandinavia, the peninsula of Kola, and north-eastern Finland, demonstrates that the great *mer de glace* radiated outwards from the high grounds of Norway and Sweden, flowing north and northeast into the Arctic Ocean and east into the White Sea, and thus clearly proving [proves?] that northern Europe was not overflowed by a vast ice-cap creeping outwards from the North Pole, as some geologists have supposed."[15]

Pp. 41,44.—It is not known that a continuous ice-front ever stretched across the American continent, since a portion of the region eastward of the Cordilleras remains unexplored. Dana remarks, "since evidence of the great southward moving glacier fail over the region west of a line passing from a few degrees west of Winnipeg, southeastward through Western Minnesota and Iowa, near the meridians of 98°–100°, and all the way westward to the borders of California and Oregon if not to the Pacific coast, the ice thinned out toward the interior of the continent and was mostly absent except about the higher parts of the Rocky Mountains."[16] There is moreover no sufficient reason for believing that the American ice-sheet swept down from polar regions. Hitchcock's map of directions of ice-flow, which is reproduced in the work under consideration (following pl. XX.), indicates that the principal American center of dispersion was probably in the northern Laurentian Highlands;—a view which is corroborated by more recent observations of the Canadian Geological Survey.[17] Houghton has also shown that the boulders of the Arctic archipelago were carried northward.[18]

P. 42.—The quoted remarks describing the southern limit of ice-action in the Mississippi valley display unpardonable disregard of the work of Cox and Collett in Indiana, of Worthen and his associates in Illinois, of the several Missouri geologists, of White and St. John in Iowa, of Aughey in Nebraska, of N. H. Winchell and Upham in Minnesota, and even of Hitchcock's map appearing in the volume. The southern limit of the drift does not pass through either Iowa or Minnesota, but through southern Indiana and Illinois, northern-central Missouri, and Nebraska. The statement possibly originated in confounding the great Kettle Moraine with the southern drift-line, though as specifically pointed out by Upham,[19] and hardly less distinctly by Chamberlin,[20] these lines are 300 miles apart.

The glacial phenomena of south-western British America have been carefully and tolerably fully studied by G. M. Dawson.[21]

Pp. 66, 68.—An explanation of the origin of kames and aasor which is satisfactory to students of glacial phenomena was independently offered by N. H. Winchell,[22] Holst,[23] and Upham.[24] The hypothesis is as definite and probable as almost any other portion of the glacial theory.

Pp. 70, 90.—Tyndall has shown[25] that a diminution of terrestrial temperature could never inaugurate a glacial epoch; it has never been demonstrated that augmentation of temperature would be in any degree likely to produce a similar effect; and, accordingly, Poisson's and Le Coq's hypotheses can hardly be regarded as "reasonable" or "likely" in the present state of knowledge. As Croll has urged[26], there are grave reasons for questioning whether anything like half of the heat reaching the earth comes from the stars.

P. 75.—Loomis, describing the orbital motion of planets undisturbed by exterior forces, says: "the curve cannot be a circle unless the body be projected in a [particular] direction * * *, and, moreover, unless the velocity * * * is neither greater or less than one particular velocity;"[27] and Stockwell, speaking of the solar system in its actual condition, says: "the eccentricity of the earth's orbit will always be included within the limits of 0 and 0.0693888."[28]

P. 95.—Sound bases for the assertion do not sppear. Hilgard says[29]: "the relations mentioned by Tuomey (Second Report on the Geology of Alabama, p. 146) as existing between the shore of the Tertiary sea and the region of occurrence of the southern [northern?] drift on the Atlantic slope, are not so clearly recognizable in Mississippi and Alabama;" and further westward no relation whatever is apparent. Furthermore the "northern drift" of Hilgard and Tuomey was deposited far beyond the southern limit of the ice.

P. 107.—Le Conte shows graphically[30] that, admitting the influence of eccentricity, glaciation would only be possible after protracted secular refrigeration. The period in which this refrigeration reached such a degree as to permit of glaciation has not been determined. If in the Cambrian, Le Conte's diagram is, of course, incorrect; but it is not seriously maintained by working geologists in America that such was the case. Speaking of the Quaternary Le Conte, referring to Nordenskjold's observations,[31] declares[32]: "that glacial conditions were

ever before reached, even in polar regions, seems more than doubtful."

The foundation for the second statement quoted does not appear.

P. 108.—It has not been empirically established that the effect of fog-banks is to diminish temperature; and analogy with the known observation of finely disseminated water suggests that a directly opposite result ought to be produced. Croll's argument has been considered by Newcomb [33] and the writer.[34]

P. 113.—G. M. Dawson[35] has investigated the late-Quaternary depression of Vancouver's Island and British Columbia, and finds it to have been practically commensurate with that of the Atlantic coast.

P. 119.—Geologists are not united as to the age of the great pachyderms. Thus, Collett[36] records observations indicating that they were recent; while Phillips[37] and Godwin- Austen[38] regarded them as wholly pre-glacial, and Hall[39] and Belt[40] have shown that at least some individuals existed before the advent of the ice.

PP. 119-20.—Howorth has recently (mainly since the publication of "Glaciers") examined the evidence relating to the former existence of the mammoth in Siberia, and reaches the conclusion (among others). 1st, that the animals lived where their remains now lie; and 2nd, that the climate was comparatively mild at that period[41].

P. 134 A subsequent and apparently complete study of the locality by Lewis leads to the conclusions; 1st, that the implements are confined to the Trenton River gravel: and 2nd, that this gravel was deposited "at a period immediately following the last glacial epoch." [42]. If, as suggested by F. W. Putnam, [43] the flints were dropped into this gravel while in process of formation by the paleolithic men who hunted and fished along the old river-bluffs of New Jersey, it follows that these men were post-glacial; and even if the correctness of Lewis's views are not fully established, as intimated by Dana,[44] this instance does not demonstrate, or even indicate, man's pre-glacial existence.

P. 140.—Tyndall mentions[45] that Scheuchter first propounded the dilatation theory in 1705, that in 1760, or nearly forty years in advance of De Saussure, Altman and Grüner enunciated the sliding theory, and that in 1773, or thirty years before the publication of De Saussure's "Voyages dans les Alpes," the plastic theory was put forth by Bordier.

P. 142.—The re-opening, not incidentally or even judicially, but in a ludicrously partisan tone, of this now almost forgotten though erstwhile bitter controversy, would be quite unjustifiable even if the statements where not erroneous. Forbes' first visit to the alpine glaciers (as published by himself in that year), was on the 9th. of August, 1841; [46] during which visit he was in the company of Agassiz. Throughout this season his observations, as indicated by his published results, were confined to superficial phenomena; chiefly "ribboned structure" and "slaty cleavage." On the 24th of June, 1842, he again reached Montannent[47] with a set of instruments of precision, avowedly and obviously carried thither for the express purpose of instituting a series of measurements of the motion of the ice—the necessity for such measurements having been pointed out in lectures in December, 1841, and January, 1842,[48] and also in the *Edinburg Review* for April, 1842[49];—and the "First Letter on Glaciers," containing the "account of the first experiments, undertaken in June, 1842, to determine the laws of motion of the Mer de Glace of Chamouni" (published in October as already noted), was dated "4th July, 1842"; on which very day as stated by Dana on Tyndall's authority,[50] Agassiz' measurements proving the more rapid flow of the medial portion of the glacier, were published in the *Comptes Rendus*. Lyell, speaking of the more rapid medial than lateral motion of glaciers, says [51]; Mr. Agassiz, at p. 462 [of the "Systeme Glaciere"], states that he published in the *Deutche Vierteljahrschrift* for 1841, this result as to the central motion being greater than that of the sides, and was, therefore, the first to correct his own previous mistake." Comment is unnecessary.

Pp. 143-4.—Substances not previously regarded as viscous, as for instance Stockholm pitch "so hard as to be fragile throughout, and present angular fragments with a conchoidal fracture" and a glassy lustre[52], are also referred to by Forbes.

The "followers" who hold the view indicated are not advocates of the viscous theory proper, which is essentially molecular. The motion of viscous, as of fluid bodies, may, however, be very imperfectly *illustrated* by the movement of a heap of independent spherical masses.

P. 145.—The re-statement of this view, which it is painful for admirers of Croll's important labors in other directions to discuss, is hardly excusable. Readers may satisfy themselves as to its validity by referring to the criticisms of Blakie[53] and Teal[54]. The authors should have pointed out the differences between solid, liquid, and gaseous molecules of H_2O.

P. 148.—The motion of the alternately freezing and thawing snow unquestionably occurred in the manner assumed in the dilatation theory as advocated by Scheuchzer, Charpeutier, and, especially Mosely; but it is just as unquestionably distinct from the true flow of glacier ice. The recognition of miniature glaciers in the New England snows, far transcends the peculiar ideas of Muir, which are so strongly deprecated by King[55].

Pp. 151, 154, 159.—The extraordinary conclusions reached are perhaps to be attributed to the inadequacy of the theory of glacier motion adopted. The statements may be looked upon as representing unduly emphasized ideas of a purely speculative nature.

P. 165.—So long as a majority of leading students of Quaternary phenomena classify the upper and generally yellowish portion and the lower and generally bluish portion of the drift respectively as Upper Till and Lower Till, and look upon them as distinct in either time or mode of formation, as do Newberry, Upham, Hitchcock, Aughey, N. H. Winchell, Stone, and many others in the United States, and so long as these deposits are distinctly separated by a characteristic vegetal stratum, as they are at least in southern Ohio,[56] northeastern Iowa,[57] and Nebraska,[58] the first quoted statement must be regarded as unsupported by facts, notwithstanding the possibility that atmospheric and vegetal action might, as urged by Hawes,[59] Julien,[60] and Van den Bröck,[61] produce a similar discoloration of a single homogeneous formation having the constitution of the Lower Till; and since the bluish clays quite frequently (and indeed over some considerable

areas generally) approach or even reach the surface toward the southern limit of ice-action, as in southern Indiana,[62] Illinois,[63] Iowa,[64] and Nebraska,[65] and in northern Missouri,[66] the second statement must be viewed in a similar light.

P. 170.— The cave-fauna, especially in Europe, is essentially identical with that commonly regarded as Quaternary or Champlain; and as already intimated, there is good reason to suspect that this fauna was at least partially pre-glacial. Moreover, the same facts relied on by the elder Buckland to establish the anti-diluvian age of the ossiferous cave-deposits,[67] must today be considered equally conclusive of the pre-glacial existence of these remains.

On passing to a more general survey of the work there is found to be less occasion for criticism, and indeed some grounds for high commendation. Thus, the influence of aqueous vapor and other substances diffused in the atmosphere upon terrestrial temperature is rarely lost sight of, the existing glaciers are faithfully and accurately described, and the general character and effects of Quaternary glaciation are fully and clearly dealt with. The teachings as regards the recurrence of glacial epochs and their influence upon the successive geological formations of the globe are, however intensely radical. The evidence relied on to demonstrate the glacial origin of sandstones and conglomerates, azoic shales and slates, and unoxidized argillaceous rocks generally, is quite inadequate. For instance, the idea that the iron of glacial mud alone is normally unoxidized while that of river silts is normally oxidized, appears to be expressly contradicted by the facts that the iron of the Lörs (which is almost certainly formed of impalpable glacial debris), is nearly universally peroxide, even when the deposit is one or two hundred feet thick, while that of the post Lörs alluvium of the lower Mississippi is invariably protoxide, even within a few feet or even inches from the surface; and the opinion that paleozoic ice-action cannot be proven by the same evidence as that attesting Quaternary glaciation is directly opposed by the facts that the Talchir (lowest paleozoic) beds of Peninsular India contain striated and polished boulders imbedded in the finest silt, and that the underlying Vindhyau (azoic) rocks bear similar markings; though even in this case the original observers do not refer the phenomena, with any degree of certainty, to glacial action. Again, while the discussion of glacial hypotheses and theories of glacial movement is tolerably full and (unless possibly in a single instance) eminently impartial and candid, the "composite theories" adopted are quite valueless, since the detailed investigation given to the subjects is in almost every case much less searching and exhaustive than that upon which each hypothesis was originally based. It may be questioned, indeed, whether the method of throwing together a number of essentially distinct and imperfectly weighed hypotheses, and taking the sum or the mean of all as the only consistent theory, will ever come into general repute, however strongly it may be supported by a confusing array of glittering generalities. Thus, with regard to the problem of ice-motion; it is of course true that the dilatation, fracture-and-vegetation, and pressure-melting hypotheses are based on the observed behavior of ice; but it does not necessarily follow that these properties, either individually or collectively, produce the phenomenon of flowing in large bodies of ice. To illustrate:—solids generally expand and contract with alterations in temperature; they may be fractured by irregular strain or impact; they may be united into homogeneous bodies by pressure as shown by Spring; and those which expand on solidifying may be melted by pressure; yet no physicist attributes the flow of solids (which has been investigated by Tresca, Roberts, Ware, and others) to any or all of these properties. Finally, there are important omissions, notably with respect to the widespread hipartite structure of the drift in many if not most glaciated regions, which has led many European and several American geologists to conclude that it was formed during two distinct periods, separated by a considerable era of mild climate. The general neglect of the results of American (and indeed Foreign) study has been incidentally noted in preceding paragraphs.

The illustrations, which are of the finest character and elaborately described, are mainly reproduced from photographs of existing glaciers and of interesting phases of glacial phenomena in America and elsewhere. They are of course open to the objection which may be urged against all photographs of natural scenery—*i. e.*, that the most instructive and valuable details are often obscured or concealed;—though many of the plates are of remarkable clearness and beauty. The illustrations are not, however, superior or even quite equal to many which have already been published by Agassiz (for instance, in the atlas accompanying "*Etudes sur les Glaciers*;" Neuchatel, 1840—"Untersuchungen über die Gletcher," Solothurn, 1841), and others.

It should be added that the necessity for all the foregoing criticisms appears to have arisen from the peculiar design of the work and the circumstances under which it was prepared. The authors explain in the preface that in order to meet the agreement with the publishers, it was necessary to prepare the text with far greater haste than was desirable; and remark that,—"if the reader will consider that the main object in the book is not to afford a complete history of glaciation, but to present a body of graphic illustrations of glacial phenomena, and that the text is designedly subordinate to this purpose, he will then better understand the apparent short-comings of the work."

Viewed as a whole, it appears that the work describes no new phenomena and presents no new theoretical views, while it exhibits many deficiencies and inaccuracies. It cannot therefore be regarded as in any sense a valuable contribution to the subject dealt with, or even as a satisfactory exposition of the present state of that subject. To the working student it will accordingly be worse than useless, since it will impose upon him a heavy financial and

a no less mental tax, without adequate recompense. To the teacher, however, for whom it is especially designed, it will doubtless prove quite acceptable as an auxillary to the more elementary text-books.

Several considerations appeared to demand a rather full examination from the "standpoint of the working-geologist of Glaciers." (1.) There is so urgent a demand for a standard work representing fully the present *status* of American Surface Geology (or Kaineontology, as the writer prefers to term that branch of Geology), that almost any book on the subject might be adopted as such without duly weighing its fitness for the position. (2.) In its ambitious style and assumptious *ensemble* the work under review is quite unlike the ordinary text-books. (3.) It is the initial volume of an extended and costly series of works which, from their titles and the fact that they carry with them the prestige of a leading university, might naturally be regarded as the highest American authorities on the subjects treated. (4.) It was not deemed just to working geologists to suggest that the book could well be dispensed with without at the same time furnishing, as fully as practicable, the means of forming an independent judgment.

FARLEY, Iowa, *Nov.* 12, 1881.

LIVING OBJECTS FOR THE MICROSCOPE,

Mr. A. D. Balen, of Plainfield, New Jersey, has undertaken to collect living organisms suitable for microscopical investigations, and forward them by mail to those interested in such studies.

This is a great convenience to those living in cities, or those who are unacquainted with the localities where collections of particular forms can be made.

Among the living objects which Mr. Balen has sent out to his correspondents may be mentioned—

POLYZOA.—Pectinatella, Plumatella and Fredericella.

INSECTS.—Larva of Dragon Fly and Dyticus (water tigers).

ENTOMOSTRACA.—Bosmina, Daphnella, Diaptomus and Sida.

WORMS.—Nais, Stylaria and Planaria.

ROTIFERS.—Lacinularia, Conachilus, Floscularia, Melicerta, Limnias and Noteus.

POLYPS.—Hydra, with the curious parasite Urceolaria pediculus.

BELL ANIMALCULES.—Vorticella, Carchesium and Epistylis, Stentor, Vaginicola and Cothurnia.

INFUSORIA.—Spirostomium, Euglena and Dinobryon.

RHIZOPODS.—Arcella, Actinophrys and Clathrulina.

SPONGE.—Spongilla.

PLANTS.—Utricularia, Vallisneria, Anacharis and Nitella, Volvox, Protococcus and Pediastrum.

DIATOMS.—Surirella, Gomphonema and Fragilaria.

DESMIDS.—Scenedesmus, Desmidium and Micrasterias.

We hope that microscopists will support Mr. Balen in this little enterprise, for it will prove of the greatest benefit to them. A specimen package will be sent for 30 cents.

THE giant forces which scientific discovery is putting in the hands of engineers bid fair to develope a particular form of the profession.—*Engineering News.*

SATURDAY, JANUARY 14, 1882.

We refer our readers to another column of this issue where a letter written by Professor George S. Morris, A. M., of the University of Michigan, and Lecturer in the Johns Hopkins University, may be found. This letter is a reply to an editorial in the *Popular Science Monthly* for January of this year, which repudiates the assertion that Herbert Spencer is an atheist, or that his writings have an atheistical tendency, the writer claiming for Spencer that the world is under an obligation to him for elevating man's conceptions of the character of the Deity, and that Spencer, so far from being an atheist, has contributed new and powerful arguments for the existence of an "Infinite and Eternal Spirit," and further that Spencer is ever bringing us to the underlying truth and therefore doing the highest religious work.

As a masterpiece of special pleading the article in the *Popular Science Monthly* to which we refer, will be read with interest, and if it were possible to reason or talk an Augean stable into cleanliness, the editor of the *Popular Science Monthly* might have succeeded in the task he had in hand. Professor Morris has torn off the hypocritical mask of divinity assumed by the editor of the *Popular Science Monthly* for Herbert Spencer, and exposed the real nature of his teachings. Had the editor of the *Popular Science Monthly* merely claimed some mitigating circumstances,or some underlying truths in Spencer's teachings which merited recognition, he might have succeeded in deceiving his readers, who he evidently believes are at the mercy of his sophistry, but to claim for Spencer, the position of a great religious teacher was proving too much, and gives a ludicrous aspect to the whole discussion. As Shakespeare says:

> 'Tis too much prov'd,—that with devotion's visage
> And pious action, we do sugar o'er
> The devil himself.

Let us calmly examine what Herbert Spencer really teaches, and to those who desire to follow us, and have no time to wade through Spencer's voluminous works, we advise a perusal of Professor Morris's valuable work, "British Thought and Thinkers," published by S. C. Griggs & Co. of Chicago. We will now make a few quotations from this work, and as the author is a teacher of this subject in two of the leading Universities in the United States, he may be acceptable as an authority sufficient for our purpose.

What is the "Infinite and Eternal Spirit" which Spencer would have us accept as God? Spencer merely terms it "*the unknowable*," a something or a nothing, which "is absolutely beyond our knowledge." Whatever it may be "it does not come within the range of sensitive consciousness." In plain English this "*unknowable*" may be a God, a Devil, or it may be an ether, electricity or anything else. One thing is certain, that it is not spiritual and is devoid of intelligence.

All that relates to mind or matter is purely mechanical in Mr. Spencer's estimation. He contemplates man in common with the whole universe as the subject and scene only of purely mechanical, automatic, irresponsible and unreasoning processes, in fact the whole knowable universe is brought under the one category of mechanism.

Man is simply "sensitive flesh and blood alone," his very individuality denied, for Spencer says that "the reality of a belief in *self* admits of no justification." *Mind* is a mere bundle of phenomena of a mechanical nature, and *consciousness* simply "molecular oscillations and the transmission of motion in the nervous system," and as if to strike from man the last vestige of his humanity, *morality* is annihilated, for *good and evil* are measured by the amount of pleasure or pain which results. Thus the perfect man, like the perfect hog, is the one whose nervous organization is perfectly adapted to surrounding physical conditions, the man and the brute on one level, soulless and devoid of any spiritual nature.

Such is the Spencerian theology. Readers, picture to yourselves such a God, and man as we have described, and then knowing the real nature of his teachings, imagine Herbert Spencer elevated to the rank of a spiritual teacher who "is ever bringing us near to the underlying truth, and therefore doing the highest religious work," and the sickening hypocrisy of this whole business is apparent.

Well did the rugged philosopher Carlyle exclaim, "There is but one thing without honor; smitten with eternal barrenness; inability to do or be: Insincerity, Unbelief. He who believes no*thing*, who believes only the show of things, is not in relation with Nature and Fact at all."

Much more could and perhaps should be said on

this subject, but as we cannot spare eleven columns to editorial remarks, we will conclude by stating that a wrong is inflicted upon Science by those who suppose it is answerable for Mr. Spencer's debased views of God and man. In summing up Spencer's teachings Professor Morris exclaimed to the students of the Johns Hopkins University, "all this is gratuitous, extra-scientific absurdity, contradiction and dogmatism." Professor Morris does not stand alone in this opinion, and he has at least our hearty endorsement.

It is possible to believe strongly in the theory of evolution and accept every scientific fact that has ever been demonstrated, and yet receive no shock to a belief in a Divine Providence, while the accumulation of scientific facts in our opinion all tend to confirm such belief, and to demonstrate scientifically that an intelligent Creator has designed and pre-arranged the order of both matter and mind.

In conclusion, we desire to say decisively, that science is not answerable for the vagaries of Mr. Herbert Spencer, his editorial supporters, and others of the same class; his atheistical dogmas are neither founded on scientific investigations or in harmony with scientific discoveries. The mere fact that a scientific journal is made use of for proselyting such views even to the extent of attacking editorially, a President of a university who declined to use a recent work of Spencer's as a class-book, should not be considered evidence that scientific men, as a body, have any regard for the extreme views of Herbert Spencer. On the contrary, those engaged in real scientific work, do not care to interfere with their neighbor's religious opinions, much less do they desire to force atheistical views upon them.

Lastly, we say emphatically, that there is no real conflict between Science and Religion at this present day. Some persons appear to consider that they have a mission to stir up discord and contention between scientific men and their best friends, and the worst feelings are engendered by continued attacks against men holding any religious views who form nine-tenths of the population in all civilized countries.

What better evidence can be given for the correctness of the position we take than the fact, that a large number of our most esteemed scientific workers are men in holy orders. We could fill a page by the mere enumeration of their names. Dallinger, the biologist, who has carried off the highest scientific honors, is a Protestant Clergyman. In astronomy we have a Catholic priest who successfully investigates the mysteries of the heavenly bodies, for Secchi's name will always be classed among eminent astronomers. If there was any real conflict between science and religion, would these men have continued their investigations? Of course not. The conflict at this day is wholly imaginary, invented and kept alive for sensational purpose. If these men would cease their irritating interference, science would be welcomed in every home and be considered one of the most convincing evidences of a divine Providence, instead of being hated and dreaded, as not in harmony with any religious belief.

We do not deny that there are many who cling to religious dogmas which have been exploded by facts revealed by science. For such we have compassion, but we hold in far higher contempt the bigoted blustering fanatic who has no religious belief whatever.

Hume admitted that he dared not select his own confidential servant from such as held his own principles. We believe we are correct in saying that Professor Huxley, who holds views somewhat akin to Spencer, is careful in selecting a school for his children where the Bible is taught. These facts appear to show conclusively that these advanced thinkers considered that there was a possibility that they might be wrong, and that some discretion was necessary in teaching their atheistical views, at least in their own families.

We apprehend that similar prudence should be practiced by all who are directly or indirectly answerable for now *popularizing* views and principles which, if successfully propagated, will be destructive even to a simple belief in God, and aim to undermine society itself by denying the intrinsic value of morality.

Finally, we ask that science shall no longer bear the odium of atheism; that it be freed from this pernicious parasite, and that atheism being published in journals devoted to that subject, shall be supported only by its own devotees.

WE trust the above remarks may not be interpreted as an attack on the "*Popular Science Monthly*" as a journal, or personally on the editors. The latter are gentlemen, honored and respected wherever science is known, and have been pioneers in the good work of introducing scientific knowledge into the homes of the people; their journal has always been conducted in a manner to defy criticism, and is an honor to the house which publishes it. The recent editorial was a bold demand for criticism on the policy of the journal teaching doctrines, which appear to lie outside of its province as a scientific journal. To this we have responded.

The root of the question at issue lies in the interpretations of the works of Herbert Spencer. We consider Professor Morris a safe guide in this matter, and a perusal of his letter will show that Spencer's writings have a dual character, they *partly* confirm the position taken by the "*Popular Science Monthly*," so far as showing Spencer believes in a "*something*," but are fatal to all the deductions drawn by the editors of that journal, and strictly in accord with the position we have reluctantly taken in this controversy.

NEW YORK ACADEMY OF SCIENCES.

Dec. 12, 1881.

SECTION OF GEOLOGY.

The President, Dr. J. S. NEWBERRY, in the Chair.

Forty one persons present.

Mr. N. L. BRITTON presented

"ADDITIONAL NOTES ON THE GEOLOGY OF STATEN ISLAND." *

Two wells have recently been sunk to a considerable depth on Staten Island, in the vicinity of Stapleton. One of these is on the property of Mr. J. J. Cisco, near the summit of the Serpentine hills; the section as given by the Superintendent of the Pierce Well-boring Co., who sank it, is as follows:

Glacial drift, ...	50 feet.
Soapstone, ...	150 feet.

* These notes are supplementary to the paper on this subject read by Dr. Britton on April 4, 1881. (Ann. N. Y. Ac. Sci., II, 161.)

The well is six inches in diameter, and sufficient water was obtained to make it a success.

The other well is at the pump-house of Bischoff's Brewery, some 500 feet east of the most eastern serpentine outcrop at the foot of the hills. This has now (Dec. 1st) reached a total depth of 210 feet, and the boring is still unfinished. The section thus far has been as follows:

Glacial drift........................80 feet.
Various kinds of tough hornblende schist, apparently varying to serpentine,....130 feet.

As yet no gneiss nor granite has been reached.

An outcrop of clay occurs near Clifton, about three-fourths of a mile south of the Forts, near the southern edge of the terminal moraine; it has been found, by borings made by Mr. Charles Townsend, in excavations for cellars, to be at least ten feet in thickness, and of a light color.

The clay is probably of Cretaceous age, and if so, this is the most eastern point at which beds of that age are known on Staten Island.

Mr. W. T. Davis has recently observed a large fossiliferous boulder of Schoharie Grit on the shore at Brighton Point. The fossils have been submitted to Dr. Newberry, and the following species identified:—*Dalmanites anchiops*; *Orthoceras Pelops*, *Strophodonta hemispherica*; *Atrypa reticularis*; *Strophomena rhomboidalis*; a *Fenestella*; and *Zaphrentis prolifera*.

Glacial groovings have recently been noticed on the hornblende-rock, which is exposed at tide-level on Brighton Point. Some of the grooves are at least one-quarter of an inch in depth, three inches wide and four feet long. Their bearing varies from N. 15° W. to N. 17° W.

DISCUSSION.

Prof. D. S. MARTIN considered the specimen of so-called hornblende schist from the well-boring, not to consist properly of that rock, but to be partly hydrated—apparently a less altered condition of the rock which higher up gives us the soft, semi-fibrous serpentine of the island.

Dr. NEWBERRY regarded the serpentine of Staten Island as probably a pseudomorphous condition of hornblende slate. It differs considerably from the mottled serpentine of New York Island, which is "verde antique"; that is, is composed partly of serpentine and partly of carbonate of lime, and is scarcely distinguishable from the Moriah marble, which is quarried at Moriah, Thurman, etc., in the Adirondack region. It is a peculiar rock, and one of the connecting links between the rocks of New York Island and those of northern New York and Canada. Taken together, these afford strong indications of the Laurentian age of the New York Island and Staten Island crystalline rocks.

Dr. Newberry further said that the accurate determination of the age of the rocks of New York Island, of Staten Island, and of those underlying the drift of Long Island, was in the highest degree desirable and important; and while he was satisfied that the former were Laurentian, and the latter Cretaceous, it was eminently desirable that unquestionable proof should be found of this, if it is true. At present no positive assertions could be made, and the duty devolves on the geological members of the Academy to rid the subject of doubt.

The fossils in the boulder referred to by Mr. Britton prove to have come from the Schoharie Grit. In its original condition this was a hard, compact blue limestone, but is here presented in a leached state, by the passage of waters containing carbonic acid, with a loss of its lime, color, and density. It was derived from northern New Jersey, to which locality a belt of this rock runs down from Schoharie county. Its transit by ice was effected without doubt through the valley of the Hackensack, which lies east of the Orange Mountains and west of the Palisades. This glacial movement is indicated by the direction of the striæ observed by Mr. Britton, as well as by those in the Hackensack valley.

Mr. A. A. JULIEN recalled the results of his lithological examination of the serpentines both of Staten Island and of Hoboken, presented before the Academy two years ago, in which it was shown that sections of all these rocks abounded in minute fragments of more or less altered amphibole. The conclusion then stated, that these serpentines must be certainly derived from hornblende schist, was confirmed by the interesting discovery of the latter rock, both in well-boring and on Brighton Point. Serpentines of the same general character and origin occur frequently throughout New York and Westchester counties. The mineral serpentine is also found in small quantity as a vein-deposit, not pseudomorphous, like the main mass, but presenting an amorphous material with banded vein-structure, associated with magnesite, dolomite, etc.; e. g., the marmolite of Staten Island, a translucent green variety found at Hoboken, and also at West 60th street on New York Island, etc. At all these localities the amphibole survives in a more or less altered condition; e. g., the tremolitic talc schists and slaty tremolitic serpentines of Staten Island and Hoboken, the hydrous anthophyllyte and unaltered tremolyte rock of West 60th street, New York, the tremolitic amphibolyte of New Rochelle and Rye, in Westchester county, etc.

Mr. BRITTON confirmed the last remarks, by the statement that a vein of material, strongly resembling the hydrous anthophyllyte of New York, had been struck at the bottom of one of the wells on Staten Island; also that veins of mixed serpentine and calcite were observed at Stapleton, possessing a banded structure parallel to their walls. At that point the apparent thickness of the serpentine bed is 150 feet, but the crest of the hill is composed of talcose schist.

MR. W. LE CONTE STEVENS then read a paper on "THE MAMMOTH CAVE OF KENTUCKY,"

He also exhibited specimens of the blind fish (*Amblyopsis spelaeus*), and blind crawfish (*Cambarus pellucidus*), and stereoscopic views of various points in the interior of the cave.

(Abstract.)

At the close of the Cincinnati meeting of the American Association for the Advancement of Science, in August last, he was one of a party of seventy-five members who visited the Mammoth Cave, remaining there two days, during which the greater part of the time was spent in exploration. He made no claim to new discoveries, but wished to call the attention of the Academy especially to recent observations, for the most part by Rev. H. C. Hovey, of New Haven, in regard to the temperature and structure of the cave. Mr. Hovey read a paper on this subject in Cincinnati, only a brief abstract of which has yet appeared in print, making use of a map, which is the first of its kind ever exhibited. The strictest precautions are observed by the authorities controlling the cave to prevent visitors from taking surveying instruments in with them: but the present manager, Mr. Francis Klett, has made a careful survey of the most interesting parts, and in time this will probably be given to the public, though possibly the scale of measurement may be withheld.

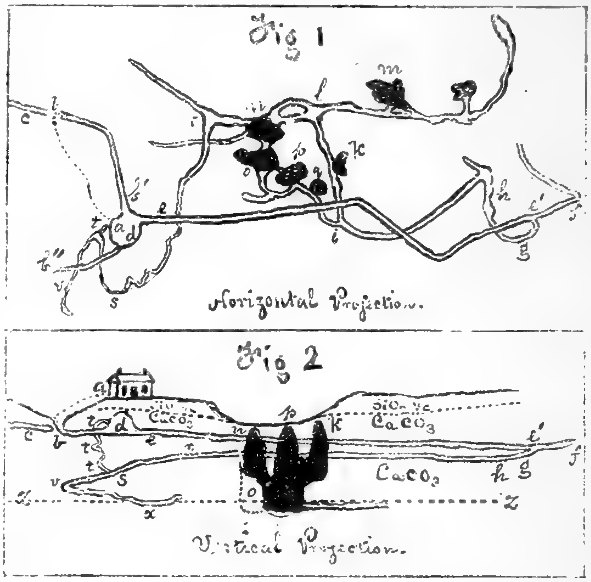
The central and right-hand portions of the map exhibited by Mr. Stevens had been enlarged by him from a copy of Mr. Klett's map. The left-hand portion was drawn only from recollection of the localities traversed, and not to scale, being intended only to illustrate principles. The same remark applies to the vertical projection, the lettering of which corresponds with that of the horizontal projection.

The temperature observations of Mr. Hovey were con-

ducted with much care, and the very best instruments had been confided to him by the Director of the Winchester Observatory at New Haven. In August, 1881, while the external temperature at the neighboring hotel varied between 90° F. and 100° F., at points farther than 100 yards within the cave, the reading of the thermometer was never more than 56° nor less than 52½°, the mean temperature being 54° for the summer months. At a point 1,000 yards within, a thermometer had been left for six months, including the autumn and winter, and daily visited by Mr. Klett, who reported the variation to be only from 54° down to 53°. The underground temperature in this latitude, for points 60 or 70 feet below the surface, is usually assumed to be constant and about the same as the mean annual temperature above. According to Prof. Guyot's maps, the isotherm of 60° passes about thirty miles south of the Mammoth Cave, while that of 50° passes about forty miles north of Cincinnati. The temperature of the Mammoth Cave is fully 6° lower than has been commonly supposed, and may be taken as a fair representation of that of the crust of the earth in the country immediately surrounding it.

Mr. Stevens exhibited a geological map of Kentucky, showing the area of sub-carboniferous limestone in which the Mammoth Cave is situated. This is overlaid with a thin stratum, mostly of sandstone, that is pierced by thousands of sink-holes, through which the surface drainage is carried down into limestone fissures and thus to the general drainage level of the Green River. This stream passes at the distance of less than a mile from the Cave Hotel, the floor of the latter being 312 feet above the water and 118 feet above the mouth of the cave. He briefly explained, with a diagram, the general mode of cave-production in limestone strata, showing that subterranean tunnels must be started by the solvent action of slightly acidulated rain-water, and subsequently enlarged by erosion, along the fissures in the limestone. These agencies are still at work in portions of the cave, and the whole of this limestone country is thus honey-combed with caverns. No tunnel can be thus formed at any point lower than the general drainage level, since there must be an exit for the saturated water. The production of the fissures is referable to the general upheaval of this area at the close of the coal period: but, that there has been subsidence since the completion of much of the Mammoth Cave, is indicated by the fact that at its lowest parts to-day the floor is covered with water to the depth of thirty feet or more, having subterranean connection with Green River. The fissures intersect at various angles, but many of them are nearly or quite coincident with the dip of the strata, which is very gentle. Water passing through these forms the tunnels, while that passing through the vertical fissures scores out the pits which pierce them. The same pit, starting from a sink-hole at the surface, may have successively lower tunnels as exit passages. If the visitor encounters it while walking through the higher, and therefore older, tunnel, the upper part appears to him as a dome, the lower as a pit.

The rate of erosion in the Mammoth Cave has been variable. The older parts are perfectly dry, and entirely free from stalagmitic deposits, indicating rapid erosion, followed by elevation, so as to deviate the water completely into other channels. In the newer parts the water is still dripping from the surface above, and depositing stalactites and stalagmites; but as a whole the cave is by no means remarkable for these formations, being much surpassed in this respect by the neighboring White's Cave, of more recent origin. Those which do occur are moreover deeply colored with iron, which exists in the soil in the form of both oxide and sulphide. In the dry parts, the ceiling of the cave is more or less covered with efflorescent calcic, magnesic and sodic sulphates, which contrast with the iron-stained limestone, giving rise to the beautiful effects that have conferred celebrity on the opening known as the Star Chamber, and the myriad rock flowers of Cleveland's Cabinet.



The structure of the pits and domes was then illustrated with the aid of the accompanying map, by describing a journey through the cave. From the hotel, (*a*, figures 1 and 2,) the visitor walks to its mouth (*b*), by the side of a shallow ravine, terminating in what was formerly a large sink-hole. The door of this fell through, about seventy years ago, producing the present mouth of the cave, and cutting off part of the gallery, now known as Dixon's cave (*c*), which opens out near the Green river, a half mile distant. A walk of 1000 yards brings him to the Great Rotunda (*d*), about 170 feet in diameter and 100 feet high. It is immediately under the hotel, its roof being not more than 40 or 50 feet from the surface. Besides the gallery, called the Narrows (*b'*), by which access has just been obtained, another tunnel from the further side terminates in the Rotunda, to which the name of Audubon's avenue (*b''*) has been given. The large, almost hemispherical opening, seems to have been cut out by the meeting of nearly opposite streams of water, which found exit, probably, through the main cave (*e*). At some distance within Audubon's avenue, a small opening in the floor is found, connecting it with the roof of the Mammoth Dome, a vast cavern 400 feet long, 100 feet wide and 250 feet high. These figures are of course only approximate, but it is believed that they are not exaggerated. Into this cavern the water is still trickling, and stalagmites are forming with sufficient rapidity to have cemented firmly to the floor a lamp dropped in 1812 and found in 1843. Returning to the Rotunda and passing through a half mile or more of the main cave, the visitor reaches, at *e'*, a large fallen slab of limestone to which has been assigned the title of "The Giant's Coffin." This makes the entrance to a side passage (*g*) which leads off to the lowest part of the present cave. The main cave forms an acute angle (*f*) and may be followed for several miles, terminating abruptly in a pile of rocks, where the roof has fallen in the same manner as at the terminus of Dixon's cave. Many of its side passages and avenues are yet unexplored.

Returning and entering the side passage near the Giant's Coffin the visitor passes obliquely beneath the main cave, starting upon what is known distinctively as the Long Route. At an expansion (*h*) are successive deposits of gravel, sand and clay, indicating the downward course of the water which was here partially arrested.

Some distance further on, the passage forks (i). Keeping to the right, the dangerous Side Saddle Pit (k) is encountered, which measures 65 feet in depth and 20 feet across. It is surmounted by Minerva's Dome, 35 feet high. The pit yawns across the right half of the floor of the tunnel, leaving a narrow path on the left. A short distance beyond (l), the tunnel again forks. Keeping to the right as before, Gorin's Dome (m) is reached, and may be viewed with the aid of magnesium lights, from a small opening on the side, ten feet above the pathway. The abysm extends 117 feet downward, 100 feet upward and 60 feet across. Leaving this and passing the fork (l), the tunnel is completely interrupted by the so-called Bottomless Pit (n) across which a bridge has been laid, resting upon a ledge. Despite its ominous name it does not defy measurement, having been found to be 95 feet deep on one side of the ledge and 105 feet on the other. Almost immediately overhead is Shelby's Dome, 60 feet high. Between the Bottomless Pit and Side Saddle Pit are a pair of very large pits, discovered not a year ago by one of the guides, William Garvin, and examined for the first time last August by Mr. Hovey, who gave to them the names Scylla (p) and Charybdis (o) on account of the narrow, rugged passage which separates them and the great difficulty and danger of access. By timing the fall of pebbles into the water at the bottom, the depth of each was ascertained to be about 200 feet. Charybdis was seen to be directly connected with the Bottomless Pit. Indeed the latter may be regarded as only a part of Charybdis, its depth, 105 feet, being only that of a jutting ledge, or the floor upon which water ceased to fall after being slightly deviated into Charybdis, where the sound of its trickling is still audible. Shelby's Dome is simply the upward continuation of this combined pit. So narrow, moreover, are the ridges separating Scylla from Charybdis on the one side and from the Covered Pit, (q), on the other, and so small is the distance to the Side Saddle Pit (k), that it seems in the highest degree probable that this group of pits compose merely the upper branches of a single large pit into which they are all united, or at least directly connected before the bottom is reached, and the small relative depth of the Side Saddle Pit is explicable in the same manner as that of the Bottomles Pit. Such an extraordinary group of pits, forming an apparent nucleus of cave drainage, might be expected to have its counterpart in an unusually large depression, or group of sink-holes, at the surface. Impressed with this idea Mr. Hovey found in the woods, scarcely half a mile from the Hotel, in the known direction of these pits, a depression (p Fig. 2.), many acres in extent, and so deep that from its edge he could overlook the tops of the pine trees that rose from the middle.

Leaving this region of pits and domes, the route leads still downward, passing again under the main cave through the narrow tortuous channel known as "Fat Man's Misery" (s) where the distance from floor to roof is in many places not more than three feet. Through the floor a winding passage has been worn away, varying in width and depth from one to three feet. This terminates in a chamber which has received the appropriate name of "Great Relief," where the succession of pebbles, gravel, sand and fine clay again records the work of erosion and deposit. This bed is not more than 50 or 60 feet above the drainage level, and from here down to the River Styx, the ground becomes more or less damp. A succession of bodies of water are then encountered, including the tubular Echo River, which is navigated in boats. It is a part of the tunnel which has subsided below the water level, and is in connection with Green River, being filled to within a few feet of the roof in summer, and completely closed in winter when the Green River rises. The column of air between the water and the impervious roof, closed everywhere except at the two ends, which are three-fourths of a mile apart, serves as a resonator for any note within the range of the human voice, and multiple echoes gliding imperceptibly into each other, continue to be returned for many seconds after the voice has been hushed.

Beyond Echo River, the cave may be followed, with continual ascent, through Silliman's Avenue, the Pass of El Ghor and Cleveland's Cabinet, for about five and a half miles. A pile of jagged rocks, 100 feet high, is then surmounted and the wearied climber is confronted with a large cavern, 100 feet wide and 70 feet deep, where three short branches have united in one tunnel. Following the left branch for a few yards, a hall is found, in the floor of which is a pit 175 feet deep. The corresponding dome overhead is scarcely noticeable as such, for the surface of the ground is not more than 30 or 40 feet distant. The end of the Long Route has been reached.

In returning, the passage through Fat Man's Misery is avoided, and nearly two miles of walking are saved by climbing through a very steep, narrow, winding "Corkscrew" pass (t, Fig. 2), starting from the neighborhood of Great Relief and terminating at the side of the Great Rotunda. The vertical ascent is about 140 feet. To even stout-hearted mountaineers, if stout-bodied also, this Corkscrew is an intensified Fat Man's Misery, and upon them it rarely fails to leave strong and deep impressions, which may be of more kinds than one.

In regard to the animal life of the Mammoth Cave, conflicting opinions have been expressed by those who have made a special study of this subject. The bats, lizards and rats that have been found cannot be strictly called cave-dwellers, as they are always at points not so far removed from the outer light as to make this inaccessible, The cave crickets and blind crawfish have particularly long antennae and acute powers of hearing. Most of the crawfish are pale in color, some of them almost white; and this feature has been attributed to the continued absence of light. Crawfish, however, with well developed eyes and of dark color have been often found. These are without doubt either wanderers from Green River or the immediate descendants of such; and many generations of cave-dwelling are required to bring about such changes as have caused the application of a specific name, *Cambarus pellucidus*, to the white variety with only rudimentary eyes.

In regard to the blind fish it is a significant fact that the rudimentary eyes of the young are apparently less atrophied than those of the mature fish. Although to these cave dwellers also a specific name, *Amblyopsis spelaeus*, has been given, they are by no means the only fish found amid this stygian darkness. The existence of fish with perfect eyes, apparently prospering where eyes are useless, shows how much less dependent these creatures are than more highly organized vertebrates upon approximate uniformity in external conditions. To those who have already accepted evolution, there is far less difficulty in believing that the colorless blind fish are the modified descendants of dark-colored ancestors with perfect eyes, which have wandered from Green River into Echo River, than in concluding that they have always constituted a separate species, as held by Prof. L. Agassiz, and subsequently contended by Prof. F. W. Putnam.* Nevertheless, Prof. Putnam has shown that the differences between the blind fish (*A. spelaeus*) and their nearest living congeners are much more than in respect to mere color of skin and power of vision. Whether the internal anatomical differences on which he reasonably lays much stress can be proven to be a natural result of the external conditions imposed by cave life, is a question which, if settled at all, must be settled by zoologists alone. Prof. A. S. Packard, Jr., and Prof. E. D. Cope are as pronounced in their opinion that the blind fish have been evolved from fresh-water ancestors possessing good vision, as is Prof. Putnam in the opinion that their ancestry were denizens of salt or brackish water, with which

* The Mammoth Cave and its Inhabitants. By A. S. Packard, Jr., and F. W. Putnam, Salem, Mass., 1879.

he believes that the cave was supplied at a time when this region was a salt or brackish water estuary. Prof. Putnam therefore concludes that the blindness of these fish has been in no respect a consequence of subterranean life.

DISCUSSION.

Mr. BRITTON inquired whether any flora existed in the cave.

Mr. STEVENS replied that, so far as he was aware, no kind of vegetation had ever been found within it.

Dr. NEWBERRY remarked on the geology of the region adjacent to the Mammoth Cave. The limestone beds of this high table-land are jointed in the manner common to rocks, apparently by some sort of polarisation, producing fissures which run in a north and south, and an east and west, direction. The plateau is about 500 feet above the drainage, part of the drainage passing into the Green River, and part into the Ohio. No streams occur on the surface and the drainage is quite gradual. At the angle between these two rivers several streams are seen, bursting out of the cliffs at various heights above the Ohio; they are, so to speak, subterranean sewers, representing the underground drainage of the country; at one point three such streams pouring out of the rock form very beautiful cascades; and near Sandusky a full grown river flows out of the cliff of cavernous limestone. The beds consist of lower carboniferous limestone, with sandy layers beneath. In the vicinity occur portions of the great "blue grass region," one of the oldest parts of the continent, once an extensive highland, forming an island in the sea. Around this, rims of sediments were deposited, consisting of sandstones and limestones; while on the other hand, the continuous process of erosion, during the lapse of a vast period, removed the material of the table-land within, and converted it into a broad depression or basin, the "blue grass region," above which the present plateau of the encircling sediments now rises to a height of 500 feet.

The erosion of the joints in this plateau has resulted in the formation of the pits described by Mr. Stevens, but it is probable that some of these may reach 200 or 300 feet below the Ohio and Green Rivers. There is evidence, from borings in the Delta of the Mississippi, etc., that the Continent was formerly more elevated, standing 500 to 600 feet higher at New Orleans than at present; the drainage was much freer, the Mississippi being a free flowing stream, as well as the Ohio and other tributaries. Borings have been sunk in the present trough of the Ohio river, to a depth of over 100 feet below its present bottom, without reaching the true bottom of the trough, the ancient bed of the river, which is perhaps from 100 to 200 feet further down.

Evidences of the same elevation of the continent were observed in caves on an island in Lake Erie. Long stalactites projected from the roof of a gallery whose end was ordinarily filled with water at the present level of the lake. At times a strong and steady wind has blown down the level of the lake and partially drained this gallery; but even then a guide, John Brown, resident on the island, has swum through the gallery and found the stalactites projecting from the roof as far as he could go.

In regard to the origin of the blind animals, the view of Prof. Cope is probably correct, that they have been derived from the degeneracy of ancestors who once had perfect eyes. No fish is formed with poor eyes; but any organ may be atrophied by disuse, with consequent feeble flow of blood, decreased nutrition, and inevitable shrinking of important parts. An analogy is shown in a comparison of the jaws of prehistoric and modern men. At present our "wisdom teeth" are useless, there is no room for them in the shortened under-jaw; our food being softened by cooking, cut up, and boneless, requires less vigorous mastication; and from disuse, and the consequently insufficient development, these teeth often speedily fall away. In the prehistoric man, on the contrary, the jaws were longer, roomier, supplied with more teeth—the "wisdom teeth" being well developed and kept in strength by constant use on coarse and rough food. The absence of the well-known stimulation produced by light, from the dark waters within the Mammoth Cave, has in the same way resulted in the atrophy of the organs of sight.

CORRESPONDENCE.

The Editor does not hold himself responsible for opinions expressed by his correspondents. No notice is taken of anonymous communications.]

To the Editor of "SCIENCE."

We can sympathize sincerely with the Editor of *The Popular Science Monthly* in his indignation at being held a promulgator of the views of "pronounced atheists," because of his publication of "the papers of Herbert Spencer, and others of his class." "Pronounced atheism" finds little place in the history of philosophy or science, as in the history of mankind and human civilization in general. And Dr. Youmans is certainly in the right with his emphatic denial that Mr. Herbert Spencer, in particular, pronounces himself an atheist and seeks to persuade others to do likewise. He "and others of his class" have, indeed, been very out-spoken in questioning the literal truth of many popular beliefs and sacred traditions. But that there is in "religious ideas" no "vital element," that they correspond to no fact and represent no truth, Mr. Spencer has been far from asserting. On the contrary, the precise opposite is most strenuously maintained by him (see especially Spencer's *First Principles*, Part I.).

And yet, while all this is verbally true, we fear that Dr. Youmans, in his just zeal to defend himself and his friend, both goes too far in his statement of the latter's real position, and forgets those grounds which lend color of justification to the perfectly sincere supposition of many thoughtful people, that the practical, if not the professed or intended, tendency of Mr. Spencer's philosophy, is in the direction of virtual atheism.

If it were really true that "no man of the present age has reasoned out the foundations of man's belief in the existence of the 'Infinite and Eternal Spirit' with such a depth of analysis and logical force as Herbert Spencer," if, as Dr. Youmans further declares, it were strictly true that Mr. Spencer "has sought to show that the 'Infinite and Eternal Spirit,' of which all the phenomena of the universe are but manifestations, is the most absolute of all realities," then religion would owe to him a debt of gratitude, which it is inconceivable that the intelligent defenders of religion should not gladly recognize and avow. But we are at a loss to know on what grounds the above assertions are made by the Editor of *The Popular Science Monthly*. Perhaps it is in esoteric discoveries, delivered to a select few of his admirers, that Mr. Spencer has "reasoned out" the aforesaid "foundations" and "sought to show" the pre-eminent absoluteness and reality of the 'Infinite and Eternal Spirit,' and Dr. Youmans's statements may have been made on the basis of what he has personally been privileged to hear of these discoveries. Thus the writer of these lines was once informed by an admirer of Mr. Spencer's, who had recently come from a personal interview with the philosopher, that the latter believed in "a God"—*supposing, not without a good deal of reason, that this would be a piece of news to one who knew of Mr. Spencer and his opinions only through his published writings.*

It is in the latter way, only, that Mr. Spencer is known to the general public. We, for our part, cannot claim for ourselves familiarity with every line which Mr. Spencer has ever written. But we have studied with great care and with great interest, what we supposed to be Mr. Spencer's of the redistribution of matter and motion. Some of these phenomena have indeed a *mysterious "obverse"*

most important philosophical works, and we do not remember any where to have noticed any evidence of concern on the author's part to prove the existence of an "Infinite and Eternal Spirit." On the contrary, we are every where forbidden by him to regard the Infinite and Eternal, or the Absolute, as either Spirit or matter. Both of these "antithetical conceptions" are held to be purely finite, relative, phenomenal. The absolute is simply "the unknown reality which underlies both," (see *First Principles*, last sentence of the book, *et passim.*) The absolute we are constantly reminded is "wholly unknowable." It is neither Infinite and Eternal Spirit, nor Infinite and Eternal Matter, but simply an altogether indefinable and incognizable somewhat. "That through which all things exist" is in Mr. Spencer's language, "The Unknowable."

The Unknowable is further held to manifest itself to us only as an "inscrutable force" whose operation is exclusively confined to the evolutionary and mechanical "redistribution of matter and motion." Since this operation takes place under the form of rule or law, it is held to conflict with, and render impossible, the supposed "free will," and hence the truly *spiritual nature* of man.

The case is therefore as follows: That there is an absolute reality, we are held to know through "a dim" or wholly "indefinite consciousness," which is called the "*raw* material of mind," but which utterly refuses to be grasped, defined, or known. The "Infinite Something," which is thus demonstrated for us, is, so far as our definite knowledge extends, and hence practically, an "Infinite Nothing." Strictly known to us are only phenomena aspect, which we term spiritual, ideal, or mental. But no scientific interpretation of these is possible, no knowledge proper is possible concerning them, except so far as they are reducable, directly or proximately, to terms of the redistribution of matter and motion in physiological processes. All our definite knowledge, therefore, is both in its data and its substance, exclusively physical and materialistic, and even the "indefinite consciousness," by which we are held to be assured that an Absolute Something exists, in as regards both its subject and object, also physical; it is certainly not spiritual.

Now, if God, provided he exist, is necessarily a spirit; if man, as the subject of religious emotions and relations, must also be a free spirit; and if, as is the case, there is found in Mr. Spencer's philosophy *no recognition of either God or man as a spirit*, then it is obvious that much ground is given by Mr. Spencer for the supposition that his doctrines—considered *per se*, or independently of their author's intentions—*are virtually atheistic and anti-religious*, and those who honestly entertain this supposition are entitled to be met, not simply with a vigorous *assertion* that they are in error, but with a dispassionate and objective demonstration that they are so.

The whole basis of Mr. Spencer's theory of knowledge is, as is well known, sensational and physical. From such a basis it is and has always been found impossible to rise to the recognition of the absolute as spirit, or man as spirit, or to *comprehend religion otherwise than as a necessary historic incident in the development of ideas.* But the whole basis of human knowledge is not sensational and physical. Free religion implies this, and the grander historic forms of philosophy demonstrate it. The *pre-eminent* intention of knowledge in physical science is indeed sense. The attempt to make this criterion universal leads necessarily to agnosticism with reference to the non-sensible (the Spiritual, Living and Powerful). But it is not *science* which dictates this attempt, and *so Mr. Spencer's agnosticism is not to be charged to science.* The rather, it is due to a purely arbitrary determination on his part, supported, it is true, by the influence of a conspicuous line of predecessors in the history of British speculation. The fact that many theologians have been equally—and some of them—*e. g.*, William of Ockham—even more absurdly agnostic than he, is not to Mr. Spencer's credit, but to the theologians' discredit. Besides, the agnostic theologians have generally made vigorous affirmation, on the authority of the heart, of that which to their heads was inscrutable. They have, like Kant, practically affirmed that which seems theoretically incomprehensible. However, all this belongs to the sadder side of the history of human thought. Philosophy and theology have existed and still exist in larger, more positive, and more fruitful forms, founded on a completer science of knowledge, which recognizes the spiritual factor in knowledge, or the knowing agent, and so, necessarily, the spiritual nature in the absolute object of knowledge or God.

We say, then, that Mr. Spencer is by no means to be charged with intentional atheism or irreligion. To theism and religion he gives all the meaning which it is possible for him to give them on the basis of that physico-scientific theory of knowledge, which he sincerely believes to be the only possible one. But this meaning really falls absolutely short of meeting the actual requirements of theistic doctrine and living religion. And Mr. Spencer's doctrine in this regard is not that of science, whether "popular" or otherwise, but of a highly artificial and arbitrary "philosophy" It has no more necessary relation to the doctrine of evolution than to the doctrine of gravitation, both of which have been and are (in some form) unquestioningly held by many leaders in spiritualistic or positive (*vs.* agnostic) philosophy.

The dissemination of the eminently valuable results of Mr. Spencer's scientific labors is certainly in place in a *Popular Science Monthly*. But with what special propriety such a periodical should also be made the peculiar vehicle for the promulgation of his extra-scientific *philosophy* it is hard to see. It is not that we would have a line, which Mr. Spencer has written, suppressed or kept from the knowledge of the world. But regard for the honor and purity of * science, to mention no other consideration, is enough to make one ardently wish that it should not be constructively put forward as sponsor for doctrines whose basis is only quasi-scientific, and which, in truth, belong to another domain—the domain of philosophical inquiry.—GEORGE S. MORRIS, *Professor of Philosophy, University of Michigan; and Lecturer in the Johns Hopkins University.*

THE HOLLAND HYDROGEN FIRE APPARATUS.

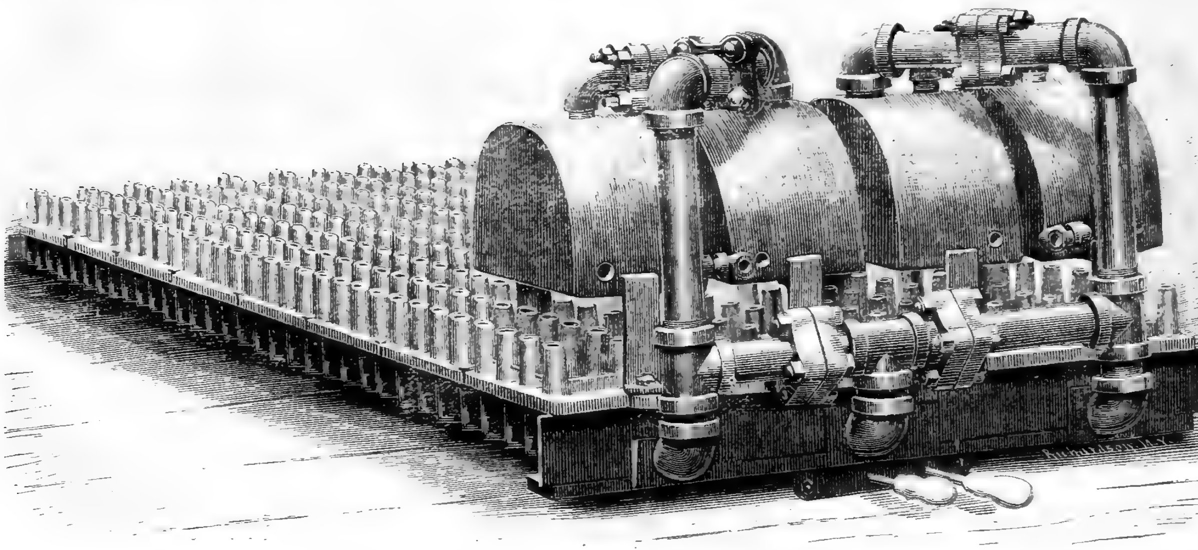
No little interest has been excited during the past year, both in the scientific and practical world, by the remarkable development of results from the Water Gas Apparatus of Dr. Charles Holland, in an ordinary locomotive, as reported by a careful and disinterested observer, through the daily press, and subsequently discussed from a scientific point of view in this journal.

A review of the subject, which has lost none of its importance in the light of further experience and deliberation, will be timely and interesting at the present date.

At Flatbush, the apparatus was placed in the fire-box or furnace of a large (forty-ton) passenger locomotive, of the usual coal-burning pattern, with 16x24 inch cylinders, 5-feet 2-inch driving wheels, and a boiler 23 feet long. In place of the ordinary grate bars are laid three hollow bars or pipes the length of the furnace (8 feet). and from each side of each pipe rise burner-tips at short intervals, making 352 in all. On these pipe-bars, as sleepers, is laid a floor of iron plates studded with open thimbles, through which the 352 burner tips rise to within half an inch of their openings. Over the first 44 burners, next the door, are set four retorts —heavy, hollow blocks of iron—in a row. Two of these retorts receive naphtha, and two water or steam, through separate pipes, and when heated, unite and discharge their vapors through connecting pipes into the pipe bars under the iron floor, and thence through the 352 burners.

The observations at present available enable us merely to compare the firing-up of the same locomotive to the same pressure under substantially equivalent conditions,

* By "science" we mean, in accordance with the now prevalent usage, the mathematico-physical or descriptive science of sensible *phenomena.*



FIRING APPARATUS OF THE NEW HYDROGEN-BURNING LOCOMOTIVE.

first with the Holland Hydrogen Process, and afterwards with coal and wood. This comparison is practically sufficient in a broad sense, yet for more exact purposes it is to be expected that opportunity will soon be taken to obtain the result in pounds of water evaporated per pound of naphtha, and also to exhibit chemically a specimen of the gas. We learn that the boiler of the new hydrogen-burning locomotive, since built at Paterson, after having been tried with very small flue, has proved that the highly expansive and voluminous gas produced requires more room for its most advantageous combustion, and the small flues, are now being exchanged for larger. The production of steam pressure was still more rapid and economical than in the Flatbush experiments, but the heat was so unequally distributed, and the fire so insufficiently vented, through the small flues as to make it evident that they were not adapted to do justice to gaseous fuel as had been expected. For the present, therefore, we are obliged to content ourselves with the latest of the series of tables in which the comparative results of Holland gas and common fuel have been reported.

STEAM, POUNDS.	Time, Minutes.	Naphtha, Gallons.	Naphtha, Per lb. Steam.	Naphtha, per Minute.	Total Naphtha.
10	104	9.9	.09	.054	9.9
20	22	3.21	.32	.146	13.11
30	9½	2.14	.21	.25	15.25
40	8	1.07	.1	.13	16.33
ENGINE MOVES OUT.					
50	10	1.6	.16	.16	17.94
60	5½	1.34	.13	.24	19.27
70	4	1.34	.13	.34	20.61
80	3½	.8	.08	.23	21.41
90	3½	.8	.08	.23	22.22
100	4	1.07	.1	.27	23.29

120	3	.53	.05	.18	24.37
SAFETY VALVE BLOWING OFF.					
130	0	1.07	.1	.18	25.44
BOTH VALVES BLOWING OFF.					

This report concludes with a statement of the fuel used in firing up to 120 lbs pressure in the same locomotive, as follows, on June 20: Half a cord of hard wood, cost $3.75; a large quantity of loose pine stuff not measured; and two tons best anthracite steam coal, cost $10; out of which about half a ton was left after reaching the above pressure. Allowing half a ton of half-consumed coal left in the furnace, say one-fourth of a ton in value, the net cost was over $10, against 73 cents for identical work with the Holland gas; 24.37 gallons of naphtha, costing 3 cents per gallon, being consumed. The boiler was specially adapted for coal, but badly encrusted with scale, to the equal disadvantage of both fuels. The difference in direct cost was more than eleven to one in favor of Dr. Holland. The following description of his fire gives some data for an explanation of this surprising, and yet often repeated and verified, result:

The maturer process attained in the experiment of April 29 (and since usual) gave no light visible by day from without the cavern where it was pent, dark and stormy as the cave of Æolus. Raging, roaring, vibrating with a vehemence that shook the iron monster and the ground beneath, and vied with the increasing din of steam from the valves above and under, it was a kind of ghostly noise as well as heat, that to the more habitual organ of perception gave no sign, but seemed causeless or supernatural. In vain we peered through the mica in the door, or peeped and dodged at the small orifice from which a scorching heat spurted fully two feet. Smoke and smell had clean vanished from all parts long before; no unconsumed carbon anywhere escaped to lend the faintest lustre; the carbonic acid formed in the retorts of course came out transparent and inodorous, and so did the hydrogen, with the product of its combustion, the invisible gas called superheated steam; in short, there was nothing of a nature to be seen or smelt in all this *melee* of nature's great elements. Even the illuminating effect of heat upon iron was lost through the expulsive pressure of gases in the retorts, which doubtless projected the flame too far to heat the thimbles that no longer enclosed it, and now stood, like all else, invisible. All ended and came to light again (save the carbonic acid) in a delicate cloud of vapor that rose from the smokestack scalding hot, but too pure to soil white cambric.

To this description it is pertinent to add the following remarkable fact since observed in the trial of the new hydrogen-burning locomotive at the Grant Works, with the small experimental flues referred to as having been afterwards condemned. The fire had been turned down low and the valves set so as to allow the steam gauge to remain stationary at 120 lbs., which it did with perfect steadiness, showing the peculiar controllability of the heat in this process. After about half an hour of this test, the experiment of turning on double water (steam) into the two water retorts was tried, and the valves were set open for this purpose, without restoring the oil feed. The fire was evidently unchecked, and no further notice taken for a few moments, the engineer sitting with his back turned toward the boiler, as the weather was cold; when a violent discharge from the safety valve suddenly caused him to jump nearly to the middle of the tender from the unexpected shock. The steam had run up to 132 lbs., with which the valve was loaded, before a change had been noticed, and so continued blowing off indefinitely, showing a rate of evaporation many times

multiplied by no other change than the addition of more water (steam) from the boiler.

The phenomena and effects of combustion above cited seem to justify the following statement of theory:

The Holland locomotive retorts liberate a pure hydrogen fuel from the mutual decomposition of certain proportions of naptha and steam. The regular temperature of the furnace keeps the retorts hot enough to disengage the oxygen of steam in the presence of the carbon of naptha, the chemical attraction of these two elements causing them to unite in the proportions of full combustion, and to form carbonic acid within the retorts. The released hydrogen is the only combustible ingredient left to issue at the burners. All the heat of both of these combustions—that of the carbon within the retorts and that of the hydrogen at the burners—is conserved and utilized in the same furnace for the making of steam.

The question now arises on the true causes of the enormous excess of calorific power developed by a given amount of fuel through the water gas process, as compared with the results of direct combustion of the same fuel. Assuming that the amount of carbon entering the retort takes oxygen from the steam with which it mingles, to the proportion of full combustion, and thus liberates just sufficient hydrogen to re-engage the same amount of oxygen; we have first to inquire what proportion exists between the amounts of heat generated by the union of that or any given quantity of oxygen with its proper complements of carbon and of hydrogen respectively. A number of authorities have determined this question experimentally, with results not widely different. According to Grassi, the number of pounds of water raised one degree by the union of one pound of oxygen with its full combining equivalents of carbon and hydrogen, respectively were 2,893 and 4,333. The direct gain by exchange, therefore, would be almost exactly fifty per cent. Numerous experiments by Bunsen and Fyfe are also said to have proved (in indirect accordance with those above referred to) that the fuel (hydrogen) obtained by the decomposition of water, yields a considerable excess of heat above that absorbed in producing the decomposition.

We have made a close scrutiny of the Holland apparatus and its operation for domestic purposes, as exhibited in this city, at the offices of the Heat, Light and Power Company, No. 18 Vesey street. An even pressure of both water and naphtha is secured by an elevated tank for each purpose, at the top of the room. The pipes running from these tanks to the cooking-stove and range are laid in full view, and strict tracing and examination of their course and connections at every point showed that there was no other possible source of supply, of any kind, for the retorts and burners. The oil tank measured 25⅞ inches in diameter, and was computed to hold nearly 2.22 gallons to the inch in depth. In running the cooking-stove, with the oven constantly at a sharp baking heat, the oil was lowered only $\frac{1}{16}$ inch in half an hour, or about one quart (¾ cent) an hour. The whole interior of the store, which had been used a year last May, was free, not only from ashes and soot, but from discoloration, which, obviously, much assisted the effectiveness of the fire, as compared with the coating of non-conducting material accumulated in using crude fuel. It was found impossible to obtain a trace of smoke or odor from the flame upon a white handkerchief; so that, of course, the usual free carbon, hydro-carbon, carbonic oxide, and other gases of crude fuel, could affect neither the atmosphere nor the flavor of food cooked in direct contact with the flame. In the large cooking-range, a third pipe is introduced for the distillation of illuminating gas, simultaneously with the ordinary use of the range. The adjustment and operation excited much admiration. In the progress of the oil through successive coils of this pipe, within the fire box, the several hydro-carbon mixtures it contains are converted, by successive gradations of heat, into a single homogeneous and fixed gas, which resists the most extreme cold of our climate, without condensation, and runs free from sulphurous and other impurities, requiring only dilution with air. After burning a scant $\frac{1}{16}$ inch of oil, the time being taken, the gas-making pipe was opened by simply turning a cock, and in exactly one half the time enough gas was made and measured to amount to 12.55 cubic feet, if diluted to twelve-candle power; when the total oil out was found to be exactly $\frac{3}{32}$ inch, showing a barely perceptible difference from the rate of consumption without making gas, but too fine to measure with the instruments at hand. Roughly allowing it to be $\frac{1}{64}$ for the gasmaking, the cost of the 12.55 feet would be .0347 gal., or about 2¾ gal. per 1,000 feet. This is ¼ gal. in excess of more exact measurement previously taken by gas experts.

But the rough experiment with the locomotive evidences a gain of fully one thousand per cent, from the exchange of carbon for hydrogen, estimating the fuels by cost, in a practical way; although the liquid fuel is of course the dearer of the two, and the gain over the intrinsic value of the exchanged carbon, if it could be ascertained, would therefore be still greater. Fifty per cent from the exchange, then, is at best but five per cent of the total gain, and the remaining 95 per cent must be otherwise accounted for. Nor is there any lack of good reasons for even this enormous difference. In the first place, the carbon is consumed in pure oxygen from steam, no atmospheric air having access to it in the retorts, and therefore the large absorption of heat by the nitrogen of the air that feeds the coal fire, is wholly saved in the water gas process. The consumption is also perfect both of the direct and the produced fuel, against a semi-consumption in the coal furnace. Thirdly, the combustion of the carbon, with all its heat antecedent and consequent, is closely confined in the retorts, from which the heat can escape only by radiation into the boiler, with the exception of the very restricted vent of the hot gases through the burners. Fourthly, the hydrogen obtained issues from the burners at a very high prior temperature, whereas the coal enters the furnace cold. Finally, the hydrogen flame is a vastly more advantageous heating agent than any form of crude fuel, from its unequalled intensity and rapidity of action, and also from its direct contact with the iron, as against the slower processes of radiation and conduction employed by the coal in the furnace. The rapidity with which heat is imparted increases in a geometrical ratio to the increase of it sintensity, and since the hydrogen flame is many times hotter than incandescent carbon, this concentrated heat must have a vastly greater effect, unit for unit, in any given time of passage through the flues. Considering that 90 per cent of direct waste is a moderate allowance in the ordinary firing of a locomotive, it would seem on the whole that we are justified in expecting yet greater economy from this process rather than in theoretically distrusting the results so far reported.

PROGRESS IN MIXED METALLURGY.

By William C. Conant.

Of the fundamental mechanic arts substantially developed before Science or History had a name, Metallurgy was the beginning and the common parent. When Adam was yet in middle life, the genius of Tubal-Cain divined and explored the capabilities of the workman's metals, copper, tin, zinc, and iron; fused and mingled them, wrought from them the tools of every craft, and became "the instructor of every artificer in brass and iron." It were hopeless, therefore, to question subsequent records of Time for the era or the occasion of any of the more essential developments in this art of arts. So far as the native surface metals are concerned, it is probable that all the more important metallurgical processes were understood, for substance, long before the flood. Copper and tin, the principal ingredients of bronze, being found comparatively pure at the surface, were naturally the earliest

metals combined and used for mechanical and military purposes. The same precedence of these metals continued, locally at least, and, so far as can be discovered, down to historic times. The Roman historians record it. Weapons, armor, and tools of bronze, hard enough for cutting granite, abound among the remains of primitive antiquity, and have given to that vague epoch the title of the age of bronze: the so-called stone age being of no particular order in time, but rather the universal age of savageism, from the earliest vagrants of the human race down to the recent aborigines, so-called, of our own country.

The disposition to try what will come of mixing materials may be assumed as a prominent native factor of invention in all ages, and as especially prominent in the infancy of knowledge, when every material and every property of materials was a mystery only to be experimented on. Nay, the bare factor of accident would be sufficient to insure the mixture of various metals, ores and earths in the very first experiments. Copper and tin coming out first, as bronze, at once stimulated and assisted an eager search for further discoveries. They built the furnaces and quarried the fuel that ultimately brought to light the treasure concealed in dull brown rocks of iron ore. The more facile ore of zinc (in the presence of copper) if accidentally at hand, would enter earlier, or, possibly, earliest, into the kaleidoscopic series of the smelter's products, with the most exciting brilliancy of effect; promising coveted gold without limit, and preparing, perhaps, the first sad catastrophe of inventive expectation unrecorded in any patent office or prospectus of incorporation. Down almost to the 19th century (1781) brass was made by mixing the zinc ore directly with copper; and down to the 16th century this had been done, from the earliest times, without a suspicion that the magical stone was anything but one out of hundreds of like mysterious minerals, among which a potent and supreme "philosopher's stone" might yet be found. No wonder that infinite possibilities of metallic splendor and preciousness stretched out before the imaginations of the alchemists in the vast field of unexplored mineral combinations before zinc was discovered as a metal and the nature and scope of the alloys were defined.

To these limitations, however, modern philosophy and discovery have given a new and again undefinable extension. They have not revived alchemy, but they have revived a more trustworthy probability, and a more philosophical pursuit of radical improvement in the character of the alloys. In general it may now be stated that the labors of new experimenters with the new lights and resources already promise to popularize little less than the beauty and incorruptibility of the precious metals in the equipage of common life and arts, and in combination with some of the qualities hitherto inseparable from a coarse, dull and corruptible texture, as in iron.

The discovery of nickel and German silver were marked steps in the direction of the new era, yet failed to approximate it; as we see in the fact that nickel has proved hitherto but a material, and German silver a basis, for the temporary and unsatisfactory varnish of beauty called plating. Nickel was found too refractory a metal to be worked solid for purposes of general utility or even of ornament. Qualified by other metals, as in German silver, the same refractory temper still rendered it impracticable, except in proportions too small to impart its clear color and splendor, with its clean, resistant texture and temperature, to the composition formed. Every workable substitute for silver betrayed, more or less, a constitutional sickliness, of jaundiced tint, sweaty feel, and corrupt odor. No actual progress was possible until the discovery that the refractory quality of nickel was due to its absorption, when in a molten state, of certain gases which might be chemically removed. This discovery was made and published in Germany, two or three years ago, with the magnesium method of purifying and reducing the metal to malleability. In practical results, however, we know of little to report as yet from the other side of the Atlantic; whether it be on account of expensiveness in the process, or inability to form alloys of this in itself too expensive metal that are satisfactory at once in cost and in qualities. One suggestion of possibly great importance comes from the German nickel manufacturers, in the comparison of the purified metal with Bessemer steel, with which it is represented to be almost identical in practical properties; raising even a suspicion in some minds whether the two may not be modifications of one metal, or of some protean metallic element, of unconjectured range. The whole range of metals, indeed, would not be more extreme, nor, perhaps, more difficult of practical reconstruction than that of carbon. The speculations and partial successes of Mr. Lockyer in the direction of a theory of unity, or rather of duality, and convertibility, in matter, are here forcibly recalled to mind; suggesting that all its families may be the progeny of two universal parent substances, such as hydrogen and oxygen. What if the truth of Nature, after all, lay, metaphorically, near to the surface and to the mystical vision of the old child-like sages, who saw in the "elements" all-generative powers, as Science finds in one of them (fire) a form, and as represented in the Sun the prime form perhaps, of all organic energy? What if Science should yet discover that the alchemists themselves had a true, if not practicable, end in view? Man's dominion in Nature is too marvellous in its present beginnings, for anything to be incredible as to its future perfection.

On the American side the modern philosopher's stone has beensought of late years, with sanguine ardor. A number of different fortunes of respectable size have been sunk in the melting-caldrons, out of which have arisen a succession of bright apparitions, only to prove intractable for use, or turn the old inevitable sickly cast after brief shining. None of our practical experimenters, so far as I am aware, have struck the true lead, the purification of nickel, with one exception. No other man of our day, probably, has given so many years of metallurgical labor so hard and practical, together with study so profound, to the assimilation of the necessary alloys for gold and silver, to the appearance and properties of those metals, as Mr. Charles Wessell of New York. What our chemists may have accomplished, or seemed to accomplish, with a few ounces of metal in the laboratory, it is of less importance to inquire than would be generally supposed. Such achievements, whatever they might be, would have no necessary value, or even validity, in practice: none possible, indeed, unless there were given with them a practical metal-mixer uniting scientific genius and research with the technical knack and stalwart physical capacity for handling metals by the ton in the furnace, to the purpose for which he intends them. Mr. Wessell, indeed, meets this description; but it would be needless to tell any manufacturer of brass or German silver, that no other known counterpart exists. The men they depend on for this service work solely by blind knack, which they catch and lose alternately in the most unaccountable manner, contributing a material percentage to the market cost of these common compositions by their own inevitable percentage of uncertainty, failure, and destruction of materials.

Charles Wessell, the metallurgist of the Holmes & Wessell Metal Company of New York, came to this city from Rome, in this State, a modest working man, whom the future famous discoverer of a genuine popular rival to the precious metals must make haste to head off, if indeed it be not already too late. It is thirteen years since Mr. Wessell began his metallurgical experiments and inventions, by undertaking successfully to electro-deposit a combination of three metals which most chemists would even now pronounce it impossible to hold together under the battery. A very distinguished chemist to whom the product was submitted, gave this assurance in absolute

terms, before making his analysis. His own analysis confounded him; he frankly certified the three metals found in the deposit; and in his subsequent lectures has referred very pointedly to undiscovered possibilities in the philosophy of metals. Undiscovered—for it is the good fortune of the solitary discoverer that the mediating agent vanishes in his thaumaturgic-metallurgic act into thin air, leaving no clue by which the scientific detective can shadow him as yet. Hence it is impossible for the metal worker, or even the chemist as yet, to recast certain of the Wessell metals; since it is too much to ask of him to give away the "combination" that locks his own hard-earned reward against the rapacity of mankind. Science itself must be content for the present with the accomplished facts shown, and with what their author can afford to disclose of methods and principles. Thus, it has become possible to give the necessary alloy to silver and gold with more suitable ingredients than could be used heretofore; ingredients which but imperceptibly deteriorate either the color or the incorruptibility of the precious metals, and, so far as silver is concerned, effect even a remarkable improvement. Stranger results have followed and are still progressively following, from the same discovery, in building up towards gold and silver from the basis of alloys. All of Mr. Wessell's novel compositions—already sufficient to constitute an era in the history of the art—have their origin and their constant method of development in that stroke of genius; for I know not what else to call it in view of the systematic unfoldings and correlations of it in the hands of the same master. The depositing battery, instead of the crucible, is the instrument by which the practicability and the effect of every combination conceived by him is tested in the first instance. As a consequence, partly of this scientific certainty in method, partly of practiced genius in adjusting heat and other delicate conditions according to bulk, weather, color, radiance, fumes, and the hundred unspoken mysteries of his art, Mr. Wessell's matured mixtures, from common brass and German silver upward, come out uniformly and infallibly what they are intended to be; astonishing to veteran manufacturers of metals who have associated him with them in their affairs, and a fact which I hazard little in opining to be without precedent in mixed metallurgy.

In the course of his novel processes of research, Mr. Wessell discovered, probably first, or at least long before it was promulgated elsewhere, the secret of making nickel pure and malleable, and not only so, but also of keeping it pure and malleable, throughout all combinations, processes and proportions, in which he chooses to introduce it. Magnesium was first or independently tried by him; but discarded for a more practical and economical agency, incidentally discovered in experimenting on qualifying or auxiliary mineral ingredients. The means also by which it turns out that the gases so fatal to nickel are kept out after being once eliminated, were a part of the general precautions of an extremely vigilant and, as it were, sensitive operator, rather than preconceived expedients for that express purpose. The methods and results are no worse, perhaps all the better, that their theory was learned from them, rather than they from the theory. It became a significant observation to Mr. Wessell, that various metals, malleable in the original smelter's ingot, grow unmalleable by remeltings. He reasoned that in the large smelting furnaces, from which the metal is drawn off at the bottom, the most of the mass is secluded from unfriendly influences, whatever these may be, until it is suddenly poured into close moulds and cooled: whereas, in the small open furnace or crucible of the foundry, the metal is poured off from a freely exposed surface; suggesting that to his own closely-covered processes was due the continued freedom of the metal from the refractory temper once extracted.

With the chronic intractability of the superior metal has been removed the hitherto insurmountable obstacle to its introduction in sufficient force to impart its noble qualities to a workable composition. It can now be used in any percentage necessary, and the Wessell process for malleability, unlike the German, is one that adds no extra expense. Its remarkable lustre and beauty of color are now as familiar as those of silver, through extensive use in electro-plating, and are rapidly approaching equal favor in the public taste. What is not so familiar to most minds, is the palpable superiority of nickel, at all points, for fine utensil service, such as we require of spoons, forks, knives, &c., for the table. Color is a matter of taste; but there is no disputing the superior durability of lustre and polish as well as of form, that belongs to the harder metal. It yields only to gold in point of resistance to oxidation and corrosion, and defies the attacks of organic acids, sulphur, &c., that instantly mar the beauty and cleanliness of the best silver. Still less commonly understood is the force of character, so to speak, with which this metal suppresses the meaner colors and weaker susceptibilities of lower metals united with it, by its own noble qualities, even when the odds in quantity are largely against it. To this we already owe solid Wessell-silver table ware, not noticeably inferior in any respect to pure nickel, yet at no greater cost than the perishable sham of plated goods. Manufacturers of the latter may not look with favor on the substitution of goods that would last four generations for goods that must be renewed four times in a generation. But such a revolution as this comes of its own weight and carries all before it. The present vast production of plated ware must in a few years become a mere reminiscence, in all its numerous departments.

To an important class of readers and interests, the bearing of Mr. Wessell's discoveries on the metallurgy of gold and silver will seem most worthy of attention. Alloys are necessary to these metals, both for mechanical and commercial reasons. It is no longer necessary, however, to impair their properties or appearance in making them workable or saleable. All grades of gold treated with the Wessell alloys are of uniform color and lustre with eighteen-karat gold, and require more than usually severe and expert testing to detect any differences whatever, between them. By way of illustration, it may be stated that the alloying compositions themselves do not oxydize perceptibly when exposed to the action of the atmosphere in cooling from the molten state, nor yet in the process of granulation. Manufacturing jewellers pronounce the alloy for gold in all respects equal to eight-karat gold itself, although there is not a particle of gold in it. The alloy for silver is a specially important improvement in the non-tarnishing quality. This may be illustrated by an incident in the experience of a leading manufacturer of sterling silver ware—the celebrated Whiting Manufacturing Company. A quantity of sterling had been made up with Wessell alloy, according to standard, 925-1000ths fine. Of the goods manufactured from this lot, a few were wrapped up with others of the same standard (uniform in all the goods of these manufacturers) but made with the usual copper alloy. After lying some twelve months forgotten and undisturbed, the parcel was met with in taking account of stock and opened. The regularly alloyed metal was found coated with the inevitable black oxide, while the original brilliancy of the Wessell-alloyed metal had barely acquired a warm tint. The writer is indebted for this information to one of the chief managers of the Whiting Manufacturing Company. The alloyed silver, electro-deposited on a spoon by Mr. Wessell, was declared pure by the testing chemist of one of our large plating establishments, who hotly called the metallurgist a fool to his face for insisting that it was or could be otherwise. Being requested to expose the spoon to the action of sulphuretted hydrogen in company with another of chemically pure electro-plate, the chemist was non-plussed by finding that while, of course, the latter was instantly blackened, the

color and brilliancy of the Wessell-alloyed silver remained unaffected. The same peculiarity has been observed by the writer personally in Mr. Wessell's low-priced nickeline metal, which holds a pure and strong lustre throughout indefinite exposure to every test that befalls (and befouls) a silver spoon in domestic use.

"INTEGRAL LUBRICATION."

Integral lubrication is an expression that has been selected to describe the effect of a lubricating element which is itself an *integral part* of the surfaces in contact and relative motion, as distinguished from a foreign or extraneous lubricant introduced between the surfaces, requiring constant renewal, and subject to displacement, consumption, waste, deterioration by heating, &c., and to various other imperfections and inconveniences.

Friction results from the resistance of particles in contact to change of position. Lubrication consists in their non-resistance to change of position, as in fluids. Within themselves, therefore, fluids have the property of integral lubrication. Interposed between solid surfaces, whose fixed particles resist change of position, fluids serve to separate such surfaces by a stratum of non-resistant or mobile particles, and thus supply *extraneous* lubrication.

The idea of establishing the lubricating, non-resistant or mobile element integrally in the bearings themselves, rather than extraneously as a distinct intermediate stratum, was the conception of Dr. Stuart Gwynn, the noted engineer and inventor, of two generations, to whom we owe the Gwynn pump and numerous other long established appliances. This idea is the basis of more than twenty patents, relating to the series of compositions by which it is realized under different conditions, all known under the common designation of METALINE.

The conception of union between the opposite properties of solidity and non-resistance, and of integrity and distinctness, in one metallic body, certainly had the boldness, as its realization showed the power, of a stroke of genius.

The important point to be reached by Dr. Gwynn, after his discovery of the possibility of "Integral Lubrication," to render it of practical value, was to make exact determinations of the effect produced on metals, their alloys, oxides, etc. by enormous pressure when they are put into hardened steel moulds of great strength. These trials extended over several years of time and under pressures from five tons or 666⅔ atmospheres to one hundred tons or 13,333⅓ atmospheres per square inch. In these trials he found, without doubt, the true law of the "*Flow of Solids.*" His determinations were finished in 1860.

This department of physics has, since then, been extensively worked by other scientists, and many of the results arrived at have been published. One of the latest of these contributions is an interesting memoir published in 1881 in the "*Revue Scientifique,*" by Mr. W. Spring, a German chemist, from which we abstract as follows:

The substances experimented with were taken in the form of fine powder, and subjected, in a steel mould, to pressures varying from 2000 to 7000 atmospheres per square centimeter. Lead filings under a pressure of 2000 atmospheres were transformed into a solid block which no longer showed the least grain under the microscope, and the density of which was 11.5, while that of ordinary lead is 11.3 only. Under 5000 atmospheres the lead became fluid and ran out through the interstices of the apparatus. Toward 6000 atmospheres, zinc and tin appeared to liquefy. Powders of zinc and bismuth at 5000 to 6000 became solid blocks of a *crystalline* fracture. Powders of soft and of prismatic sulphur were transformed into solid blocks of octahedric sulphur. Red phosphorus appeared to pass into the denser state of black phosphorus. Binoxide of manganese and the sulphides of zinc and lead in powder, *weld* when compressed, and exhibit the appearance, respectively, of natural crystallized pyrosulite, blende, and galena. A number of pulverized salts solidify through pressure and become transparent, thus proving the union of the molecules.

The common property in Metaline and the natural lubricants (fluids) is, of course, mobility or non-resistance to change of position in the particles. This property or effect, results, again, from exceeding minuteness, hardness, roundness and polish of particles; obtained in the artificial instance, by pulverization, attrition, and extreme sifting of metallic particles. It is obvious that the particles of soft or brittle substances, such as flour of wheat or dust of stone, are not capable of the rounding polish and consequent slipperiness (integral lubrication) of metallic particles; nor yet of a kindly interpenetration with the surface particles of solid metal. Hardness, also, or resistance to change of form, coupled with non-resistance to change of position, may be an essential requisite to fluidity; so that possibly the particles of water or oil may be much harder as well as finer than those even of metals. The metals, however, are generally susceptible of a degree of polished and rounded comminution that yields a very slippery product. The fluid-like mobility of small shot is a rough illustration of this condition.

The next stage of the invention is to penetrate and incorporate the solid bearing surfaces with the non-resistant or mobile particles. This is effected by two operations, one the product and complement of the other. The prepared particles are in effect compressed into frequent sockets in the bearing surface, so as in the first place to occupy directly the larger part of its area, and in the second place to allow the outer particles (slightly raised) to attach to the microscopic inequalities of the revolving journal, and so migrate, filling both surfaces with a fine permanent ingredient of particles non-resistant to change of position. The particles are forced in with great power, by running a heavy journal at moderate speed, or a light one at a swift rate, with the cap screwed tight enough to stop the machinery or twist off the journal if oil instead of metaline were the lubricant. Under such incalculable concentration of force, the particles, instead of being worked out from between the surfaces, are held and incorporated, forming new surfaces of a permanent but peculiar character. Thenceforward, the interaction of these surfaces works infinitesimal movement, or mutual yielding to each other in their numberless infinitesimal particles, which nevertheless retain permanent cohesion by the same law that unites the more fixed particles of the solid metal; a state of movement in stability, foreign to our sensible impression from solids, yet quite as conceivable as the universal molecular motion supposed to constitute heat. A mechanical union of metallic substances seems to be realized, as different in effect as in method—and yet perhaps not so different in principle—from the results of cofusion or amalgamation.

There is nothing in experience to indicate abrasion between these surfaces, except from the gradual breaking off of the high points which the microscope reveals on the surface of the most highly polished journal, projecting above the metaline surface. In the course of years of running on heavy bearings, these points (which so rapidly blacken oil where it is used as the lubricant), become dislodged in such quantity as to cover the surfaces with rigid specks looking like emery under the glass. To prevent this, it is found advisable, once in two or three years, according to circumstances, to replug the bushing or box with metaline (again projecting a hair's breadth) so as replace that which is removed. By this means the bearings improve with use and progressively acquire a higher and higher finish, such, as tested by the microscope, that it is impossible to approximate it by any other method of finishing. Running in oil, on the contrary, wears out journals and misshapes boxes. The longest periods for which journals have as yet been run in metaline—say ten years—have developed no heating or wear, if the bushings have been properly cleaned and replugged once in two or three years. A "shakeless fit" can be secured with metaline, which, as before remarked, would render movement impossible with any mere interposed lubricant. Journals in metalined bearings, under the heaviest weight, or at the highest rate of speed (as in spindles and polishing lathes)

and even hot, as in the case of calendering and laundering rolls, or coffee-roasters, run perfectly dry, the year round, without attention, without heating unduly, or being injured by external heat, without perceptible wear or loosening, and with a usual reduction of power required, as compared with companion bearings running with oil under the same conditions. Thus the cost of oil is entirely saved while the cost of power is materially diminished; the usual wear of journals and bearings is practically eliminated, while the fit is so close as to exclude dust and preserve or rather improve their round and polish; the labor of cleaning and oiling, and interruptions and bills for repairing are saved; the greasing of fabrics, goods, buildings and machinery is abolished; and the serious danger of fire from oil and the spontaneous combustion of oily waste is wholly removed.

The authority for these comprehensive statements stands in the form of numerous certificates from prominent manufacturing firms, a few of which it will be only proper to cite in this connection, using their own words. Thus: Messrs. Bagnall & Loud, the Boston manufacturers of pulley-blocks, certify that their planing machine was fitted with metaline bearings four and a half years ago, and is still running on the same at the rate of 5000 revolutions per minute, averaging six or seven hours a day. No oil has been applied, and the shaft shows as handsome a polish as could be desired.—Day, Farrington & Co., hardware manufacturers, Brooklyn, report that their emery grinder, with heavy journals running 1600 revolutions per minute, after three and a quarter years without oil or attention, required new bushings from neglect to replug with metaline, which would have kept them up indefinitely. "The journals are a shakeless fit, and run cooler than another grinder running in oil."—In the machine shops of the New York & Harlem Railroad, a circular saw and a Daniels planer had been running on metaline bearings, 1800 and 2000 revolutions a minute, respectively, for three and four years: no lubricants being used, no care or attention being given them, and no wear perceptible.—The Inman line of Atlantic steamships, have used metaline in their wharf machinery for ten years. Their wharfinger and engineer certify to having used metaline gibs on a forty-horse wharf-engine for five and a half years, without lubrication or perceptible wear: where both gibs and slides running in oil used to cut out and require replacement every few weeks or months.—The Excelsior Brick & Stone Company, Philadelphia, state that the metaline bushings of their loose pulleys—48 inches diameter, 12-inch face, 2⅞-inch bore, friction-clutch, and runing 225 revolutions a minute—are as good after four years as when first put in, and fit the shaft as well, having had no lubrication or attention whatever.—The Washington Steam Laundry, New York, state that they introduced metaline bearings for the heated rolls of their ironing-machines about four years ago; resulting in complete relief from the constant difficulty, disadvantage and expense caused by such machinery running with oil.—A number of the most prominent manufacturing jewellers in New York, give certificates to the same effect with that of Baldwin, Sexton & Peterson, who say that they have used metaline bearings for five years without lubrication, at very high speed on polishing-lathes etc., the journals running cold and with less power than others running with oil.—The Windsor Hotel, New York, after using metalined gibs for passenger elevators for several years, certifies that they are in good order and save the difficulty of keeping the well-way clean and free from the smell of oil.—One of the most extreme pressures that could be tried was that to which the leading blocks were subjected in hoisting granite and iron for the New York & Brooklyn Bridge, frequently causing a strain of four tons on a sheave. Before introducing metaline, the bushing and hardened steel rollers of a patent sheave would be cut completely out (says Engineer Collingwood) in four or five days. "Since metaline was put in, (over 18 months) we have had no occasion even to take out the pin, nor can we discover any appreciable wear."

We learn from *Iron* (London) the contents of a paper read by A. H. Bateman, Esq., F. C. S., before the British Association of Foremen Engineers and Draughtsmen. Mr. Bateman stated that, in London, there had been running, on metaline bearings, for the best part of a year, various kinds of main and counter shafting from 1½ to 3½ inches diameter, and from 150 to 450 revolutions per minute, loose pulleys as high as 700, and latheheads, 2000 revolutions. Elsewhere in England, there were five-inch shaftings and calendering rolls, under more than ten tons pressure; also, spinning frames, circular saws, planing machines, sewing machines, printing machines, cranks, bicycles, etc., running on the same material, without the use of oil. Works have been established on an ample scale in Dundee, Scotland, for metalining all kinds of machinery.

On the practical importance of this invention it seems unnecessary to enlarge, as every practical mind realizes at once that its value must be as diversified as the uses of machinery, and its desirable applications would form a catalogue too long for reading. A few of the lines of vast extent, in which beginnings or preparations have been made for applying metaline, may be noted with interest. The value of metaline to the millions of sewing machines in use suggests itself forcibly enough, from the repulsiveness of oil to the ladies who use them in contact with their carpets and clothing, and in making up rich and costly or delicate fabrics, which a spot of oil from the machine often ruins. The time taken up in oiling the machine is a burdensome tax on the operator, and the destruction of thousands of machines, through forgetfulness to oil them, is a still larger loss. Moreover, the nearly frictionless running of a metalined sewing machine yields the operator a sense of almost spontaneous motion in the instrument, and a delightful relief to the usual fatigue of propelling it; a strain which has, in fact, resulted in sad consequences to many female constitutions. No less obvious, too, is the value of integral lubrication, from its absolute cleanliness, in all machines for making and dressing fine fabrics of any kind.

Railroad journals running with oil cause daily detentions on every road, and frequent disasters by heating their boxes until the Babbitt or other metal is melted out and the train can be moved no further without great caution, delay and danger. A tragical train wreck resulted in Iowa, but a few days since, from the bursting of a wheel by a hot journal, in consequence of the exhaustion of the oil. Great numbers of men are constantly employed in examining, cleaning and oiling, and the expenditure for oil alone is an enormous amount, as well as that for replacing worn-out bushings and axles. When once a car or locomotive is properly fitted up with metaline bearings, these are all in order for one year at least, without a penny-worth further of material or labor, and without a possibility of danger or detention from hot boxes, want of lubrication, or wearing-out of journals and bushings.

Under the several patents for special applications, such as these and others, the American Metaline Company gives exclusive privilege to proper parties wishing to develop a particular use of metaline as a specialty. Metalined sewing machines are already the property of a New York company under the presidency of Madame Demorest, of fashion and pattern fame. Railway cars and engines are to be metalined by a close corporation of capitalists headed by Wm. Jennings Demorest, Esq., with a capital of $3,000,000. The application to sheaves, pulleyblocks, &c., has been taken up very successfully by Bagnall & Loud, Boston. Samuel S. Webber & Co., Manchester, N. H., have the manufacture of metalined spinning frames, &c., which has been tested thoroughly for years, and is now going into mills with many thousands of spindles. Metaline packings for steam, water and gas joints, pumps, &c., &c., are a specialty of Frank

Baldwin, 33 South street, New York. The Hopkins and Dickinson M'f'g Co,, 76 Reade St., N. Y., and Darlington, N. J., have the exclusive specialty of metalined sliding door sheaves and builders' hardware generally. But these illustrations need not be extended.

THE SUN.

By Professor C. A. Young.

To the Editor of "SCIENCE."

Dear Sir,—May I avail myself of the columns of your journal to correct a few serious errors which have come to light in my recent book on the Sun.

P. 16, near bottom.—The interval from the vernal equinox to the autumnal is 186 days, instead of 184, as stated. Of course the remaining part of the year is 179 days, not 181.

P. 44.—The earth would fall to the sun in about two months, not four.

P. 240, 241, and 279.—The candle power of the sun is given just four times too great. The figures printed express the number of candles which, distributed over the surface of an opaque globe, would give the same amount of light the sun does, each flame being considered as a small FLAT radiating surface.' But this does not express the true ratio between the sun's light and that of a candle radiating freely in all directions.

P. 271.—In the formula for the number of calories of heat generated by the stoppage of a moving body, the denominator ought to be 8338 instead of 850. The factor g (9.81^m), having been accidentally omitted. In consequence, a few lines below, another 850 becomes 8338 also, and 300° becomes about 30°

There are a number of other minor errors, which it is hardly worth while to notice here, though they will be corrected in the second edition. C. A. Young.

To the Editor of "SCIENCE."

A friend of mine who is a reliable observer relates an incident which forcibly illustrates the power of parental affection to overcome fear. The gentleman found a nest of young mice and removed them to the ground near by. The mother mouse made her appearance and carried away one of her young and while she was gone the gentleman took the remaining mice in his hand. When the mouse again appeared and could not find her young she seemed to hesitate a moment and then ran up the gentleman's clothes, took one of the young and carried it away. This was repeated until all the young were removed to a place of safety. J. H. PILLSBURY.

Springfield, Mass., *Dec.* 27, '81.

BOOKS RECEIVED.

A Treatise on Comparative Embryology, by Francis M. Balfour, LL. D., F. R. S. Vol. II. Macmillan & Co., New York, 1881.

An extended notice of this admirable work will appear later, we now simply announce that Messrs. Macmillan are ready to supply the second volume which completes the work, and we feel sure that every Biologist and Anatomist will avail himself of the mass of information included in Professor Balfour's book, which in competent hands must prove one of the most valuable aids to original work in this direction.

Elementary Lessons in Electricity and Magnetism, by Silvanus P. Thompson, Professor of Experimental Physics in University College, Bristol. Macmillan & Co., Bond St. New York and London. Price $1.25.

An Elementary Treatise on Electricity. By James Clerk Maxwell, Professor of Experimental Physics in the University of Cambridge, England. Clarendon Press Series, Oxford, 1881. Price $1.90. Imported by Macmillan, Bond Street, New York.

Students, and the many practical men who are now studying Electricity with a view to its application to the manufactures and arts, will find that these two books will exactly meet their requirements, in being comprehensive thoroughly practical and reliable. Those who cannot purchase both works, should commence with that by Professor Thompson, and follow with Professor Maxwell's as being more advanced.

The doctrine of the *Conservation of Electricity*, now growing into shape, but here first enumerated under that name, is thoroughly explained in Professor Thompson's book, and may be studied with profit by all interested in the science of electricity. This theory teaches us that we can neither create nor destroy electricity, though we may alter its distribution. According to this view all our electrical machines and batteries are merely instruments for altering the *distribution* of electricity by running it from one place to another, or for causing electricity, when accumulated or heaped together in one place, to do work in returning to its former level distribution.

Ideality in the Physical Sciences. By Benjamin Peirce. Messrs. Little, Brown & Company. Boston.

This work by the late Professor Benjamin Peirce is an admirable illustration of the fact, that a man of individuality and sound judgment may pursue the highest scientific work and still find himself in harmony with the religious sentiments of his fellow man.

A great portion of this work is devoted to a review of past astronomical research, and will be read with interest as a reliable exposition written for those who require scientific work explained in simple language.

Photographic Exhibition.—The substitution of a film of dried gelatin for the thin layer of wet collodion, which the photographer formerly employed as a vehicle to retain the sensitive salts of silver in a suitable condition on his glass plate, has involved considerable alterations in the mechanical appliances used in photography. For out of doors work, or work away from home, the photographer no longer requires to carry what was practically a portable laboratory. Not having to "develop" his pictures on the spot, he need take with him neither dark tent nor chemicals. On the other hand, he must have some provision by which his store of dry plates can be placed, one after the other, in the camera and properly "exposed" without the risk of the slightest particle of light reaching their sensitive surface, other than the light properly directed upon them by the lens. As he wishes to carry an ample supply of plates with him, and as the glass plates themselves make an appreciable burden in a long walk, it is essential that the apparatus for carrying them should be as light as possible; hence have arisen considerable improvement in the camera and its "slides." Again, the increased sensitiveness of the gelatin films makes it possible to give exposures shorter than can be affected by the hand uncapping and re-capping the lens; hence the invention of numerous "instantaneous shutters," by which exposures of a few hundredths of a second can be given, and pictures of moving objects readily secured. These are but instances of the many novel appliances which recent progress in photographic science has originated, and, besides these, there has been, during recent years, many and important improvements in the application of photography to the production of permanent illustrations for books and newspapers. All these varied applications of the art are to be illustrated by an exhibition of photographic appliances which the Council of the Society of Arts announce will be held during January and February next, in connexion with a course of Cantor lectures to be given before the Society by Capt. Abney. Full particulars of this exhibition are given in the *Journal of the Society of Arts* for last week.

STANDARD TIME.

At present there are said to be more than seventy distinct "railroad times" in the United States; in some single cities there are as many as four, differing from each other by amounts varying from five to twenty minutes. This state of things of course involves confusion and inconvenience to travellers, and all Americans travel. In some cases it has been the cause of serious disasters.

It is beyond doubt, then, that there would be great advantages in a uniform standard of time for the whole country. Can they be secured without too much counterbalancing inconvenience and expense? We believe they can, and without any very great difficulty.

A *single* standard for the United States (and still more, for the whole world), while in many respects highly desirable, would be exposed to the fatal objection that it would bear no relation to the true local time determined by the Sun's position. Now this local time is what we must necessarily live by. Nature compels us to work by day and sleep by night; to rise in the morning and retire at evening. A time-standard which does not recognize this cannot be practically convenient, and will never be adopted. Suppose, for instance, that Washington time were made the standard for the country; at San Francisco every thing would be three hours out of joint; and though undoubtedly, such good people as live there, and always stay at home, could, after a while, become accustomed to having noon come at 3 o'clock by their watches, and other things to match; yet there would probably be some grumbling first. Changes so radical are always hard to accomplish. But, what is worse, whenever the San Franciscan journeyed, or changed his residence, he would have to unlearn all his time-relations, and begin again.

In fact, if a uniform time-standard were adopted over the whole world, all allusions to the time of day in literature now existing, such statements of the hour as are involved in almost every accurate description of an event, would become unintelligible except by a process of translation.

The late Professor Pierce proposed a plan, which, while securing most of the advantages of the uniform standard, avoids its worst difficulties. It is to adopt, not *one* standard for the country, but a series of standard, (*four* would be needed) agreeing exactly in their minutes and seconds, but differing by entire hours. We should then have Atlantic time, Mississippi time, Mountain time, and Pacific time. Since the minutes and seconds would be everywhere the same, telegraphic signals from a correct clock would be directly available for regulating the time wherever received; the difference of one or more entire hours could never cause confusion. And yet the standard time at any place need never differ more than thirty minutes from the true local time. This amount of difference, though of course in itself undesirable, is not so great as to be intolerable in view of the attendant advantages. We hardly notice the discrepancy of fifteen minutes between sundial and clock, which occurs at certain seasons of the year, in consequence of the Equation of time.

As to the time to be chosen for the standard of minutes and seconds, unfortunately there is not yet an agreement among our astronomers. Naturally enough many think it should be Washington time, just as in England, Greenwich time is used. So far as landsmen are concerned it is really a matter of almost no importance what time is selected, but with the shipping interest it is different. Almost all nations use Greenwich time on the ocean; and for this reason it would probably be best to lay aside national prejudice, and make our Atlantic time differ from Greenwich time by just five hours; this would agree with the correct local time for a meridian passing between New York and Philadelphia. The meridian of Mississippi time (six hours from Greenwich) would then pass between Chicago and St. Louis, that of mountain time would run near Denver, and the Pacific meridian near San Francisco.

The meridian theoretically dividing Atlantic from Mississippi time would nearly bisect the State of Ohio. In a case of this sort the legislature would be likely to adopt one or the other of the two times as the standard over the whole State; so that in practice the boundaries between the standards would probably follow State lines.

The establishment of some such system need not be very difficult or long delayed.

The Signal Service proposes to receive by telegraph, from such observatories as choose to co-operate, their respective time-determinations; to combine them, and then to transmit the resulting standard-time daily to every important place in the country; besides this, at every port they would drop a time-ball, at some exact hour of Greenwich time, so that navigators would be able to rate their chronometers.

At present we have a number of more or less extensive and accurate time-services run by different observatories. But the signals sent out are more or less discordant, not unfrequently to the extent of one or two entire seconds, for the simple reason that no clock can be depended on for any length of time unchecked by star observations; and such observations are sometimes prevented by cloudy weather for several days together. Since it would seldom happen that the observatories in widely different parts of the country would all have bad weather at once, the Signal Service plan would obviate the difficulty. The most serious objection to the proposal seems really to be that the observatories which now distribute time would lose the revenue they derive from the work, unless, indeed, as would be only fair, the Signal service should continue to pay them for their observations the same compensation they now receive.

If the Signal Service can obtain from Congress the small appropriation they ask for ($25,000) to carry out their plan, and if the railroad, steamboat and telegraph companies will adopt the standard time and use it *exclusively* in their business advertisements, the thing is done. The community will follow suit and hardly notice the change.

SECTION OF PHYSICS.

Vice-president, Dr. B. N. MARTIN, in the Chair.

Thirty persons present.

A specimen of acicular hornblende in quartz was exhibited by MR. W. L. CHAMBERLAIN.

The following paper was read by Prof. W. P. TROWBRIDGE:

ON THE DETERMINATION OF THE HEATING SURFACE REQUIRED IN STEAM PIPES EMPLOYED TO PRODUCE ANY REQUIRED DISCHARGE OF AIR THROUGH VENTILATING CHIMNEYS.

To ventilate a room properly requires the frequent removal of vitiated air and the introduction of fresh or pure air, the quantity, by weight, of the air introduced and rejected being equal in a given time.

If the process be continuous, and the proper amount of air be admitted and removed every hour or minute, the only other requirements are that the entering air shall be pure, that it shall be properly warmed in cold weather, either before it enters the room or by the mixture and diffusion of warm and cold air in the room; and that the introduction and removal of air shall take place by gentle or inappreciable currents in such a manner that the pure air may be thoroughly diffused throughout the room before it is removed.

These simple rules are easily stated and comprehended. It is also well understood that to produce a movement of air requires force in proportion to the mass moved and the velocity imparted to it.

The problems which arise in ventilation consist mainly in determining the position, arrangement and sizes of the passages through which the air enters and leaves, and the proper adaptation of these passages to the forces which produce the movement.

On the correct solution of these problems, too often misapplied or misunderstood, successful ventilation depends.

The various modes of producing the movement of air for ventilation are:

First.—Ventilating chimneys or flues in which the movement is caused by the difference in weight between the heated air in the flue and the cooler air outside. This requires that the air before entering the flue shall be warmed, and the heat necessary may be that due to the heat of the room when fires are necessary for warmth; or the heat may be imparted by stoves in the base of the flues, by gas jets, or by steam heated pipes.

Second.—The movement may be produced by fans or blowers or by steam jets—the latter being seldom applied.

The object of this paper is to investigate the laws which govern the ventilation when the air is heated at the base of the flues by steam pipes, the air in its passage to the flue receiving heat by its contact with the exterior surface of the pipes. As far as I am informed these laws have not heretofore been developed, and, as this system is a very simple one, capable of very extended applications, it is hoped that the following analysis may at least lead to a full discussion of the subject:

Let it be supposed that the air in a room is to be renewed at the rate of (W) lbs per second. Suppose also that it is to be rejected through a flue whose cross-section in square feet is (A), and height in feet (H). And that it is to be heated by steam coils whose aggregate exterior surface in square feet is (S)

The following notations will be used:

W. Weight of air removed per second (lbs).

H. Height of flue in feet.

S. Exterior surface of steam pipes (sq. feet).

A. Area of cross-section of flue (or flues).

T_a. Absolute temperature of external air (found by adding to the thermometric temp. Fahr. the number 459.4).

T_c. Absolute temperature of air in the flue.

T_s. Absolute temperature of steam in the pipes.

D_a. Weight in lbs. of a cubic foot of the external air.

D_c. Weight in lbs. of a cubic foot of the flue air.

V^1. The theoretical velocity of the air in the flue.

V. The actual velocity.

r. The rate in units of heat per hour, per square foot of the surface (S) (and for each degree difference between T_s and T_a) at which the air receives heat from the pipes.

k A coefficient of loss of velocity such that $kV=V'$.

p The unbalanced pressure (upward) due to the difference of weight between the column of air in the flue and a corresponding column of external air.

Then,

$$p=H.D_a-H\,D_c \text{ or } p=H\,(D_a-D_c) \qquad (1)$$

This pressure may be represented by the weight of a column of flue air of a height—

$$\frac{p}{D_c} = \frac{H(D_a - D_c)}{D_c} \quad , \quad . \quad (2)$$

and the velocity in the flue will be found from the expression

$$\frac{V'^2}{2g} = \frac{H(D_a - D_c)}{D_c} \quad . \quad . \quad (3)$$

or,

$$V' = \sqrt{\frac{2g\,H(D_c - D_a)}{D_c}} \quad (4$$

But from the Mariotte-Guy Lussac law we have—

$$\frac{D_c}{D_a} = \frac{T_a}{T_c} \text{ or } D_c = D_a \frac{T_a}{T_c} \quad (6)$$

substituting this value of D_c in formula (4) then results—

$$V' = \sqrt{2g\,H.\left(\frac{T_c - T_a}{T_a}\right)} \quad (7)$$

In this expression the theoretical velocity of flow is expressed in terms of the height of the flue and the absolute temperatures of the flue air and the external air. From formula (7) we have—

$$T_c - T_a = \frac{V'^2}{2g\,H} \times T_a \quad . \quad (8)$$

The quantity of heat transferred to the air may be represented by

$$\phi = W.\,c.\,(T_c - T_a) \quad . \quad (9)$$

in which ϕ represents the quantity of heat in units of heat per second, and c the specific heat of air at constant pressure ($c = 0.238$.)

All of the above formulas are well known. The following are believed to be new:

The quantity of heat imparted to the air may also be represented by $\phi' = \frac{S.\,r.\,(T_s - T_a)}{3600}$ in which is the quantity of heat imparted per second, and as from the nature of the problem $\varphi = \phi'$ we have

$$\frac{S.\,r.\,(T_s - T_a)}{3600} = W.\,c.\,(T_c - T_a) \quad (10)$$

or

$$T_c - T_a = \frac{S.\,r.\,(T_s - T_a)}{W.\,c.\,3600} \quad . \quad . \quad (11)$$

combining this equation with (8) we have—

$$S'.\,r.\,\frac{(T_s - V_a)}{3600} = \frac{V'2}{2g\,H.} \times T_a \quad . \quad (12)$$

and

$$S' = \frac{V'^2.\,W.\,c.\,T_a}{2g\,H.\,r.\,\frac{(T_s - T_a)}{3600}} \quad . \quad . \quad . \quad (13)$$

This expression gives the total heating surface in the pipes in terms of the velocity, the height of the flue, the weight of air discharged per second, and the absolute temperature of the external air.

If we substitute for V′ its value in terms of V, the actual velocity, we have—

$$S' = \frac{K'^2\,V^2\,W.\,c.\,T_a}{2g\,H.\,r.\,\frac{(T_s - T_a)}{3600}} \quad . \quad . \quad (14)$$

and since

$$W. = D_c\,V.\,A.$$

$$S' = \frac{K^2\,V^3\,D_c\,c.\,A.\,T_a}{2g\,H.\,r.\,\frac{(T_s - T_a)}{3600}} \quad . \quad . \quad (15)$$

another expression for S'.

These two expressions exhibit the laws of the movement of the air, giving the quantity of heating surface required under any special conditions of area and height of flue, temperature of external air, and velocity of discharge.

The constant (r) may be found approximately from the experiments of Mr. C. B. Richards, made at Colts Arms Co., of Hartford. The constant K depends upon the frictional resistance which the air encounters in its passage into and through the flues. The velocity V may be assumed, and should not be greater than four or five feet per second. The smaller the velocity and the larger the flues, the less will be the required heating surface, and the greater the economy of the apparatus for ventilation.

The following paper was read by Prof. H. L. FAIRCHILD:

ON A PECULIAR COAL-LIKE TRANSFORMATION OF PEAT, RECENTLY DISCOVERED AT SCRANTON, PENN.

The material which we shall notice this evening has naturally been regarded, on account of its associations, as illustrating in some degree the formation of coal. A brief description of that alteration of peat which has resulted in the formation of coal, is therefore desirable.

Peat results from decomposition of vegetable matter under water. The latter excludes the atmosphere and largely prevents the oxidation, which removes the vegetable debris on the upland, and which if rapid we call combustion, or if slow, decay. In northern regions peat-swamp vegetation is commonly a sort of moss (Sphagnum) which grows upward as it dies below. Great peat deposits are also produced in lower latitudes from the debris of forest trees. The great Dismal Swamp is a fine example, and in the Hackensack and Newark meadows we have examples of peat-formations of great depth, produced by the slow subsidence of the region and the accumulation of salt-marsh vegetation.

In former geological ages, immense peat deposits were produced in the vast lowlands along the borders of the continents, or at the deltas of the ancient rivers. These great swamps were frequently submerged in the sea and deeply buried beneath mud and sand. This event occurred perhaps many times in a single locality. The buried peat slowly decomposed. Much of the hydrogen and oxygen of the vegetable tissue, and some of the carbon, were eliminated. The remainder was consolidated by the weight of the superincumbent strata, and the result is bituminous coal. Thus we have the six to twenty coal beds of Pennsylvania, or the one hundred coal-seams of Nova Scotia.

The evidence that our coals are primarily formed in this manner is abundant, clear and incontrovertible. Few subjects are by our inductive science more definitely settled than this. We find these buried vegetable deposits in every stage of decomposition and alteration. Where the containing rocks are undisturbed, lying in their original positions, the coal contains a large proportion of volatile matter, and is bituminous. But where the rocks are dislocated and folded the coal is, by the pressure and heat, changed to anthracite or perhaps to graphite. The proportion of fixed carbon, or the degree of alteration, is always proportionate to the amount of disturbance which the associated rocks have suffered. Hence anthracite coal is a metamorphosed coal, just as marble is metamorphosed limestone, or quartzyte is metamorphosed sandstone. The metamorphism of coal is still going on. The escape of the volatile matter, in which the change consists, is observed in the mines, in the production of the explosive "fire-damp," and the poisonous "choke-damp."

Running from cellulose through wood, peat, and coals up to graphite we have a complete series; the difference being the loss of hydrogen, oxygen and in a less degree of carbon. This table, after LeConte, exhibits the proportions of the elements *by weight*, the carbon being reduced to a fixed quantity:

	Carbon.	Hydrogen.	Oxygen.
Cellulose	100	16.66	133.33
Wood	100	12.18	83.07
Peat	100	9.83	55.67
Lignite	100	8.37	42.42
Bituminous Coal	100	6.12	21.23
Anthracite Coal	100	2.84	1.74
Graphite	100	0.00	0.00

Anthracite coal, it will be seen contains a very small proportion of volatile matter, and graphite none at all. No two specimens of coal from different beds or areas are likely to yield upon analysis exactly the same results. This is due to differences in degree and manner of decomposition, the varying degree of metamorphism, the varying impurities, and perhaps a difference in the kind of vegetation. Anthracite coal naturally contains more ash than bituminous, because it is more concentrated, and of course peat has the least proportion of ash, simply derived from the inorganic matter of the plant.

The substance to be described was found in a peat-bog in the city of Scranton during the past summer. It has received attention from the newspaper and scientific people of the eastern coal region of Pennsylvania; and has been recently mentioned in the *Am. Jour. of Science* for Dec. by a quotation from a letter of a Scranton gentleman to the *Engineering and Mining Journal.*

Scranton lies in the midst of the Lackawanna anthracite coal-basin, which forms the northern half of the Wyoming basin. Since the financial panic of 1872 the city has grown but slowly, and a swamp lying in the midst of the city had remained unoccupied, except as an old dumping-ground for cinders from the furnaces. The city having been lately made the county-seat of the newly created Lackawanna county, this swamp was selected as the site for a court-house. In excavating for the foundations there was found a bed of excellent peat, 10 to 14 feet deep. I visited the excavation and collected specimens from depths of 3, 5, 8, and 13 feet. These specimens, of which a series are before you, were, of course, when fresh and saturated with water, several times their present bulk.

The peat from the greatest depth was highly decomposed, or very "ripe." It was fine-grained, close in texture, and although soft held its shape well, cutting like cheese. The color, when freshly cut, was a yellowish-brown, but changed rapidly to a dark-brown, almost black, in a few minutes. Upon drying, the color becomes a lighter or grayish-brown. The rock below the ripe peat is a clayey sand. This is somewhat impervious to water; but it is likely that beneath it is a more clayey bed which originally held the water and occasioned the swamp.

In the midst of the ripe peat, termed muck in the letter above mentioned, there was found, at various times and at different places, in excavating for the division walls, a substance resembling to the eye a bright coal—anthracite if you please. This did not occur in beds or layers, or in any apparent regular manner, but in irregular scattered or branching masses. You will observe in these dried specimens how intimately the coal-like matter and the ordinary peat are mingled. The two kinds cannot be separated, and it is with difficulty that the dried material can be gotten entirely pure for purposes of analysis. It shrinks upon drying, to a greater degree than the unchanged peat. Masses which I thought would afford fair-sized dry samples have nearly disappeared. The fresh material has been described as a tough jelly, which is perhaps a fair description. It was somewhat elastic, like a mass of soft india-rubber, but would break before bending greatly. I should compare it to a very firm but brittle jelly. The fracture had the lustre of a true coal, and in the dried state the resemblance is perfect. Being found in the midst of an anthracite basin, unscientific people naturally supposed from its associations that whatever bearings it might have upon coal would relate to anthracite coal, not knowing, or not remembering, that anthracite is a metamorphic coal.

Mr N. L. BRITTON, Geological assistant at the School of Mines, New York, has made approximate analyses of this altered peat, from material which I carefuly selected; also of the peat contiguous to the transformed matter (within the distance of an inch); and of the ripe peat from a depth of 13 feet in another part of the excavation. The analyses are of thoroughly and equally dried samples, and afford the following percentages:

	Moisture at 115° Cent.	Volatile Matter.	Fixed Carbon.	Ash.
1. Ripe Peat	6.225	63.875	4.625	25.275
2. Peat adjacent to 3	3.775	22 125	4.625	69.475
3. Transformed Peat	11.350	52.800	24.725	11 125
4. Transformed Peat	66.758	9.826	4.012	19.404

Number 4 is by the Pennsylvania State Chemist, as published in the *American Journal of Science.* The moisture is taken at 212° Fahr., and the analysis is evidently of the fresh material.

To obtain a fairer comparison, and if not strictly accurate, yet sufficiently so for our purpose, I have computed the percentages with the moisture eliminated.

	Volatile Matter.	Fixed Carbon.	Ash.
1. Ripe Peat	68.115	4.932	26.953 (White)
2. Adjacent to 3	22 993	4.806	72 201 (White)
3. Transformed Peat	59.560	27.891	12.549 (Pink)
4. " (State Chemist)	29.559	12.069	58.372
Bituminous Coals	30. to 60.	40. to 70.	3 to 6

From this table it will be seen that the composition of the transformed peat, number three, is about that of a very "fat" bituminous coal, that is, one containing a large proportion of volatile combustible matter, such as are desired for making gas. In number four, the volatile matter and the fixed carbon have nearly the same proportion to each other.

The very large amount of ash in these samples is to be expected, on account of the small size of the peat-swamp, which allowed much inorganic matter to be blown or washed in over the whole surface. But the varying amount of ash would indicate that the peculiar physical character of the peat was not due to the *amount* of inorganic matter. The ash of numbers one and two was white, while that of number three was decidedly pink. This color probably indicates iron; which may possibly afford a clue to the cause of the transformation. The presence of considerable iron either inherent in the mass itself, or derived from the surrounding mass by something like concretionary action would probably hasten the decomposition; bearing upon this point, the large amount of inorganic matter without iron in the peat contiguous to the transformed peat is remarkable. The physical characteristics are undoubtedly due to the finely divided state of the carbon, mingled with the water and volatile matter. But, however produced, we have here something that is apparently coal, in the midst of peat that is not yet coal.

Except as this substance illustrates a degree or phase of peat decomposition, it is not likely to have any bearing on the formation of coal. The decomposition of a buried peat, bed under great pressure probably involves the whole mass at the same time, and does not proceed by the expansion of such centres of decomposition as are here found.

Samples have been placed in the hands of Mr. Spencer B. Newberry, of Cornell University, who is making a full chemical examination.

DISCUSSION.

DR. L. ELSBERG then said that some 20 years ago he was engaged in experiments on the subject of converting peat into coal by a more rapid process than that occuring in nature. He found that moisture, heat and pressure were, as he supposed, the elements which, together with time, nature had employed; and these three factors could and can be used really to make a very good coal. On some future occasion he would bring specimens of the manufactured coal and of various kinds of coal to the Academy, and

give an account of these experiments and the methods. For a long time his experiments were futile, because it was impossible to make a machine of iron or steel strong enough to withstand the pressure which must be applied to the prepared pulp to reduce it to coal. By the action of super-heated steam, peat is converted into a perfectly homogeneous pulp. By passage of this through any of the ordinary compressing machines used for making bricks, etc., blocks or cylinders are obtained of a substance which, so far as its economic uses are concerned, is not inferior to most qualities of bituminous coal, for gas or fuel. Every effort was made to render the bore perfectly smooth and polished in the cylinder from which the peat was finally pressed out, and for this purpose even glass and porcelain were employed. However the peat was found to be so impalpable that it was forced into the microscopic pores of the metal, and even of porcelain and glass. The peat thus inserted itself in the finest possible particles which acted like wedges, chipping off small pieces from the interior of the cylinder. No matter how fine and smooth the bore of the cylinder was made, after very beautiful working for a few days, gradually this material would insert itself in the microscopical interstices of the metal, until gradually the working of the machine was stopped or an explosion ensued. A great many trials were made and much money spent, and finally the enterprise was given up.

MR. A. A. JULIEN remarked upon the voluminous literature connected with the study of peat, and the widely varying results, notwithstanding the enormous amount of labor that has been expended. The study of this material has been approached by investigators from two economic points of view; its relations to agriculture, and its employment as fuel. In investigations of the former class the larger number of analyses have been ultimate—*i. e.*, to determine the carbon, oxygen, hydrogen, nitrogen, etc., which make up peat and its allied products. This gives very conflicting results; the slightest possible change in the amount of water, the oxidation or dissociation of the material, even while during analysis, yielding very different results even in the hands of a single investigator. The other method is approximate, simply intended for the estimate of the value of coal or peat as applied to the purposes of fuel, and is that represented in the analysis of Mr. Britton. Such analysis, however, can throw but little light on the origin of the substance; organic acid seems to be further indicated by the red ash derived from the coal-like substance (Analysis No. 3), the white ash of the enclosing peat showing the residue of silica and alumina insoluble in the humus acids.

Further, the physical characteristics of the substance described by Prof. Fairchild, its brittle jelly-like character while moist, and extreme shrinkage on drying to bright coal-like brittle flakes, are identical with those of apocrenic, humic and other organic acids. These considerations render it highly probable that this substance has been produced within the peat at Scranton merely by the leaching out of the upper portions of the bog and the concentration of soluble salts of organic acids, in part crenates, along certain planes and in small cavities within the denser part of the peat toward the bottom of the bog. There is as yet no evidence, however, that these facts have any important connection with the formation of bituminous coal, much less with that of anthracite, represented by these specimens. A third method of the examination of peat is founded upon the determination of its proximate constituents or compounds, both those of amorphous character and various organic acids. From insufficient knowledge of the exact constitution and nature of these acids, especially in their various hydrated forms, the method is very difficult and has thus far had but limited application. Only such a mode of examination can throw light upon the character of the bright jelly-like substance in the Scranton peat.

Some statements by Prof. Fairchild, however, give a clue to its identity. He has mentioned a rapid change of color in specimens of the peat taken from a depth of thirteen feet, the yellowish brown color of the surface becoming blackish brown in a few moments while being handled. This seems to indicate not the trifling change produced by drying, but the characteristic reaction of crenic acid, well known to chemists by its immediate oxidation and partial conversion into apocrenic acid. This affects not only the acid but its ordinary salts, *e. g.*, those of iron, and has been observed both in its artificial product in the laboratory, and in nature, in the deposit of iron crenate beneath peat bogs and from the waters of many springs.

Prof. D. S. MARTIN called attention to the resemblance of the lighter colored and solid variety of this peat to the darker variety of the "turba" of Brazil. In the latter he had also observed thin seams of a black bituminous substance which was much like that which occurs in this peat.

The subject was further discussed by Prof. Hubbard and Mr. Parsons.

MICROSCOPICAL SOCIETY OF ILLINOIS.

The regular meeting of the State Microscopical Society of Illinois, was held at the Academy of Sciences, No. 263 Wabash avenue, on Friday evening, December 9, 1881, President Dr. Lester Curtis in the chair. After the reading of minutes and other routine business, the secretary announced the following donations:

From Dr. Schmidt, of New Orleans, one dozen slides, consisting of nerve-fibers and other Histological preparations.

"Botanical Notes" from Prof. E. J. Hill, of Englewood, Ill.

Bulletin of Microscopical Society of Belgium, and the report of the Microscopical Society, of Liverpool.

Dr. Angier, of St. Madison, Iowa, spoke in reference to some Acari which he had found under the skin of a chicken.

Prof. Burrill, of Champaign University, was introduced and spoke in reference to the poison of the poison ivy. He took some of the exudation and found it teeming with bacteria, and he questioned whether the poisoning and the bacteria come from the plant or otherwise. The speaker stated that upon examination of the workings of the leaves, he found the same forms; the milky fluid which exuded from stem contained numbers of them and the effect of placing some of this upon his arm had been attended with quite serious results.

The speaker went on to say that he had found the foregoing facts true with other plants among which he mentioned the chicory, buckwheat and dandelion.

Dr. Curtis described a new half-inch objective made by Gundlach and owned by Dr. J. Hollist. The glass was claimed by the maker to have an angle of 100°. Its angle had not been measured since leaving his hands.

It has the society screw and can be used on any ordinary stand. The back lens of the objective is large and extends beyond the border of the opening in the screw. This opening, therefore, acts as a diaphragm. In order to secure the benefit of the full aperture the portion of the objective can be removed and an adapter furnished with the Butterfield broad range screw can be substituted. It has also another screw of about the same diameter as the Butterfield screw, but provided with a finer thread, the name and description of this screw was not known. The front of the objective is ground down to a conical shape. For ordinary use this front is covered with a brass cap, having an aperture in the centre to allow the conical end of the objective to pass through. The cap can be removed when it is desired to use the objective for the examination of opaque objects. On removal of the cap the conical sides of the lens are seen to be covered with some sort of black varnish to prevent the passage of

outside light. A lieberkuhn is furnished with the glass which can be screwed on in place of the cap while examining opaque objects. The speaker had not had the glass in his hands long enough to become perfectly acquainted with all its qualities, it certainly is a good one, however. It resolves angulatum very satisfactory, and bears eyepiecing extremely well, working admirably on anatomical structures.

The lieberkuhn seems to be a valuable addition for some sorts of study as it brings out surface workings with unusual clearness, even in transparent objects. Mr. E. B. Stuart exhibited a Hitchcock lamp which he stated commended itself to the use of microscopists. No chimney is required, it being a blast lamp, the flames of which is fanned by a passage of air from the bottom, the top of the lamp driven by a noiseless clockwork. The oil well is entirely separate from the outside part of the lamp, and is kept cool by the cold blast of air constantly surrounding it. It gives a light of about a six-foot gas burner and the flame is steady and more free from flicker than gas or the ordinary carbon burner. He also showed under the microscope specimens of the gelatine-bromide plates for photographic work, that had been submitted by a photographer as imperfect. An inspection under the microscope showed three kinds of spots. One caused by dust particles which had settled on the gelatine while still soft, and as the emulsion hardened, became firmly fixed on the plate. The second kind of spots were caused by, apparently, the solvent action of some substance on the film, as it could be seen to be less dense at those points, while the third were thicker and evidently caused by carelessly spattering the emulsion on partially dried plates.

The meeting was then declared informal.

WM. HOSKINS, *Secretary*.

THE AMERICAN CHEMICAL SOCIETY.

The papers appointed to be read on the evening of the December meeting were, owing to the election of officers, omitted and therefore at the *Conversazione* held on Dec. 16 they were again brought up for consideration.

The first and second papers were "On the Separation and Estimation of Manganese" and "On a Modification of Mohr's Burette; adopting it to use in delivering corrosive solution" by Nelson H. Barton. Both of these papers consisted of descriptions of details of manipulation which the author had been lead to use in his own laboratory resulting from his experience and which under favorable considerations might be desirable to employ.

The third paper was by Mr. Casamajor and titled "Analysis of Soghum Juice" an enumeration of the results obtained by him in his laboratory with comments on them.

"A new Laboratory Filter and Aspirator" was the next paper, also by Mr. Casamajor. The apparatus referred to has recently been patented, and in the above paper it was thoroughly described and a model exhibited. The fifth paper was by Dr. A. R. Leeds, entitled "A Chemical Inquiry into the Self-purifying Power of a Flowing Stream." In this paper the complete results of the work done by Dr. Leeds for the New Jersey Board of Health were presented. It will be recollected that in a previous number a synopsis of this paper was given to the readers of SCIENCE. On the present occasion charts were exhibited showing the exact relations existing between the various estimations which were made. These were peculiarly interesting to chemists although unfortunately the entire subject of water analysis is in such a state of confusion that it is difficult to make much headway in the accumulating and conflicting mass of literature which is current on this subject. The entire paper of Prof. Leeds will be published in the N. J. Board of Health Reports. The final paper of the evening was "A New Method for the Analysis of Mustard" by the same gentleman with the assistance of Mr. Everhart. The ordinary methods given by Hassall, Blyth and others were so unsatisfactory in their results that an effort was made to produce something more definite. After some little study it was found best to separate the various constituents by different extractions with various reagents, so that an addition to the conventional determinations of moisture, oil and ash (for the mineral adulterants) extractions of alcohol and ether are made for the remaining ingredients.

M. B.

SUICIDE, an Essay on Comparative Moral Statistics. By HENRY MORSELLI, M. D., Professor of Psychological Medicine, Royal University, Turin. Being abridged from the original, as Volume XXXVI of the International Scientific Series. New York. D. Appleton & Co.

The present moment seems peculiarly favorable to the presentation of a work on the subject of suicide. Whether it be the great accumulation of financial and political crises, or the increase of mental derangements, or a fundamental change in the *morale* of the civilized races, it would seem as if a great suicidal wave was sweeping over our social horizon. The labors of Buckle, Wallace and Bagshot have taught the necessity of studying such complicated problems synthetically. The statistics of no one community, the analysis of no one cause, will suffice to explain their phenomena. Professor Morselli, fully recognizing this fact, has undertaken a study of the question of suicide from a statistical point of view, and one involving in its analysis the results of Social Scientific, Anthropological, and Medico-Psychological inquiries.

The first fact demonstrated by a careful study of statistics is the regularity and the increase of suicide in civilized countries, which finds its expression in the painful conclusion, that "in the aggregate of the civilized States of Europe and America, the frequency of suicide shows a growing and uniform increase, so that generally, voluntary death since the beginning of the century has increased and goes on increasing more rapidly than the geometrical augmentation of the population and of the general mortality."

Among individual elements serving to explain this increase of suicide, climate deserves the least prominence as a direct factor. The only ascertained fact in this direction is that in the centre of Europe on an area of about 942,000 square kilometers comprised between 47-57° of latitude and 20-40° of longitude, are found the people who manifest the greatest inclination to suicide. The least amount of suicide is found on the isothermal line of + 17.°5 C, running through Portugal, Spain, Italy, Corsica and probably Greece. That the mere feature of temperature is not a very important one, is shown by the fact that on the isothermal line of + 10° C, there is the greatest variation. In the United States for example the suicidal rate is 35 per million; in Ireland 16, in England 67, in Belgium 55, the Netherlands 35, Hanover 140, Prussian Saxony 228, Galicia 98. A more direct and constant relation is found with other cosmical influences, thus the regions of the great rivers are most afflicted by suicide *coeteris paribus*, while on the contrary marshy or excessively low lands, like the Landes in France, the low countries about the Zuyder Zee and Jutland, show a lesser proportion. That suicide is most frequent in the warm seasons, is confirmed by Morselli, this observation is a familiar one to New Yorkers. In our city a perfect suicide *furore* occurs in certain summers, and the direct influence of the heat has no doubt much to do with this as with the summer increase in violent crimes similarly the results of insanity or passion, a fact to which, however, no reference is made by the author before us. It is certainly a noteworthy fact, in which he confirms Guerry, that the maximum of suicide falls under the summer solstice, the minimum under the winter solstice.

The most interesting portion of the volume, is the one relating to the influence of race and nationality as determining the suicidal rate. We have always believed that a most important contribution to the elucidation of the problem of suicide could be made from this side of the question. And it is to be regretted that the talented writer before us has not added to the numerous tables, which render his volume, a mine of valuable information, one showing in four columns, the name of the nation, the proportion in same per million, the proportion of each form of insanity, and the suicidal rate. We believe that a noticable parallelism would be observed in these columns. The Germanic race preponderates over all others, and the German and Scandinavian branches divide the supremacy. The Anglo-Saxon stock has, however, gained by its long separation from the German mother, and its admixture with other races, for its suicidal tendency is much smaller. The Celto-Romans, on the whole, show a small suicidal rate, this increases, however, with the geographical approach to the Germanic borders, and the fact is of startling interest, that as keen an analyst as Morselli, attributes the higher suicidal rate in France and Belgium to the remote, continuous and the in modern times as persistent invasion of German elements sweeping up the valleys of the Scheldt, Seine, Somme, Meuse and even that of the Loire! The lowest suicidal rate is found among the sclavonic peoples. Morselli in this part of the work fails to refer to the fact that the Bohemians, isolated from the sclavonic parent stocks by an ocean of German States, have lost the relative immunity of suicide, just as the Anglo-Saxons have gained in this respect by separation from the "suicidal" race. The general conclusion, however. would seem to be flattering to the nations having most suicides. Savage peoples commit suicide only under the stress of hunger, but as civilization progresses a thousand new motives arise, with the mental needs. The reflection is not made directly by the author, but it can be read between the lines, that a similar reason accounts for the lesser proportion of suicides among Catholics as compared with Protestants. Judaism has a very favorable influence; but this is an exceptional instance, it being the only religion tied up in a single race. A very interesting fact, is that other conditions duly considered, the votaries of that creed which is in a great minority in a given country, show a lesser number of suicides; the reason given by Legoyt is that the intolerance of the surrounding population exercises a sort of moral coercion, making the dissenters desirous to avoid giving any excuse for harsh criticisms.

As to social influences, it is concluded from the general parallelism of suicide and criminality that a deterioration of morals is favorable to suicide. To this there are however some marked exceptions, especially in southern Italy, where grave crimes are common and suicide is rare, and a revision of the question induces Morselli to modify the conclusion ordinarily held by saying that in those countries "where crimes against property predominate, suicides are more frequent than where crimes of blood are frequent." Remarkably enough it is found, with regard to the influence of economical conditions, that it is not the exact period of economical crisis, but a subsequent one that shows an increase of suicide. The influence of the Austrian crisis of 1858–1859 was shown by an increase of suicides in 1860–1861. The Franco-Prussian war of 1870–71 led to more suicides in 1872–1873.

Without any question the most interesting part of the volume consists in its appended "suicidal" maps. These are maps of Europe and of the individual European countries, exhibiting by the intensity of shading, the proportion of suicides in the population. On glancing over the map of Europe it is seen in a moment, that the highest proportion is found in Saxony; in the neighborhood of Paris and of Vienna. It is not alone race but also the density of the population which exert an important influence here, and as the contest for existence naturally culminates in the destruction of the weak, the only advice the author is able to give as a preventive against suicide, is "to develop in man the power of well-ordering sentiments and ideas by which to reach a certain aim in life; in short, to give force and energy to the moral character."

While we venture to regard this advice as a fruitless one, believing that in view of the author's earlier conclusions expressed in the same volume, all the good advice and training that might be given would not materially change the suicidal ratio. We can only commend the perusal of the work to the reader as alone calculated to furnish an adequate conception of the vast array of useful facts gathered by its author, illustrative of many profitable lessons in sociology and ethnology. That in a treatise dealing with the statistics of so many lands and with authorities who have written in so many tongues, an occasional error should creep in, is not to be marveled at, and it is only where such errors are made the basis of conclusions that the reviewer considers it his duty to call attention to them.

It is stated, in speaking of the influence of religion on suicides, that in Saxony half the population are Catholics. The fact is that Saxony is one of the most intensely Protestant countries in the world, the stronghold of the Reformation, and a land in which the slight vestige of Catholicism (not consisting of one-twentieth of the population among its votaries), is only maintained by the court which is Catholic since the time of the libertine, Augustus the Strong. ED. C. SPITZKA.

THE SUN: by PROFESSOR C. A. YOUNG, with numerous illustrations. International Scientific Series. D. Appleton & Co., New York, 1881, pp. 321, 12mo.

It is an extremely fortunate thing when we have a book on a special subject, written by a man who has himself made capital discoveries in this subject and who, at the same time, has a culture wide enough to appreciate the philosophical relations of his special subject to science in general.

If at the same time the whole exposition is written in a graceful style, perfectly plain and easy to follow, and dignified as well, we have special reason to be grateful. Professor Young is the descendant of a line of professors, and lucid exposition is natural to him, as we find from this work. It is not necessary to say that in the other degrees mentioned Professor Young is precisely the one person to whom we should first look as authority.

There are certain things which an author can best say for himself. In Professor Young's preface we find this: "I have tried to keep distinct the line between the certain and the conjectural, and to indicate as far as possible the degree of confidence to be placed in data and conclusions."

Throughout the work we have found this carried out consistently, not as a task, but as a natural outcome of the author's method of thought.

The work opens with an introduction which treats of the sun's relation to life and activity upon the earth. In this section (page 18) the accepted beliefs with regard to the sun's constitution are laid down. This is a point of departure.

Chapter I. deals with the distance, dimensions and mass of the sun. The low density of the sun is quoted as showing the strong probability that the sun is mainly a mass of vapor or gas, powerfully condensed in the central portions by the superincumbent weight, but prevented from liquefaction by an exceedingly high temperature.

Chapter II. deals with the methods of studying the solar surface.

Chapter III. relates to the Spectroscope and to the solar spectrum in general.

On page 87 we have a table of the twenty-two elements

which are present in the solar atmosphere. Oxygen is included. Nitrogen is not. The point is here made that the elements *not* present in the atmosphere of the sun are precisely those which are most common on the earth, and Mr. Lockyer's *dissociation* explanation is given and a very full and fair statement of the reasons for and against it.

We would have been glad to see in this place an examination of a paper by Dr. Hastings in the first number of the *American Journal of Chemistry*, in which the writer attempts to show that Lockyer's hypothesis is entirely untenable, and in conflict with received kinetic theories of gases.

The fourth chapter deals with the sun spots and the solar surface. In this chapter is quoted a very remarkable account of the phenomena attending the growth and decay of a sun spot, written by that veteran observer of the sun, Dr. Peters, of Hamilton College. A foot note to page 137 suggests a most interesting research in relation to the acceleration or *drift* of the spots in longitude, and it is in such suggestions as this as well as in its general views that the book will owe its great value to the astronomical student.

Chapter V. deals with the periodicity of sun spots and with the theories as to their cause and nature. "On the whole," Prof. Young says, "it seems probable that the cause of the periodicity is in the sun itself" and is not due to external causes. The relations of sun spots and climate are discussed completely, yet briefly. Professor Young is one of the few English speaking astronomers who can keep his temper upon this subject.

In giving the various theories as to the cause and nature of sun spots, the author deserves our thanks for a few very simple diagrams, for the want of which many of us have gone astray in reading the sun spot war records in the *Comptes Rendus*.

The next chapter deals with the chromosphere and the prominences, their appearances and the theories of their formation and causes.

In dealing with the lines of the chromosphere spectrum we have two lists: First, those always present, and, second, those readily seen by suitable manipulation ("on slight provocation"). The catalogue of 273 lines seen by Prof. Young at Sherman in 1872 is not given here. The discussion of the causes of the great velocities observed in prominences on pages 211, 212 is especially interesting and suggestive.

Chapter VII. is upon the Corona—its phenomena and the theories of its cause. The figure on page 225, with its explanation on page 215, appear to the writer to give too much weight to observations of a streamer in the direction of the sun's poles at the solar eclipse in 1878. It is not impossible that such a streamer existed, but it seems at any rate very improbable in the light of the photographs given in the Eclipse Volume of the Naval Observatory.

Chapter VIII. on the sun's light and heat is a rapid survey of the important work which has been done on these subjects. The light is first considered, and an expression for the sun's light in candle power deduced.

Prof. Langley's interesting comparison of the light of a Bessemer Converter to the sun's light is quoted as showing the brightness of the sun to be over 5,000 times that of the glowing metal. The positive carbon of the electric arc is from two to four times fainter than the sun.

The light from various portions of the sun's disc is next considered, and the absorption of the light near the limb brings us to the question of a solar atmosphere.

This solar atmosphere has usually been considered as gaseous, but the author quotes Hastings' lately proposed theory that this absorption is produced by matter in a pulverulent condition at a lower temperature than the photospheric clouds and dispersed through the lower portions of the sun's true atmosphere.

"If the sun's atmosphere were removed, its brightness would be increased several times. It is almost certain that the amount of light received by the earth would be doubled; it is hardly likely that it would be quintupled."

The data as to the sun's heat are more precise; and the results of experiments (fully described) are put in a striking way. The sun would meet in a single swing of the pendulum a solid column of ice 2¼ miles in diameter and 93,000,000 miles long, provided his whole power would be concentrated upon it. What is the source of this enormous energy which amounts to something like one horse power *continuously* acting to each thirty square feet of the earth's surface? Simple combustion of any matter which we know would not suffice to keep up the the sun's heat for any length of time. The *effective temperature* of the sun is next considered, *i. e.*, the temperature which a uniform surface of lamp black of the same size as the sun would have to keep, in order to radiate the same quantity of heat as the sun itself. The results of Rossetti (18,000° Fahr), are quoted with approval. The two most important theories as to the way in which the solar heat is maintained—the meteoric theory—and the contraction theory are next examined. Both causes are undoubtedly operative. Probably the contraction of the sun is the most effective agent. If this theory be accepted then the sun has a limited future as well as a finite past, so far as we can now see.

Chapter IX. opens with a valuable table of numerical data relating to the sun—a table of statistics for the solar globe.

The constitution of the solar nucleus and atmosphere with an examination of various theories of this constitution constitutes the main portion of this chapter, which closes with the statement of some of the more important and immediate problems of solar physics.

The usually received theory of the constitution of the photosphere is given (p. 290) and the first authoritative criticism of the recently proposed theory of Dr. Hastings is given on pp. 291-294. It seems to the writer, however, that Prof. Young, in urging as an obvious objection to this theory, that whatever is precipitated at a lower temperature than is the photosphere element must increase the depth of the photosphere, has overlooked an essential point of the argument. The photosphere substance is supposed to have a much higher vaporization temperature than those of other elements, *e. g.* iron, therefore any precipitated iron belongs, not to the photosphere, but to the over-lying "smoke" envelope.

This chapter closes the work proper of which we have been able to give but the barest outline. Its chief characteristics seem to the writer to be: perfectly clear statements of the facts of observation and what is far more valuable, of the theories to be considered. These are made definite by every way possible—by lucid statements and by diagrammatic figures; candid discussion of these facts and theories in the light of the best information now attainable; and lastly the drawing of the most certain conclusions which are possible from the data, taking care in each case to give a proper idea of the degree of certainty which our present knowledge allows.

These are high excellences and make the book a most important one. In pointing them out the writer has done no more than any reader can do for himself.

EDWARD S. HOLDEN.

M. COCHERY intends to spend the surplus of the Electrical Exhibition, which is said to exceed 16,000*l.*, in establishing a research laboratory for electricity.

PROFESSOR HAECKEL is at present in Ceylon, where he is to stay for three months making a scientific exploration of the island.

STEAM AND HYDRAULIC SAFETY ELEVATORS.

In large cities, where every inch of land is precious, the modern power elevator has virtually effected for building, what the locomotive engine has effected for travel and transportation—namely, a revolution. Hotels, office buildings, apartment houses, and first-class stores, are now almost invariably carried to a height of eight or ten stories, and equipped with elevators; while a tendency is fast growing and will soon become controlling, to increase the value of third and fourth rate property in the same way, and even to eliminate the toil of stair-climbing from ordinary housekeeping. This great change in the conditions of living, together with the progressive fatality already developed, as elevators without adequate safeguards begin to wear and weaken, will soon be calling in terrible tones for legislative interference. Fortunately, there are standard safety appliances that have stood the test of every possible description of breakage and accident to which elevators are liable, during a quarter of a century past, without a single failure. The sole reason that we hear from time to time of cruel destruction to human life from the falling of elevators in our hotels and apartment houses, etc., is that there are proprietors too parsimonious, or too ignorant, to provide their buildings with the perfect and proved safeguards that are everywhere before their eyes in the standard pattern of elevators used in nearly all of the most valuable buildings. They ought to be compelled to do so, whoever may profit or lose by the requirement. Meanwhile, let us see what individuals can do to protect themselves against these people by avoidance.

The improved modern safety device, introduced by Otis Brothers & Co., in their best elevators, for some years past, is quite outside and independent of the other mechanism, and acts instantaneously by virtue of any acceleration of the standard rate of motion in the car, from whatever cause. Both arrangement and action are simplicity itself. There is an independent sheave at the top and another at the bottom of the hoist well or shaft, and an endless wire rope running around the two; the lower sheave being suspended, to keep the rope taut. The rope is connected at a proper point with the safety catches on the car, in such a manner as to run the rope as the car moves, and thus to run a pair of governor balls geared to the top sheave. If the car should commence descending faster than the rate for which the governor is set – whether by accident, by overloading, or by indiscretion of the operator—the extension of the governor balls by the accelerated motion (greatly multiplied on the governor) instantly operates a clutch on the rope which pulls out the catches into the safety ratchets, and stops and locks the car in its place. It is like an automatic iron hand, always ready to clutch and pull the rope that arrests the car, the moment it disobeys the set restriction on its rate of descent. It is literally impossible by any means to move the car downward faster than the rate prescribed.

HYDRAULIC ELEVATORS.

For the purpose most interesting to the general reader —that of passenger elevators—the very recently perfected application of hydraulic power has controlling advantages, and it is probable that most pasaenger elevators will hereafter be constructed on this principle. The best hydraulic elevators are preferred to steam for this purpose on account of the perfect smoothness of their motion, their remarkable simplicity of construction and operation, easy management, and reduced opportunities for breakage, derangement or accident. To these advantages they add that of reduced expense for motive power to the extent of the head of water available on the premises. It is not to be understood, however, that all hydraulic elevators share in this preference. Most kinds heretofore, in fact have cost more in wear and tear of ropes and other parts, and in motive power to overcome extra friction, weight, &c., than any kind of steam elevators.

We shall make it our object to put the reader in possession of the leading criteria and principles necessary for a correct judgment among different hydraulic elevators in the remainder of this article.

Generally the less desirable kinds of hydraulic elevators are made with a short cylinder of large diameter, into which the pressure of a heavy column of water is introduced at one end, urging a solid piston like that of a steam engine from that end to the other. The piston rod pushes forward a crosshead bearing on each side of it a block of multiplying sheaves or pulleys around which the wire rope (from the sheave at the top of the hoist) passes, and returns many times to and from a similar pair of multiplying blocks in a fixed position at the rear of the cylinder. As these blocks of sheaves are thus forced farther apart by the motion of the piston, lengthening each of the twenty turns (more or less) of the wire rope between them, a length of rope many times the length of the piston stroke is obviously thus taken up, and the car is hoisted an equivalent distance. It is the same in effect as winding up the rope on a drum: but it is not so favorable in mode; the friction and strain being excessively increased. Moreover, the course of the wire rope from sheave to sheave in the blocks, must necessarily cross the plane of revolution of each sheave, both in taking and leaving it, so that the edge of every groove continually and severely rasps the rope as it runs into it and out of it under a tension of tons force. In point of fact, these ropes have to be frequently renewed, not only at considerable expense, but at much inconvenience from interruption. But a worse result is their great liability to snap suddenly at some point, and not only throw the enormous tension out of balance and the labyrinth of rope and blocks into violent snarl and wreck, to the destruction of everything animate or inanimate within reach; but at the same time, to cause the car to fall the whole distance to which it may have been raised. Another objection, of course, is the constant extra cost of power for the extreme friction peculiar to this mode of multiplying motion. The substitution of a rack of cog teeth on the piston rod, gearing into a pinion wheel, and that into a geared winding drum, does not mend the matter in point of safety or economy, since it is not practicable to use a belt from so slow a motor. Some of this class of machines are made doubly objectionable by placing the cylinder horizontally. The lift weight of a vertical piston can be counterbalanced; but this arrangement makes a nett increase of friction by the dead weight of the heavy piston to be dragged on the bottom side of the cylinder. Two other disadvantages are not to be avoided or counteracted: the constant wear of the cylinder and piston out of round by dragging the latter on its under side, and the accumulation under it of sediment from the water, to assist in the work of abrasion.

We conclude with a description of the more modern and matured form of hydraulic elevator, adopted for the Government buildings, on the unanimous recommendation of a board of experts appointed by the Secretary of the Treasury, and composed of Messrs. Frederick Graff, C. E., of Philadelphia; Master Machinist Geo. A. Wilson of the Washington Navy Yard; and Chief Examiner J. B. Durnall of the Patent Office. Their decision was made after exhaustive investigation in the principal cities and manufactories; and from the fact that out of nine competing methods only one was considered worthy of mention in their report, and that in terms of almost enthusiastic admiration, the reader may judge that the relative objections and advantages are fairly stated in this brief review. Six of these elevators have been running for three years, uninterupted for repair, in the "Boreel" and "Morse" buildings, and similar ones are going up in other famous piles, such as the "Vanderbilt," "Mills,

"Kelly," &c. All of the United States buildings having elevators, and in short, nearly all the most valuable public buildings, hotels, fashionable stores, apartment houses, &c., to the number of thousands, in this and other American cities, contain specimens of hydraulic or steam elevators of the same admirable manufacture.

The new hydraulic elevator is indeed a prodigy of simplicity and automatic power, with simple gravitation of air and water for its only law and mode of action, and with a conspicuous absence of the objections heretofore observed, as well as of all others conceivable. It consists of an upright cylinder and piston, only about a foot in diameter, and half the height of the lift; two pipes and two valves. That is all, save the car with its hoist ropes and sheaves, and whatever means, natural or other, may be used to bring a head of water into connection with the cylinder. One of the two pipes is a circulating pipe which connects the two extremities of the cylinder, and affords a passage for the transfer of water from one end to the other--that is, from above the piston to below it. It is also the medium for the pressure of water from the other or hydraulic pipe; a pressure thus made at all times continuous and uniform on the top of the piston head, wherever it may be, in motion or at rest. This pressure (when not neutralized) forces down the piston, thereby drawing up the car by the hoist rope attached to the piston rod.

Let us first suppose the car at the top of the lift, and the piston consequently down at the bottom of the cylinder; or, the car stationary at any point in the lift, and the piston at a corresponding point in the cylinder. As the cylinder is always full of water, and the full head of pressure always on, wherever the piston may be, the only possible way for the piston to move in either direction is for the water to get out of its way through some outlet. To let the piston rise (pulled up by the weight in the descending car) it is only necessary to open a valve that closes the lower end of the circulating pipe, thus opening communication from the part of the cylinder above the piston to the part of the cylinder below it. This allows the water above the piston to be pressed out before it, and down and back into the cylinder under it. The steadiness and ease with which the piston follows up the receding water—which, in turn, follows it up as steadily beneath—can not be exceeded by any movement in art or nature. At the same time, the movement is graduated perfectly to the will of the operator, whatever the variation of load, by opening or contracting, more or less, the valve orifice through which water is transferred from the top to the bottom of the cylinder. No water is expended.

Finally, to force down the piston and hoist the car, the circulating valve before mentioned must, of course, be closed; but this only renders motion either way impossible, because an immoveable body of water without vent fills the cylinder both above and below the piston, and it might as well be solid iron, for the matter of allowing the piston to stir. Another of the simplest things in the world must be done, namely, to open a discharge valve from the lower part of the cylinder, when the water there, in flowing out, begins not only to make room for the descent of the piston, but to make a vacuum beneath it which brings the atmospheric pressure upon the top of the piston, in addition to the pressure of the hydraulic column, which is never withdrawn. The descent is the same perfectly balanced, steady, soft and *fluid* motion previously noticed in the ascent; graduated likewise to perfection by controlling the size of the orifice with the valve rope in the hands of the operator in the car. The symplicity of the valve motion is also very beautiful. The two valves are simply two plugs a few inches apart on one stem, fitted inside a pipe, and drawn up or down by an easy motion of the hand rope. They are so adjusted with the orifices of circulation and discharge, respectively, that while they are at an intermediate position, all motion of water, and consequently of piston and car, is blocked; if lifted, they gradually and simultaneously open the discharge and close the circulation orifice, as much or little as the operator pleases, causing and graduating descent of piston and ascent of car; or if lowered, they cut off dicharge absolutely, and open circulation as gradually as desired, causing ascent of piston and descent of car.

The multiplication of the piston motion two or three fold in that of the car (which is all that can be necessary in the highest buildings with these long-cylinder machines) is done by single pairs of sheaves, and consequently without making the ropes cross the plane of revolution of their sheaves, and therefore without special friction, as well as without special strain and wear. All moves easily, naturally, straightforwardly, imperturbably, like the silent music of the spheres. The power, unlike that of steam, is as definitely limited and as invariable under all circumstances as the weight of so many cubic feet of water, with which the entire motive apparatus is exactly filled at every moment, never a drop less or a drop more, or the space of a drop vacant. The chances of breaking anything are reduced to a minimum so remote as to be hardly more than metaphysical; and yet all the standard safety appliances stand on guard against that conceptual possibility, so that there is probably no other kind of vehicle or mode of motion on sea or land so safe as that of the new hydraulic elevators above described. It is estimated that thirty millions of passengers are now annually conveyed to and from the upper stories of buildings in the elevators recorded on the salesbooks of Otis Brothers & Co. Up to the present time, this inconceivable amount of passenger business has been performed without a single reported instance of injury to life or limb from the failure of any part of the machinery. The fact is, so far as we know, without a parallel in the history of machinery, and may well direct earnest attention not only to the general qualities, but to the special features, of these remarkable machines.

OXIDIZED OIL.

To welcome a new industry is always an agreeable task, but special interest is attached to those instances in which the application of scientific principles have contributed to the results.

We have now to record a few facts relating to a means of manipulating oils, which result in the formation of a substance which has many of the advantages and characteristics of Rubber, but which can be manufactured at a fraction of its cost.

Reduced cost in the manufacture of a staple article, where a monopoly can be secured, naturally suggests great profits, and as capitalists are now competing for the privilege of manufacturing this new material, a few words respecting its nature and properties may be acceptable to our readers.

A few years ago a man of studious habits and inventive genius noticed that around the mouth of a can of oil, the oil had acquired the property of solidity, and finding that the effect was due to the oxidation of the oil, he conceived the idea of turning this property of linseed oil to practical account for various purposes in the Arts and Manufactures.

Mr. Frederick Walton, (for that was the name of the gentleman to whom we have referred) occupied several years in studying this subject, and making practical experiments relating to the behavior of oils under various conditions, and at length arrived at such successful results as to warrant his reading a paper before the London "Society of Arts," entitled "Introduction and Use of Elastic Gums and Analogous Substances." In this paper, after discussing the sources and qualities of india-rubber and gutta-percha, he described a method which he had invented of manufacturing an artificial product, which not only possessed the principal qualities of Caoutchouc and

of the gum of the Para tree, but which was considerably cheaper and had a wider application. The principal feature in the new process was the oxidation and consequent solidification of linseed oil. He found that linseed, nut, and poppy oil possessed the property of becoming concrete on exposure to the atmosphere, and that when spread in a thin layer, on a surface of wood or iron, they dried or changed into a thin skin.

This change is of course produced by the absorption of oxygen and the disengagement of carbonic acid. The power of absorbing oxygen rapidly is inconsiderable in the crude or raw linseed oil, but is greatly increased by boiling the oil, which is best effected by exposing a large quantity of raw oil to a strong heat in a cauldron, with a small percentage of metallic oxide of lead. In this condition it is called varnish, and has a viscid character. A layer of this oil requires from six to twenty-four hours to change into a skin-like substance, according as the state of the atmosphere is more or less favorable.

One of the first materials placed upon the market by Mr. Walton as the practical result of his experiments was a new floor cloth which he called Linoleum. This material has for its basis oxidized oil, which is mixed with a tenacious substance, to which is added finely powdered cork. The material thus formed is passed between rollers and pressed upon a fibrous texture.

The advantages of Linoleum over the previous oil cloths was apparent, for it was waterproof, a non-conductor of heat, while its natural body color permitted the addition of an agreable and artistic decoration. The manufacture of Linoleum has been a great success and has realized large fortunes to its original promoters, and fifteen years after its introduction was still paying 60 per cent as a dividend.

Linoleum may described as the first and crude result of Mr. Walton's expensive experiments with oxidized oil; he had however in reserve a higher development of his ideas, and at length produced a material which is a refinement of all his previous efforts.

Lincrusta-Walton, as its name implies is made from oxidized linseed oil which is skillfully manipulated with various substances, forming a material posessing most valuable properties and its principal characteristics appear to be unique.

Unlike Linoleum, which is adapted to one purpose alone, the application of Lincrusta to the Arts and Manufactures is most varied, and we shall soon find it in every house under so many forms that its future as a staple commodity is assured. One of the most valuable properties of Lincrusta lies in the fact that although originally so soft as to receive the most delicate impressions, it hardens within a few hours and permanently remains in that condition. It is a waterproof material with a natural color of a neutral shade, which can be changed in manufacturing to almost any tint. Lastly the manufacturer, by manipulating the cement, has it in his power to produce many modifications of the material, and, as we shall presently show, can make various substances which have a very wide application, and which will undoubtedly supersede many valuable monopolies, on account of its being both cheaper, more permanent, and possessing many advantages over its rivals.

Perhaps one of the most important adaptations of Lincrusta is a new and improved covering to walls, and as such it appears to us a perfect decoration. For this purpose the Lincrusta is passed through machines which leave an elegant design *in relief* upon its upper surface, and at the same time is pressed upon a thin backing of muslin or paper. Thus manufactured and hung as a wall paper in its natural tint, it is the most beautiful mural decoration known, and when colored or hand-painted the most varied effects are produced; it may present the appearance of a rich old tapestry, or the subdued tones of stamped leather. Combined with the gilder's art the brilliant effects of embossed metal in solid relief are obtained. The only limit to its development in this respect is the art of the designer and the skill of the die sinker. Bearing in mind that combined with these advantages we have a material as flexible as leather or even rubber; resilient, standing blows without injury, enduring and tough, not easily torn, waterproof and unaffected by temperature, and withal capable of being produced at a price below even the medium quality of relief papers, and it is clear advantages are combined in Lincrusta that will make it one of the most valuable products which can be manufactured, and one which will be of universal use.

The special use of Lincrusta in the United States as a wall decoration will be at once recognized, as its warmth and resistance to damp makes its application almost imperative in the case of frame buildings which form the majority of dwellings in this country.

Of the other applications of Lincrusta to the Arts and Manufactures, our reference must be brief, for they appear endless in their variety. Among other purposes Lincrusta can be used as an excellent covering for external walls. For bookbinding it takes the place of carton-pierre and papier-mâché, and even excels leather in its capability of receiving fine and incisive ornament. Mouldings of Lincrusta can be gilded with facility, and attain a hardness equal to wood, and can be applied in this form to picture frames, cornices, panels, mantelpieces, or any kind of furniture.

For wall advertisement-placards Lincrusta has many advantages, the letters are in relief, and neither sun, rain or damp has any bad effect upon it.

Railway and other traveling cars will in future be decorated with Lincrusta, and its application in steamships is acknowledged, having been largely used in the new Cunard ship *Servia*, which recently left our port. In this instance the builders state that it gave the greatest satisfaction both to the owners and to those who inspected the ship.

Lincrusta-Walton may be applied to many other purposes than those already enumerated, but the above are amongst the most important and offer an almost unlimited field for manufacturing and commercial enterprise. In short, all decorations executed up to the present time on *flat* surfaces, that is to say *without* relief, can now when desired be fashioned *with* relief, and their artistic value and appearance may thus be considerably augmented.

Among the art exbibits now to be seen in New York, that of the Lincrusta at 41 Union Square, corner of 17th street, is perhaps the most attractive. Specimens of the material have been imported from London and Paris and are here shown *in situ* and have elicited the admiration of all who have visited the rooms. The material is not yet for sale, and the exhibit has been made merely to show the public the wonderful effects of this beautiful material, by Mr. John R. Whitley, a gentlemen who has largely interested himself in this matter, and who is now making arrangements to give the American public the benefit of this manufacture.

If our description has aroused an interest in this subject, we would simply state that the exhibit is open to all who desire to verify the facts here stated and that those who desire information which is not given in this description, will there find there ample means of learning the fullest details.

PROFESSOR WILLIAM O. CROSBY has published an excellent little manual on "COMMON MINERALS AND ROCKS," which is sold by Messrs. Ginn, Heath & Co., of Boston, at 35 cents. A complete set of minerals and rocks named in the work can be had of Professor Crosby for $1, or a more extended set of larger size, including 75 specimens, for $3. With both sets 25 cents is charged for packing.

CORRESPONDENCE.

The Editor does not hold himself responsible for opinions expressed by his correspondents. No notice is taken of anonymous communications.]

CUMBERLAND UNIVERSITY,
Lebanon, Tenn., Jan. 23, 1882.

To the Editor of "SCIENCE."

DEAR SIR—When experimenting with the so-called nitrogen iodine a short time ago, I met with an accident which might have been very serious. I had prepared about a grain of this compound by the action of ammonia upon iodine, and it had stood over night in a watch-glass with a slight excess of ammonia. I proceeded to wash it with water preparatory to drying it for use in the lecture-room. When washing it through the third water and stirring it lightly with a glass-rod to make the cleansing more thorough, a violent explosion took place, filling my face and eyes. I washed them as quickly as I could with water and dilute alcohol, and there followed only a slight inflammation of the conjunctiva, which subsided in a few days.

I have repeated the experiment several times, and in every case have found that when the compound stands in an open vessel for twelve hours under ammonia, it contains a compound which is explosive under water upon slight causes. What this compound is I have not ascertained. At the same time the greater part of substance remains undecomposed and is merely scattered about by the explosion. This when dry presents the phenomena of the ordinary iodine. The subject deserves further investigation,

Very truly yours,

J. I. D. HINDS,

BOOKS RECEIVED.

THE BRAIN OF THE CAT (Felis domestica), a Preliminary Account of the Gross Anatomy, with four plates, by BURT G. WILDER, M. D., Professor of Comparative Anatomy, &c., in Cornell University, &c., &c.

This is a reprint from the proceedings of the American Philosophical Society, July 15th, 1881, and is the first of a series of contributions to the knowledge of the brain of the domestic cat. The present paper is divided into four parts, the second of which is a continuation of the paper by Professor Wilder on "A Partial Revision of Anatomical Nomenclature with especial reference to that of the Brain," published in SCIENCE on the 19th and 29th of March, 1881. Part III. relates to a number of points suggested for study, in which a knowledge of the cat's brain is not sufficiently understood. The four plates are very elaborate and well executed, and describe with great minuteness all that can be seen by natural vision of the cat's brain, both externally and in section. These valuable papers by Professor Wilder promise to mark an epoch in the literature of this subject.

THE THIRTY-SIXTH ANNUAL REPORT of the Director of the Astronomical Observatory of Harvard College, by EDWARD C. PICKERING. Cambridge, 1882.

An abstract of the report will be prepared for "SCIENCE." The report is a cheering one, speaking of the enlarged resources of the Observatory, the increased number of assistants, and efficient work of all engaged in making observations or their reduction.

THE FORMATION OF VEGETABLE MOULD THROUGH THE ACTION OF WORMS, with Observations on their Habits, by CHARLES DARWIN, LL.D., F.R.S., with illustrations. Messrs. D. Appleton & Company. New York. 1882.

As this interesting work will be reviewed in this journal the simple announcement of its publication will suffice.

STUDIES IN ASTRONOMY, by ARTHUR K. BARTLETT, M. D. 2nd edition, revised and rewritten. Published by the author. Battle Creek, Michigan. 35 cents.

As an introduction to the science of Astronomy, this little book presents many advantages, the subject is well handled and presented in a very attractive form.

BULLETIN NO. 1 of the American Museum of Natural History, December 23, 1881. Three articles by Professor R. P. Whitfield, illustrated.

This publication has been produced in a form worthy of the establishment that issued it. It proposes to be one of the most valuable bulletins published by scientific institutions.

BUREAU OF EDUCATION. Circulars of Information, No. 4, 1881; Washington, 1881.

This is an exhaustive description of the work of education in France.

PROCEEDINGS OF THE AMERICAN SOCIETY OF MICROSCOPISTS. Fourth Annual Meeting held at Columbus, Ohio, August, 1881.

This publication, which does credit to the publication committee, contains several valuable papers with seven pages of illustrations, and will be noticed at greater length on another occasion.

HOW TO SEE WITH THE MICROSCOPE, by J. EDWARDS SMITH, M. D.; Duncan Brothers, Chicago.

This book has been severely handled by some critics, but in our opinion it contains more original writing than any book on the subject issued during the last two years, and, coming from the hands of a thorough expert microscopist, merits attention from all using the instrument. The work would be useless to a beginner, who should use Professor J. Phin's excellent little manual, but to one who has made some progress with the instrument Professor Smith's work will prove quite useful.

LUMINOUS INTENSITY OF THE VOLTAIC ARC.

M. Niaudet, in his excellent work, *les Machines électriques à courants continus*, gives quite an exhaustive treatise on the voltaic arc; he particularly dwells upon the arc obtained by a continuous current, the positive pole above, and the negative below and on the same vertical line. It is to this case that the following extract has reference:

"*Relative luminous intensity of the carbons.*—It is very easy to see that the light directed against the lower pole is very much greater than that carried against the top. To see this, it is only necessary to place the two hands, the one above and the other below the arc, and to observe them. The difference is striking.

M. Fontaine has taken a series of photometric measures in a vertical plane, and in all planes varying from the horizontal to the vertical above and below the horizontal plane passing through the arc.

These experiments have proved that the intensity is maximum between 45° and 60° below the horizontal plane, and that it is about ten times greater than the intensity measured at 45° above the horizontal plane. In the same investigation, M. Fontaine has compared the luminous intensities of the voltaic arc furnished by a machine with alternate currents, with those we are now discussing. The same mechanical work was employed in the production of both arcs; the intensity was the same in the horizontal plane; but the mean intensity was much less.

According to M. Fontaine, the mean intensity of the light given by the first arc is three times that given by the second."

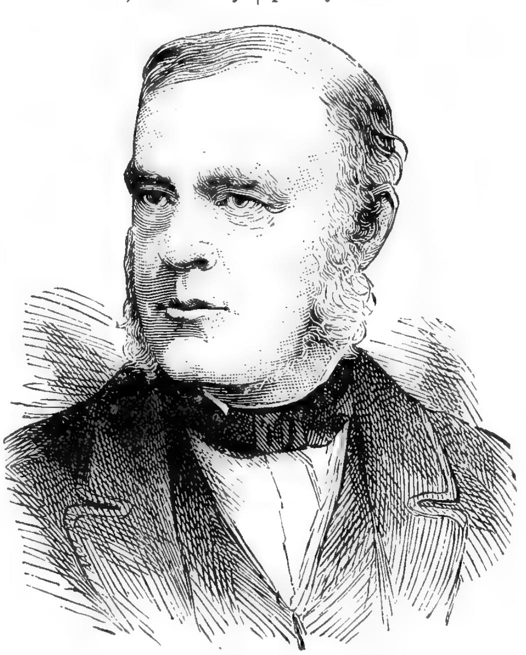
SATURDAY, MARCH 4, 1882.

JOHN WILLIAM DRAPER, M.D., LL.D.

The death of Dr. John William Draper removes from the circle of American Scientists a man who could be least spared, but the great results of his life of usefulness and devotion to science will, for many years to come, remind us of his familiar presence, and his memory will be cherished wherever the physical sciences are known and appreciated.

Born at St. Helens, near Liverpool, England, on the 5th of May, 1811, he came to this country when 22 years of age and took a medical degree at the University of Pennsylvania, and shortly afterwards he received the appointment of Professor of Chemistry and Physiology in the University of New York, where he afterwards remained until the time of his death.

Dr. Draper's scientific career may be studied with profit by all engaged in similar investigations, as an example of close application and persistent work, achieving the highest distinction in his own line of research, without any of those appeals to popular sympathy and support, which too many modern physicists are so eager to receive, and regard as elements of success.



Prof. JOHN WILLIAM DRAPER,
(Chemist and Historian) Died January 4, aged 70.

For more than 40 years Dr. Draper was quietly engaged in careful experimental researches in physiology and molecular chemistry; these researches covered a very large range of subjects, but were more particularly devoted to a study of the chemical phenomena of light in both the organic and inorganic world, a description of which may be found in his work "*Scientific Memoirs, being Experimental Contributions to a Knowledge of Radiant Energy.*" This volume is described by "*The American Journal of Science*," in its obituary notice of Dr. Draper as "a noble monument to his memory, made of the results of labors which have greatly advanced the sum of human knowledge."

In the department of spectrum analysis and photography, his original discoveries were of great value. He doubled the number of the recognized fixed lines in the spectrum, described those at the red end, demonstrated that the fixed lines might be photographed, and brought all these discoveries to bear on his investigations into the nature of flame and the conditions of the sun's surface. In conducting the long series of experiments which resulted in so many important discoveries, Dr. Draper drew largely on his private fortune, and it is asserted that no private person in America has expended more money in a purely scientific direction; his generosity kept pace with his scientific attainments, for whatever scientific discoveries he made—and they were very numerous—he freely gave to the world. He never took out a patent for any of his discoveries, nor sought to make them a source of personal profit.

In the "Scientific Memoirs," Dr. Draper claimed to have made "the first photographic portrait from the life," and he further states, "I also obtained the first photograph of the moon;" the other claims in this work to scientific discoveries are most remarkable, as the result of the work of one man's investigations in a single line of research.

In 1875 the American Academy of Arts and Sciences awarded the Rumford medals to Dr. Draper for his "*Researches on Radiant Energy.*"

Of the literary work of Dr. Draper we would speak in detail, for the subject has many attractions; but it appears unnecessary to describe books which are read

universally, and form part of the education of every liberal-minded and intelligent man. Dr. Draper's books show that he was a deep thinker in the department of the philosophy of history and human progress, and that he aimed to exalt the intellectual development of man.

The "*History of the Conflict of Religion and Science*," a work which many readers consider is incorrectly represented by the title, proves how broad and liberal were Dr. Draper's views, and it may surprise many to learn, that such opinions were not considered by him inconsistent with religious belief. The materialists appear to have written and published in vain for him, as we are told in the "*American Journal of Science*," that "it is a satisfaction to affirm that he was a theist and a firm believer in a future state of existence, for which the present is only a preparation."

On the 4th of January last, Dr. Draper peacefully surrendered his life, honored and respected by all nations, for his fame had been diffused throughout the civilized world by reason of the translation of his works into both European and Asiatic languages.

Dr. Draper leaves two daughters and three sons, the latter having already achieved distinction in pursuits kindred to the work of their father. As the work of Herschell was continued by his son, so in Professor Henry Draper we find all the special qualities for maintaining the high prestige of the family name ; his recent success in photographing such difficult celestial objects as nebulous matter, and the important discovery of the presence of oxygen in the sun, have placed him in the foremost rank of original scientific workers, and the furthur development of his investigations are anticipated with keen interest by physicists, both in this country and abroad.

VEGETABLE PATHOLOGY.

By T. J. Burrill, Ph. D.

It is not an easy accomplishment to separate physiology from pathology when, instead of dealing with the definitions of words, we attempt to classify the operations taking place within a living object, by placing them in the one or the other category of activities and effects. Indeed there is no well marked and uniformly acceptable line of division. We may speak of one as normal and healthful and the other as abnormal and injurious ; but these vary with the standpoint from which our judgment is made, and with the conditions which modify, this way and that, the results.

If these things are true as regards the vital processes of animals, they are much more evidently true concerning those of plants. In the latter, the standards of health and disease are not so well agreed upon ; less attention has been given to the life processes and their results ; the individuality of the plant has been less recognized, and its own particular good or injury less regarded. If an apple-tree produces for *us* a crop of good sized, highly flavored, richly colored fruit, we do not stop to ask whether these luscious pippins are the results of physiological or pathological operations, judged from the standpoint of the *tree*. If a cabbage has its terminal bud enormously developed so as to be called a head, the monstrosity never calls forth a compassionate word of sympathy as *we* enjoy the crisp and savory production, for a New Year's dinner. The ink with which we preserve our thoughts, flows no less freely because of a peculiar wound in a particular tree by a particular insect, and a most wonderful malformation of the growing tissues in consequence. We have not listened to the masterly disquisition of a learned and betitled oak upon *septicemia* or the curiosities of *traumatic tumors*. We have heard no complaints from suffering, bleeding grape vines ; no uneasy groans from plants perishing through the withering effects of blight and mildew.

But the terms physiology and pathology do have a meaning answering to the operations and conditions of health and disease in plants as well as in animals. The grasses of the fields and meadows may flourish in the luxuriance of bountiful supply and perfect adaption, their vital forces being attuned and harmonized into combinations of causes and consequences, all conspiring to the good of the individual and the welfare of the species ; or these members of the vegetable kingdom, may, through unfavorable conditions, through privation, through the attack of enemies, become dwarfed or distorted, weak or disproportioned, unfruitful or incapable of growth and self-perpetuation.

Without attempting to give in this place a classification of the diseases of plants, much less a description of the many that are now known and more or less clearly understood as to origin and progress, we proceed to give some account of a few of the more general facts and phenomena connected with our subject.

THE PROCESSES OF PHYSIOLOGY AND PATHOLOGY IN PLANTS ARE SLOW.

Except in the case of violently disturbing causes, like fire, frost, caustic chemicals, etc., disease or death never attacks a plant in the sudden and unheralded manner frequently known in animals. It is true that what has been called "blight," a very indefinite and loosely applied term, is usually supposed to be the work of a day or a night, perhaps of an hour ; but the facts have not been known by those who make this supposition. If by "blight" is meant the results of a tornado or even of a sirocco, with which we of Illinois can claim some acquaintance after the last summer's experience—if these are meant, we cannot say that "blight" is not sudden ; but the effects of such agencies should be classed as injuries rather than as diseases, There are really no exceptions to the rule that true pathological operations in plants are slow in their progress. The healing of wounds offers us a good illustration, if we examine the process in plants compared with that in animals. If from a healthy, rapidly growing tree, we cut off a limb close to the trunk, making a wound one inch in diameter, a whole year will scarcely suffice for complete healing, while in most animals a clean cut of this kind may be covered with newly produced tissue in a fortnight. We talk about the *circulation* of the sap ; but in plants the fluids do not circulate in any proper sense. The slow movement which does take place is at best a process of *soaking*. When water is most rapidly ascending in the stem of a leafy plant to supply the loss by transpiration, one foot per hour is more than is commonly gained ; and this is altogether exceptional speed for movements in plants generally. This feeble distribution of the fluids in living vegetation is no doubt one of the reasons for the slow workings of disease. Again the want of sympathetic

action of one part with another, so common in animal bodies, is almost or entirely wanting in plants, due probably to the absence of a well developed nervous system. Nothing is more common than to find a leaf dotted here and there with diseased parts, while the intervening tissues remain active and healthy. No organ suffers because another is affected, unless there is a direct dependence in the way of food supply or other similar reason. Hence diseased action can not be rapidly communicated from part to part. The tree never becomes flushed with fever because some one or more of its members have met with disaster. In order that disease may spread at all, it is necessary that the disease producing agent shall itself spread from its original point of attack.

INHERITANCE, OR CONTINUANCE OF PECULIAR EFFECTS.

The protoplasm of the cells is "the physical basis of life" in plants. From this flows the issues of life. Not only all other material products are secreted by the more or less plastic, often semifluid, substance known by this name, but the peculiar and unexplained products of vitality are due to the same source. Whatever potential difference exists in the seed of a thistle separating it from that of a turnip; in a bit of a twig of a Bartlett pear, used as a scion, from the worthless stock on which it is set; whatever difference there may be between health and disease, considered as a constitutional affectation, resides in this wonderful, ever-present, ever-important constituent of living plants—protoplasm.

There is nothing more wonderful in the phenomena of plant life than the peculiar tenacity with which an impression once made is held by living protoplasm. We may not be able, with all our skill, to introduce or cause a change to take place; but when an effect is produced, the changed cell may by reproduction become tens of thousands of similar cells, all having the same peculiarity of vital potency and power. It is upon this principle that horticulturists depend in the propagation of special varities of plants by grafting, budding, cuttings, etc. It is because of this mysterious but interesting quality of the "germinal matter" of the tissues of plants that Baldwins among apples, Bartletts among pears, Marechal Niel's among roses, etc., are possible.

Now any deviation from the normal character of the plant by which it is rendered less capable of succeeding in the struggle for existence on its own account, and by its own forces must be considered a disease. Usually our highly prized fruits are produced as abnormal growths, and the trees that produce them are notoriously liable to seriously suffer from enemies and unfavorable surroundings and conditions, which, to their rough, hardy progenitors would have been as the summer shower and the smiling sun.

So the blotched leaves and variously colored foliage of many decorative pets of the garden, are but indications of a protoplasmic impression continuing itself as a disease. When it happens that these disease changes of the plant are beneficial to us, or when they in any way please our fancy, we do not think of them as pathological conditions and effects; but when through the operations of the same law the opposite is true, we quickly enough talk of failure through disease. Our potatoes all go to vines with no tubers, our strawberries blossom profusely but the flowers are "blasted," our sweet corn becomes too big and coarse, our melons lose their sugar, etc. How the impressions originally occur we do not usually know, but that they are made we cannot doubt, nor too clearly see their permanence, if we would study the causes of health and disease, and try to learn how to profit thereby.

Connected with this topic is a most peculiar phenomenon not yet well understood on the botanical side and perhaps not yet adequately studied. Who can explain why it is that a certain and regular abnormal growth takes place on a given plant after the sting of a certain insect forming what is called a gall? Anyone who has seen the leaves of a jack oak ornamented with "oak apples," especially if he has broken them open and examined the complexity and regularity of their structure, can hardly have helped wondering at the peculiar something which could produce in an abnormal, diseased growth so close an imitation of a true and proper fruit. What can be more strange with our knowledge of the constancy of form and character in plant growth generally, than that a tiny wound with the injection perhaps of a minute drop of a special kind of poison by a particular insect, should entirely modify this growth and produce, not a distorted, irregular knot, but an uniform, constant and thoroughly characteristic though abnormal multiplication and shaping of cells, producing thereby an organic structure so peculiar and so uniformly the same that it may be subjected to all the procedures of natural classification and of specific identification! Though the subject has not been studied from the botanist's stand-point, especially in its physiological or pathological bearings as its importance would seem to justify and demand, it is at least questionable whether the microscope would reveal anything tending to explain the marvelous result. The structure is, like other plant tissues, formed of cells which through inherent forces and properties, rather than through external agencies, shape themselves, and by their co-ordinated and united impulses give form and character to the resulting production. It is also here as elsewhere, the living protoplasm that receives and bears the directing impulse. The cell walls passively bend and swell under its silent and incomprehensible, but dominating power. The wonder is increased when we remember that the growth is not a continued reproduction of the same thing, but that certain cells of the new structure are shaped and modified to form the external wall with its various and inter-differentiated layers, others to form the core or nucleus and still others widely differing from any of the former to make up the mediary parts of the gall. What subtle influence, what magic power is it, that thus toys with the vitalized forces and substances of the plant? What invisible barrier turns the usually inflexible current of life from its healthful and appropriate course and converts the onward rush into swelling pools with their own peculiar currents and eddies and waves, and self-controlled depths and boundaries? A gall produced by a plant in obedience to a particular act of an insect is certainly a most remarkable thing, and merits the closest and most profound study. Why should not man be able to effect as great a modification in the growth of a tender plant, as a buzzing insect? If we knew how why should we not gather grapes from thorns and figs from thistles?

But we must not lose sight of the fact that so far as the plant is concerned, a gall is a disease and sometimes a very serious one. If there is anything whatever, in plant pathology to support Dr. Lionel Beale's theory of "disease germs" being the degraded but still living cells of the ordinary tissues, it is this of insect galls. Is it not possible that a careful study of the latter might be of service to the specialist in gaining more and better knowledge of the origin and development of cancer in the human body?

PLANT DISEASES ARE DUE TO SPECIFIC AGENCIES.

There is no more important item of knowledge connected with vegetable pathology than that each disease has its own predisposing cause, or, in other words, that each disease is a specific thing itself, in the same sense and manner as a particular plant belongs to a species bearing relations to, but unlike every other species.

There is no clearer illustration of the truth of the foregoing than in the matter just before us of insect galls. Entomologists have given these structures much attention, and it is found as easy to recognize the gall as a species, as it is the insect that causes the growth. A skillful specialist in this matter will give us the name of the

insect on seeing its domicile, as readily as upon seeing the winged inhabitant itself. Each one of the hundreds of these curious structures differs from every other one, and owes its existence to a different agent from that of any other one. There are a very few possible exceptions to this if we limit the difference in insects to specific distinctions, for it is known that at least one species produces several kinds of galls on the same parts of the same plant, while others make somewhat different galls on different parts of a given plant, as in the case of the devastating *Phylloxera*. But every one knows that the individuals of a species vary much among themselves, so that our rule should be strengthened rather than broken by these apparent exceptions. There are at least one hundred kinds of galls known upon oaks; hence we may say there are one hundred specific agents, each working after its own fashion and producing its own peculiar results.

Much might also be said of diseases of plants caused by insects which do not form galls, illustrating the same thing; but these are passed without remark to save time and room for those more particularly falling under my own observation and the subjects of more personal investigation, viz: those caused by parasitic fungi.

Though having had a very good chance to find out, I do not know of a single flowering plant in our country which is not more or less injuriously affected by one or more fungi, living as parasites on, or in, its substance. Sometimes numerous species dwell on (or in) one host plant; sometime the same parasite preys on many kinds; but very often a particular fungus is found only upon a particular supporting plant. Nearly all of these myriads of thieves are so small that they cannot be seen, certainly are not usually seen by the unaided eye, except as they occur in masses. Many are at times exceedingly destructive, as witness the wholesale rotting of potatoes during certain seasons, while yet in the ground and attached to the stems of the plants; and the dreaded rust of wheat, which apparently cuts off the farmer's returns for a year's labor in a week or a day. We pay less attention to the diseases and death of uncultivated plants, but these, too, suffer as severely. I have observed great areas of thickly springing smart weed (Polygonum Pennsylvanicum and P. hydropiper) destroyed almost as effectually as by fire, by a vegetable parasite (Helmin thosporium) whose corrosive action caused the leaves, long before frost in autumn, and before the maturity of the plant, to shrivel and die, after which the entire plants soon succumbed.

Though these mischief-makers are usually invisible to untrained and unaided eyes, their peculiar effects are ordinarily recognizable at once, by an expert, even without his magnifier. Each has its own characteristic influence upon the host—one causing yellowish spots on the leaves, another a curled and distorted growth, another little cracks on the stems, another swellings like insect galls, etc., etc. A closer examination brings into clearer relief the different injuries or modifications of growth, caused by each different parasite. Each faded spot, each tumid projection, each rupture of the epidermis, each blister and canker, each puncture and corrosion, has its own more or less clearly marked characteristics; and each parasite has, as well, its own pathological influences and effects. The grapevine alone has at least thirty species of parasite fungi peculiar to it and all more or less injurious, while an entire book of some hundred and fifty pages has been filled with generic and specific descriptions of fungi, known to occur on the cultivated vine. (Thümen, Die Pilze des Weinstockes, Wien, 1878.) The list of specific and separate causes of disease in plants thus immeasurably exceeds that known to the wisest practitioner of medicine for man, for the illustration from the grapevine, though a strong example, is not exceptional. Of fungi, as a class, there are many more species growing in Illinois than there are flowering plants, putting the native and introduced together,—at least double as many. Large numbers of these, however, never grow on living plants; they are the scavengers of the vegetable world.

Two questions may now be raised. (1.) Are all these fungous growths really divisible into good specific forms? in other words, can the term species be applied to these various productions in the same sense as it is used for the higher plants and animals? (2.) Do those kinds known to inhabit living plants really cause disease, or are they mere concomitants of pathological conditions, due to other influences?

These questions are continually pressing for answer, founded on careful observation and skillful investigation. The first one has been, and must be, answered unhesitatingly in the affirmative by every botanist who has made, or may make, a special study of the plants. There are curious alternations of generation, as among the lower animals—a given species presenting itself under two, three, or even four forms. There are also deviations from the recognized type, and modifications due to circumstances and conditions; but it is doubtful whether these fluctuations are greater than in the species of higher and better known organisms. It does require, perhaps, keener perceptions to distinguish allied species than among those having greater differentiation of parts, as root and stem and leaf and flower and fruit; but none of these affect the general question. We admit the probability of evolution of species in the world, and should be theoretically disposed to look for greater plasticity in these low forms than in the higher; yet, except in the particulars cited, observation does not apparently support the deduction. I am sure that any botanist, equally familiar with the two, will as positively recognize *Puccinia graminis*, the rust, or, rather, one of the rusts of wheat, as he will *Triticum vulgare*, though the former is very variable for a fungus. The same may be said for *Ustilago maydis*, the smut of corn, and *Zea mays*; but, in this case, there seems to be no variableness nor shadow of turning in the characteristics of the parasite. Hundreds of even better illustrations might be given, all conspiring to enforce the opinion upon the skeptical, that these low, mostly microscopical plants, have specific distinctions as characteristic and rigid as those found among the higher organized, if not more respectable and reputable members of the vegetable kingdom. It is yet to be proved whether or not hybrids ever occur among the fungi; the very fact that none are positively known, or even reported as suspected, helps to indicate the goodness of the species to botanical eyes. Still there is much to be done in the way of experiment, by sowing spores and watching the development of the plants, before much confidence should be placed in the slight distinctions now used in many cases for specific separation.

Passing to our second question, a direct answer cannot be given. In the interdependence and complexity of relations existing among all living organisms, it is exceedingly difficult to pronounce upon the exact effect of any one of them, considered in and of itself. Cold water is not regarded as poisonous to man, yet individuals have severely suffered, even died, from the effects of a reasonable (so far as amount is concerned) draught. Arsenic is poisonous, yet there are those who swallow what would ordinarily be deadly doses, with impunity. Poisonous doses of opium are merely nerve restorers to the habitual eater of the drug. Shall we then say that water causes death when taken to allay thirst, and arsenic and opium are not poisonous? Shall we not rather say that whatever proves seriously injurious to man in a normal condition, under the usual circumstances of his life, is the poisonous thing, and the one which *causes* death; while we assign the peculiar and abnormal condition as the cause in other cases,—as the over-heating instead of the water.

Measured by this standard there are many parasitic fungi which must always be acknowledged as a "cause"

of disease in the higher plants, for they germinate and grow under the usual conditions of our summer weather, and penetrate and develope in and at the expense of otherwise healthy plants. Under these conditions it is only necessary to place the matured spores on the parts of the plants inhabited by the fungus to ensure its growth, and, in consequence, the disease. It is, however, even in these cases, evident that much must depend upon the peculiarities of the weather, etc., whether the host or the parasite is specially favored or repressed, and so whether or not the disease is seriously injurious.

Rust spores on young wheat leaves in spring time are as certain to germinate and penetrate the tissues as arsenic is to poison mammals. In this case development goes on but slowly however, unless specially favorable conditions occur for the parasite, when, in the latter case, it makes its presence easily recognized by the disastrous results too often witnessed. Smut in wheat is less affected by peculiar states of the climate. The spores send their germinal tubes into the tissues of the seedling plants; the fungus grows with the host, and finally, just before harvest time, matures its spores again in the aborted wheat grains. Blight-bacteria, again, need only to be introduced in few numbers into the living bark cells of a healthy pear tree, during ordinary Summer weather, to insure their reproduction and multiplication in myriad numbers, and the death of the invaded cells in consequence of their deleterious action. It is by on means true that plants must be in an enfeebled condition that such parasites may grow upon them. The very vigor of the host often adds, by furnishing more assimilable food, to the extreme development of the parasites.

On the other hand there are many fungi that only grow on the higher plants when these have been injuriously affected by something else, or when the conditions are peculiar and altogether unfavorable for their proper development or growth. Thus apples become "scabby" by a fungus belonging to the preceding class, but they often rot while hanging on the trees through the effects of other fungus never injurious to perfectly sound fruit with an unbroken skin or epidermis. Peaches rot upon the trees under the effect of a mould-like fungus which produces myriads of spores that readily float like dust in a dry atmosphere, but these do not germinate except in moisture, and, as their duration of vitality is very short, few succeed in reproducing the plant except during rainy weather, when one decaying peach may be a source of contagion for hundreds of others. There are too great numbers of leaf-dwelling fungi which only grow upon these organs when from old age or other causes they have lost their powers of existence through the diminution of their vital forces, so that the mycologist learns to look upon old and fading leaves for numerous specimens. In the descending scale we find vast numbers of still other fungi which only grow upon really dead organic matter; these however have no share in the title parasitic.

It may therefore be concluded that, in the struggle for existence, many species of fungi have acquired the physiological power of overcoming the defensive forces of certain higher plants in a state of health under ordinary conditions of plant life and growth, while others, truly parasitic in their nature, are obliged to seize upon favorable chances to take advantage of slight or serious misfortunes happening to their hosts, thus giving the kick to one already going down hill.

I have thus endeavored to point out some of the general truths of vegetable pathology as they appear to one who accounts himself a student but not a master of the subject. I enter the open gateway of a great field, and make little incursions here and there, gathering now and again from the abundance offered, material for many odd hours of microscopical work, which again furnishes "food for thought" when the lamp has been extinguished and the scalpels laid away. There is much room for many better workers, and much interest for those who will work.

CROTON WATER OF NEW YORK.

It is admitted on all sides that an improved supply of water for New York city, both in regard to quantity and quality is imperatively demanded by its citizens, and the subject in one form, will shortly be discussed by the legislature at Albany.

In regard to quantity, the solution appears a simple one, as the present supply is adequate for all legitimate purposes; in fact, if it were not for the great waste of water now practised, the supply would exceed all demands of the present population.

It is claimed by the "*Sanitary Engineer*" that this waste is due to imperfect plumbing, and the facts and figures given, show that such a supposition is, in part, correct. Every householder, however, knows that a wasteful use of the water, due to the whole supply of the city being at the command of every individual, must lie at the root of the evil.

Much printers ink has been wasted in printing proclamations from the authorities to the people, counselling economy in the use of the water, but the time has, perhaps, now arrived when the legislature should decide to employ some remedy and make radical changes in the method of distributing the supply.

The method of running the main supply direct into every house, is certainly the most primitive and least scientific or practical of all means at command. It is an inviation for waste and extravagance, and has proved an utter failure, as the means for thus distributing a supply are so defective that, while one family in a house can draw on the Croton river at will, others, less fortunate, on another level endure a constant water famine.

The whole evil of this imperfect distribution of the water could be remedied, if the supply were made by cisterns only. This system has always been in use in London and answers admirably. Every householder under this system has one or more cisterns filled twice daily, and is not restricted either to the number, capacity or location of the cisterns. Thus each householder pays *pro rata* for the actual amount of water he consumes annually, which, beyond doubt, is the only equitable method of charging a water rate. In the case of manufacturers a meter is substituted, if desired.

A natural accompaniment of this system is a universal high pressure of water throughout the city, which provides that cisterns in the highest part of every house shall receive its supply daily. This mitigates the evil under the present system, of pumping and carrying water above the first and second stories, now necessary in most houses in New York city.

The economy of the cistern system is self evident for no one would call for more water than he could legitimately use and increase the annual water tax. Thus a premium for economy rather than waste is offered. In a sanitary point of view many advantages are attached to the use of cisterns, as the large amount of impurities have time to subside and the water is consumed in an improved condition. It is usual to construct one of the cisterns with slate, which is reserved for drinking purposes.

The plea that such a system curtails the proper use of water has no foundation in fact. The writer lived in a house in London for many years, under this system of supplying water, and found he received not only abundance for family use, but sufficient to water a large garden. If the system here described were put in practice in New York city, and the plumbing perfected, the present supply of water would be found ample, and part of the money now proposed to be wasted in making new storage reservoirs might be profitably used in building pumping stations, which would give a high pressure of water to all the upper rooms in the city, and increase the efficiency of the means now at command for extinguishing fires.

In regard to the quality of the Croton water, we will give an analysis by Professor C. F. Chandler.

CROTON WATER—GRAINS IN U. S. GALLONS. (CHANDLER).

Soda	0.326
Potassa	0.097
Lime	0.988
Magnesia	0.524
Chlorine	0.243
Sulphuric acid	0.322
Silica	0.621
Carbonic acid	2.604
Organic and volatile matter	0.670

Calculating 100,000,000 gallons as the daily average water supply of New York city, the impurities would be as follows:

CROTON WATER. (CHANDLER). IMPURITIES IN 100,000,000 GALLONS.

	TONS.
Soda	2.319
Potassa	0.692
Lime	7.038
Magnesia	3.742
Chlorine	1.735
Sulphuric acid	2.300
Silica	4.429
Carbonic acid	18.600
Organic and volatile matter	4.785

We have the same authority for stating that the organic and volatile matter occasionally reaches 1.14 grains to the U. S. gallon.

It will thus be seen that the constituents of Croton water show it to be excellent as a water supply to a city, being unusually free from mineral matter and

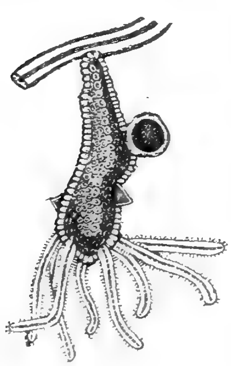


FIG. 2.
Hydra magnified.

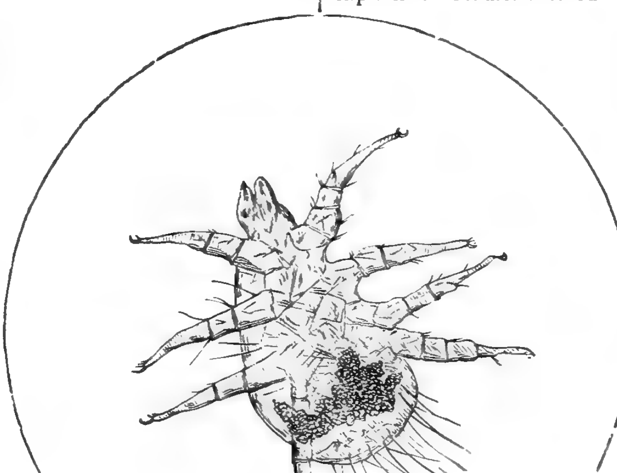

FIG. 1.
A parasite from some, bird or animal and foreign to the water. Seen for two weeks in countless numbers. They were all dead and surrounded by a jelly-like mass of putrescence.—(Michels.)

having no inorganic substance in excess to make it objectionable.

In discussing, therefore, the quality of Croton water it will be sufficient to confine our attention to the amount of organic matter it contains, and its nature.

To decide this point correctly a comparison of the analyses made by various chemists is desirable, but the greatest difficulties are here met, which are due to the erratic methods of those who have made and recorded these investigations. No two chemists appear to adopt similar methods of making analyses of water, and it is notorious that different methods give quite different results. On the other hand some chemists record their results in United States gallons, some in imperial gallons, and others in parts of 100,000,000, and others in 1,000 gallons.

From necessity rather than choice we will make an average amount of organic matter in Croton water from the following calculations:

	Tons in 100,000,000 gallons.
C. F. Chandler	4.785
E. Waller	18.324
Leeds	27.070
Herald	14.528
Average Tons in each day's supply,	16.176

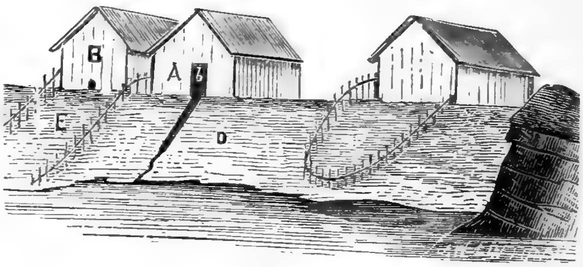

FIG. 4.
Whitlock's Slaughterhouse, showing drainage into Croton water supply.

To determine the nature of this organic and sedimentary matter a microscopical examination is necessary, and, as we have for nearly ten years continuously made such examinations, an attempt will be made to explain the results arrived at.

If a glass of Croton water freshly drawn be held up to the light, it will be noticed, that dispersed throughout

FIG. 3.
Hydræ natural size.

the water are very minute particles in countless numbers, which revolve as the water circulates round the glass, while here and there may be noticed (especially during the summer and autumn months), larger pieces having a reddish-brown color. If a piece of sponge is tied over the mouth of a faucet, and the water allowed to run for a short time, the sponge will be loaded in every pore with an accumulation of the impurities in the water. If the sponge is now squeezed in a glass, the water will be found to be opaque on account of the large amount of floating matter, it will emit a foul odor, and the resulting sediment will have the appearence of a foul blackish-brown slime. If a pipette is now used and some

of this deposit placed on a glass slide covered with a thin glass cover, and examined under a microscope, the field will be opaque with the dense nature of the impurities, but if diluted with a little fresh water, objects such as are drawn in figures—and—will be observed. These forms, which will be readily recognizable by microscopists, are composed of unacellular plants, very beautiful in form and mostly of a brilliant emerald green color. A nimallife is also well represented by forms usually found in stagnant ponds, from the purely microscopical forms to those visible with the naked eye; the hydra (figure) with its tentacles ready to grasp as its prey, the little crustaceans which are darting about.

It is no part of this paper to describe these forms specifically, but the sanitary effect of their presence will be referred to in general terms. To prevent any misinterpretation I would state that the forms shown are not seen at a single view, but the contents of the circles represent forms which are all present in the Croton water, and may be seen by making several examinations of the deposit at different seasons. While such forms may be noticed, *the bulk of the deposit* is found to be composed of dead, rotten, and decayed matter (omitted from illustration to make place for more interesting forms) from which the living chlorophil has long disappeared; the larger fragments are of a dirty brown color, in some of which a growth of fungi may be noticed, indicating its antiquity. On an average from six to eight tons or even more of such contaminations mixed with dead, effete matter, is mingled with each day's supply to the city, and when at its worst gives the water that fishy, sickening odor, which in the height of the summer is always present in the Croton water.

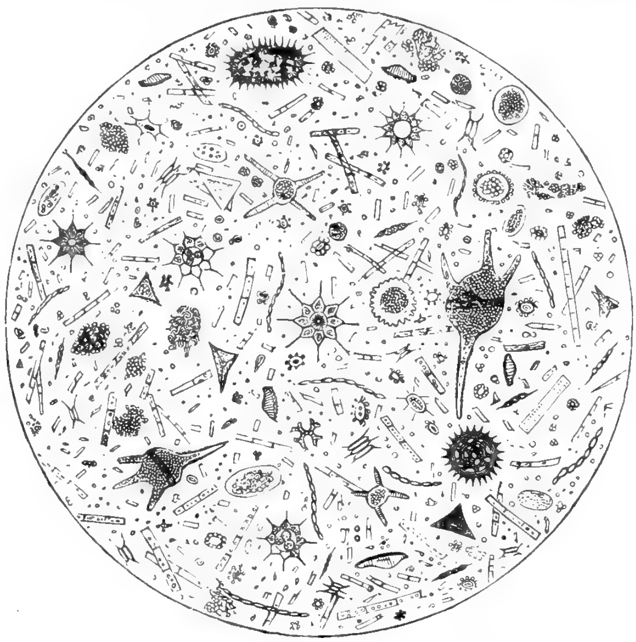

Fig. 5.
Living vegetable forms from the Croton water—(Michels.)

With the exception of the eggs of entozoa I consider most the living forms I have noticed in the Croton water to be perfectly harmless in their living state; but they are continually undergoing a process of decay, die, and when dead they are very offensive in their odor, and when present in such numbers as found in Croton water, must contribute to foul the water.

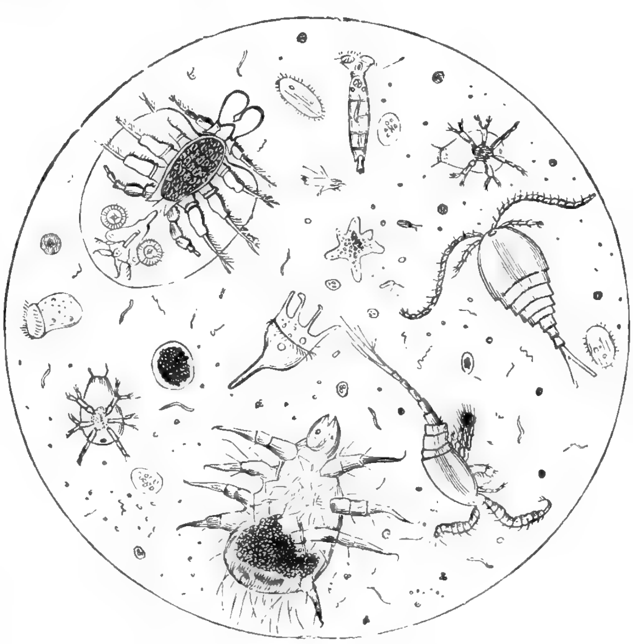

Fig. 6.
Animal organisms found in Croton water.—[Michels.)

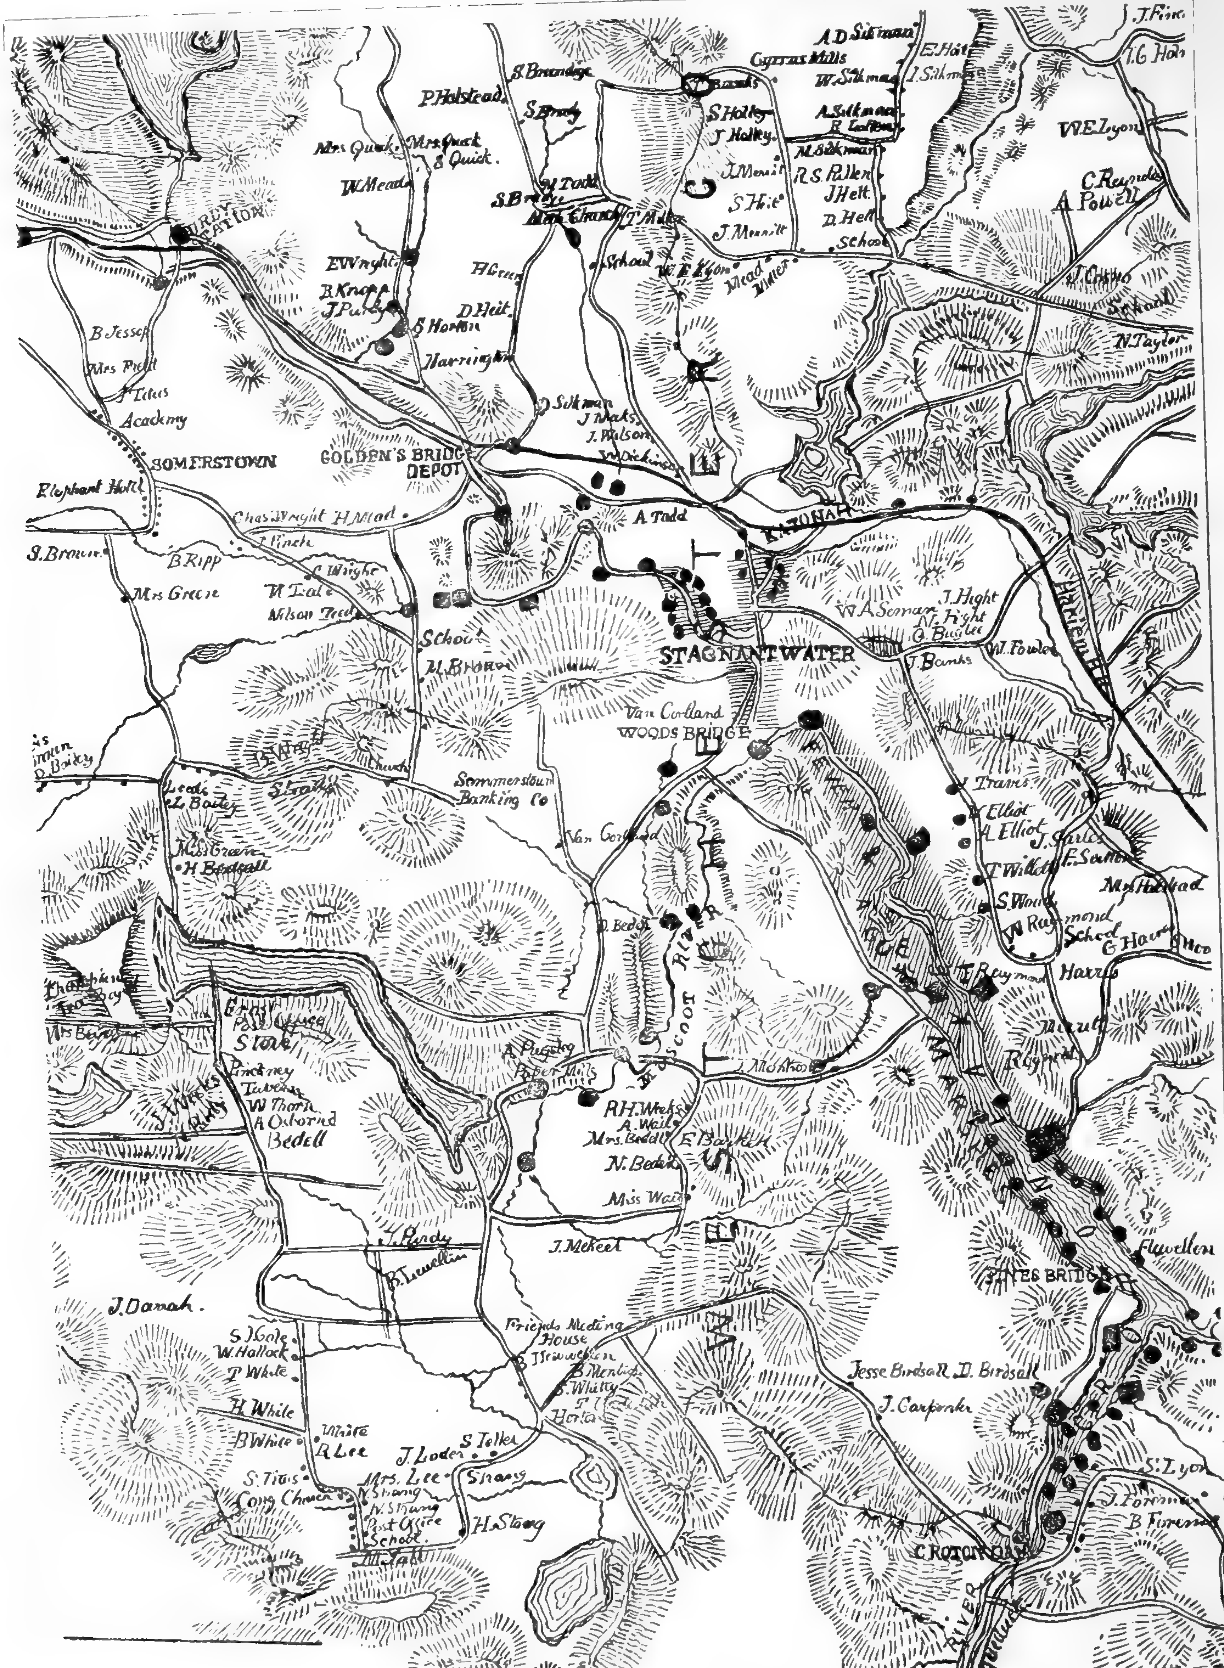
As I have stated, the bulk of the deposit is dead effete matter, forming a stinking slime which is repulsive in its nature, and must be dangerous to use as food. If collected in a spoon no person would swallow such black putrid slime; are therefore the conditions improved or changed when it is thinly dispersed in finely divided particles, so as to make its presence barely visible?

Where does all this filth come from which poisons the water of New York city? In answer to this question, a very brief description of the condition of the Croton water shed will be given, showing the condition of the source of the supply.

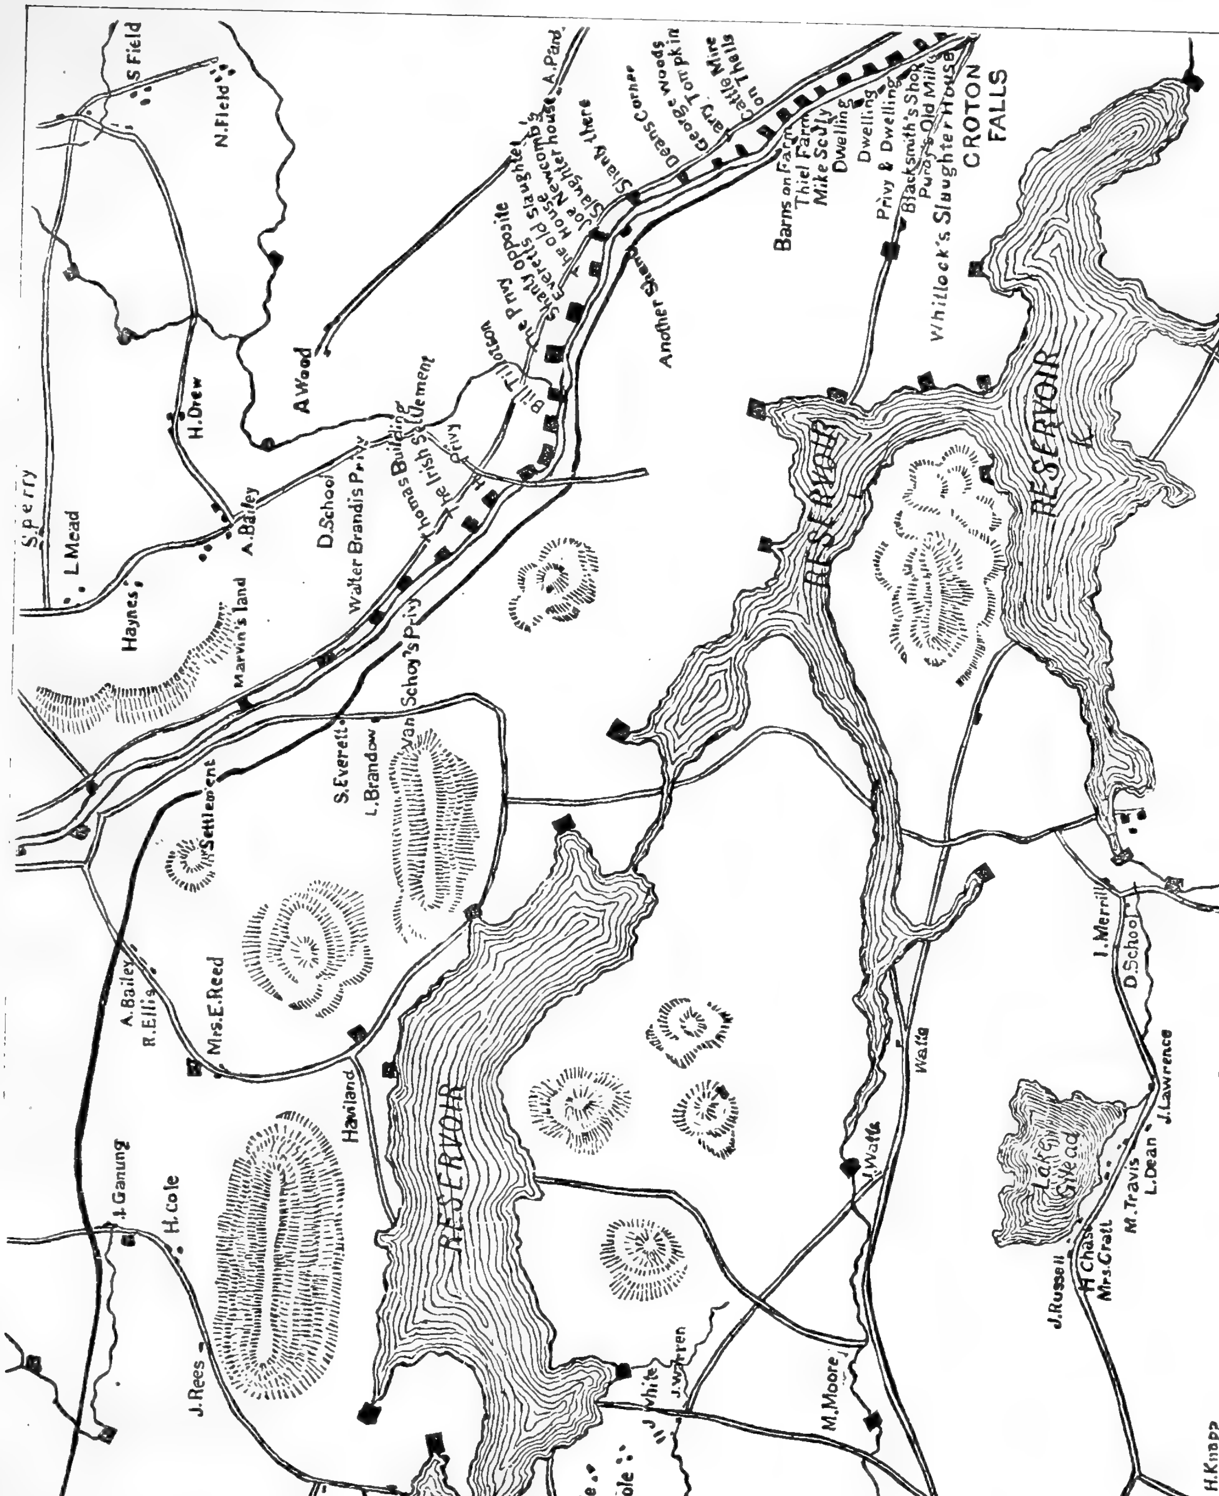
Croton water is the result of collecting the rain fall drained from a large extent of country covering forty miles, which is eventually stored in a series of reservoirs and lakes for future use. The borders of many of these lakes are very shallow and loaded with aquatic plants, and thus brought under the influence of the sun, which destroys the vegetation and converts it into a putrid deposit, which is broken up by the action of the water into fine particles, and eventually delivered at the faucets in our city.

Not long since the Croton lake and the source of the supply up to Croton dam was thoroughly surveyed by Mr. Robert Morris, for the New York *Herald*, whose report was confirmed later by Mr J. Y. Culyer, Engineer, of Prospect Park, Brooklyn, in a letter to the New York *Tribune*, and the *Sun*, *Times*, and *World* have all contributed to expose the state of things we shall now describe.

The report we refer to, states that even Croton Lake wore a green and stagnant look and its shores were sedgegrown, marshy, and laved by little streams that dripped down from barns, houses, hog-pens and farm yards. Various parts were covered with slimy grass, decomposed vegetable matter, and in parts the water was covered with a thick scum. Around other lakes he found stagnant water, fever and ague swamps, filthy drains, wayside sloughs, and on their banks cattle pens and dirty yards. In one place near Mr. Hyde's house, a hollow was found where every kind of rural filth had accumulated and decayed. On pushing his cane into the mass, a stench was stirred up that made him glad to give up further exploration in that direction,



MAP OF CROTON WATER SHED. SOURCE OF IMPURITIES MARKED BY BLACK SPOTS.



PART OF MAP OF CROTON WATER SHED. IMPURITIES MARKED BY BLACK SPOTS.

In another place right across the whole face of the lake stretched half a dozen islands, affording no foothold for man or beast, surrounded by stagnant green water filled with every conceivable vegetable rottenness.

The sewers from farm houses, cottages of laborers and factories were noticed to draindirectly in the water supply; in fact the source of water supply of New York city was found to be a common drain for about 300 cattle yards, dwelling-houses, factories, pig-sties, slaughter-houses, and other sources of impurities, every one of which are distinctly shown on the maps we present, the exact location being indicated by a black spot. Space will not allow us to give futher evidence on this point which it is in our power to offer, but we present a cut of one of these sources of pollution, showing the direct drainage into the Croton water.

Of the danger of drinking such water full of the vilest contaminations we will not dwell, each reader can take his own course, but those who are prudent will both boil and filter it before using for drinking purposes. Individuals and journals still claim that the source of the supply is free from contaminations, and the water pure and fit for drinking purposes; to be consistent they have to say that the water is wholesome.

Professor Leeds of the Stevens Institute recently showed that the Croton water contained more organic volatile mattert han the water supply of Newark, which is taken direct from the Passaic with all the sewage of Paterson and other towns. He found the organic matter in 100,000 parts in New York water to be 6.50, Newark 6.00, Hoboken 4.50. At the February meeting of the American Chemical Society (see page of this number), Dr. E. Waller, of the New York Board of Health, endeavored to deny this startling statement, by producing analyses of his own, showing quite different results. We understand that at the March meeting of the same Society, Professor Leeds asserted to the satisfaction of the Society that Dr. Waller's methods were bad and had led him to error, while the integrity of his own analysis was established.

We consider the method of storing the water supply of a city in shallow, marshy lakes, in fever and malarious districts, to be wrong in principle, and that a radical change in the management of the water supply of New York City, rather than an expensive extension of it, to be the most prudent course to adopt at the present moment.

ELECTRIC CONDUCTION AND DISCHARGE.

By F. E. Upton.

The question of the nature and the vehicle of the electrical discharge is an important one, and its determination will contribute greatly to the solution of many interesting problems in cosmical physics. It is desired in this article to call attention to some recent advances that have been made in this direction.

The view that the phenomenon is one of pure conduction, though it has received the attention of eminent physicists, can be said to be no longer entertained.

When a conductor is made to connect two poles or electrodes which are at a different potential, it is well known that the greater the cross section of the conductor, or in other words, the more of the conducting material is laid bare by a cross section, the *less* resistance will be offered to the union of the electricities of the two terminals, and the greater will be the ensuing current, with a given E. M. F.

Now, in the discharge, the contrary is observed directly. This characteristic of conduction is absent when the discharge takes place; in a tube containing air, the greater the pressure (above a certain inferior limit), or the more of the conducting material there is laid bare by a cross section, the *greater* will be the resistance to the passage of the spark, and the nearer together the terminals will have to be brought to effect a spark with a given difference of potential. Sir Wm. Snow Harris, in 1834, made an attempt to grasp at the law governing the relation of the length of spark to pressure; and he then stated that the length of spark is in the simple inverse ratio of the pressure. Gordon, in 1878, made a series of experiments to test this law, (Elec. and Mag. II. 55-62). He found that from a pressure of about eleven inches to that of the atmosphere, Harris's law held approximately good.

Representing resistance by r, and matter laid bare by cross section by s, in the case of conductor $r = \frac{1}{s}$; in the case of discharge 92 of $r=s$, approximately. Thus there is in question two entirely different order of phenomena.

Another distinctive characteristic of conduction will be recognized in the fact that whenever there is any conductor at all, however small and however long it may be, connecting two poles, some degree of current will flow, as long as there is any difference of potential. With discharge, however, a certain lower limit of distance apart of poles, and of interposed matter, is requisite for any current at all, and when that limit is reached the spark passes, instantaneously, and the discharge commences.

Whether the current passes by conduction or discharge, heat is equally developed; in the conductor in the one case, and in the interposed matter in the other. This common development of heat does not in any way assimilate the two phenomena. The condition of affairs in the two cases will perhaps become obvious if recourse is had to the corresponding hydraulic analogy.

Imagine a pond of water held in place by a dam, with a pipe leading from the bottom of the dam, for the purpose of drawing water from the pond. The smaller that pipe is in section, the smaller will be the current of water flowing through it under a given head, and a certain amount of heat will be developed by friction of the water against the interior of the pipe; moreover some degree of current will flow as long as the pipe has any size of cross section at all. That corresponds to conduction. Now let the pipe be imagined closed to the exit of water; as long as the dam is sufficient, no current at all will flow; but suppose the dam be diminished in thickness gradually and constantly, a point will be eventually reached when it will no longer suffice to hold back the water, which will break through the impediment; the friction of the water against the fragments of the dam, and of those fragments against each other will develop heat as in the first case. That corresponds to the discharge.

By this analogy the difference between conduction and discharge is clearly apparent. A conductor between two points at a different potential never offers any *resistance* to the passage of the current, strictly speaking. Instead of saying that a slender wire offers more resistance than a thick one, it would give a better understanding of the matter to say of the latter that it offered a freer passage to the current than the former. In the case of discharge, on the contrary, the matter interposed between the points acts always as a bar, or resistance to be overcome, and the more there is of it the more resistance. It is never an aid or way.

Mr. E. Goldstein, in the *Annalen der Physik*, describes an ingenious experiment bearing upon this point, which, if not conclusive, is entitled to some consideration. In a discharge tube which was filled with dry nitrogen, he placed a little sodium, which could be vaporized by heating. The positive light had a purplish red color, but in the vicinity of the sodium it was of a golden yellow. By careful heating and manipulation, the upper half of the tube could be kept red and the lower half yellow. Now the tube was brought over and near, in a horizontal and equatorial position, to a powerful magnet. The discharge light was repelled as a slender thread to the opposite (upper) side of the tube; but it was a pure eddish thread, and showed no trace of sodium yellow.

So the sodium was not displaced or repelled under the influence of the magnet, as it would have been had it been a *conductor* of electricity.

There has been considered the possibility that metallic particles thrown off from the electrodes might be the conductors of the current. To determine if this were the case, Mr. Goldstein made use of a tube with platinum electrodes, in which the light from the kathode was deflected by a second kathode. The light alone underwent this deflection, while the minute particles torn off from the platinum, which lodged on the opposite wall of the tube and formed a sort of mirror there, went exactly to the same point after the deflection of the light, as before. There was thus no connection between the light of discharge and the abraded metallic particles.

But the most elegant demonstration in this matter has been furnished by the experiments of De La Rue and Müller: they arranged that the discharge of 2,400 chloride of silver cells should pass through a circuit consisting of a vacuum tube and a large variable resistance, R—; now with different resistances R_1, R_2, the resistance of the vacuum tube formed a varying fraction of the whole resistance; and, according to Ohm's law for the fall of potential along a conductor, the fall of potential along the vacuum tube should have been variable, had its function been that of a conductor. It was found in fact, however, that the fall of potential along the tube remained constant, no matter what resistance was introduced in the remaining part of the circuit between the poles of the battery, showing that the discharge was not a case of true conduction, but that even at the lowest pressure it was disruptive.

THE AMERICAN CHEMICAL SOCIETY.

The February meeting of the American Chemical Society was held on Friday evening, the 3d inst.

Dr. Orazio Lugo was elected a regular member.

The first paper of the evening was "On Crystallized Anhydrous Grape Sugar," by Dr. Arno Behr.

It was customary in the preparation of the anhydrous grape sugar to crystallize it out from an alcoholic solution, particularly from that of methylic alcohol, but Dr. Behr was lead to believe it possible that a simpler method could be devised. After some experimenting, he found that it could be obtained from the ordinary hydrated solution. A solution with 12 to 15 per cent of water gave the best results. In the description of its properties, Dr. Behr stated that when dried in a current of dry air, the crystallized sugar would not retain more than two or three per cent moisture, its reaction was neutral, its melting point is between 141° and 145° C. When tested by the polariscope it showed birotation. Dr. Behr then briefly referred to its economic uses, how by its cheapness it would be largely used by the confectioner, the druggist, and by those who manufacture wines. He also stated that as regards its sweetening qualities, instead of requiring twice as much or more to make it equal to cane sugar, he had found that one and two-thirds as much was sufficient. Mr. Nelson H. Darton followed with a short paper "On the Precipitation of Tannic Acid as Tannate of Copper." This paper was a supplementary description of Mr. Darton's method, already read before the Society. It consists in the precipitation of tannic acid by the ammonia sulphate of copper. The precipitate was tested for ammonia with negative results, and therefore it was contended by Mr. Darton that the precipitate was composed of copper tannate and not the double salt as has been elsewhere claimed.

The final paper of the evening was by Dr. E. Waller, of the School of Mines, Chemist to the New York Board of Health. Its title was "On the Water Supply of New York City. The object of this paper was to contradict certain statements made by Prof. Leeds in his recent paper read before the Society and also published in the *Chemical News*. Dr. Waller produced the analysis made by Dr. Booth in 1843, then by Dr. Chilton running between the years 1843 and 1859, Dr. Chandler's results from analysis in 1869-72, and finally his own, which have been regularly reported since 1872. These latter were represented by means of curved lines on diagrams which showed exactly the amount of each constituent for any time during the past nine years. These we may condense and show by the following table:

	PARTS IN 100,000.		
	Maximum.	Minimum.	Average.
Mineral matter	8.44	3.20	5.702
Org. and vol. matter	4.40	1.67	0.04
Total solids	11.07	4.80	7.38
Hardness	5.40	1.88	3.21
Oxygen by permanganate method	0.383	0.047	0.180

The results ohtained by Prof. Leeds in comparison with those showed from the above table were in several instances quite different. Thus, Prof. Leeds finds the total solids to be higher than any result obtained by the New York Board of Health during the past fourteen years. In other determinations similar discrepances were shown by Dr. Waller. The statement that the Croton water was contaminated by tanneries and other factories was objected to as incorrect, the tanning having long since ceased on account of the scarcity of trees. A statement from the Chief Engineer of the Water Department was read, in which he claimed that the water shed of the Croton River was the cleanest of any from which the supply of drinking water was obtained, either in this country or abroad. The population of the country through which the Croton flows does not exceed 20,000 inhabitants, or about one person to every ten acres. In comparison with other cities, the number of inhabitants to the square mile residing along the water shed of Croton, was stated to be extremely small, thus:

	Population to the Square Mile
London	270
Boston	229
Brooklyn	119
Schnectady, Cohoes, West Troy, } Drawing their supply from the Mohawk River.	103
New York	65
Rochester	36
Albany	77
Poughkeepsie, supply from Hudson River	86

By arguments such as the above, Dr. Waller maintained that the conclusions reached by Professor Leeds were erroneous. In the discussion that followed certain of Dr. Waller's modes of analysis were criticized by Dr. Endemann, but his remarks were merely on a side issue, and had no bearing on the results. M. B.

To the Editor of "SCIENCE."

DEAR SIR:—I am sorry to find that I have been misled as to one important fact stated in my paper upon Standard Time which appeared in "SCIENCE" for January 21st. The Signal Service has not applied for an appropriation of $25,000 for the purpose indicated in the paper, but a bill introduced in the house by Mr. King of Louisiana, asks this amount to enable the *Naval Observatory* to establish and drop time-balls at the principal ports of entry; and this was confounded with the Signal Service bill in the mind of my informant.

I supposed I had good authority for what I wrote, but as the result shows I ought to have looked into the matter more closely before trusting the statement to type. I regret exceedingly to have aided in giving currency to an erroneous statement.

C. A. YOUNG.

PRINCETON.

JUPITER.

By Prof. G. W. Hough, Director Dearborn Observatory.

During the present opposition of Jupiter, the disc exhibits a variety of phenomena of interest to the practical astronomer.

Although this planet has received a good deal of attention during the past century, yet, but few new *facts* have been added, with regard to its physical aspect, since the time of Sir Wm. Herschel.

It appears to be the generally accepted idea that its surface is subject to sudden and extraordinary changes, sometimes accomplished in a few days or even a few hours. New belts are alleged to have been formed or to have disappeared in the course of an hour or two.

We believe conclusions of this kind have been too hastily drawn from the obstructions.

Owing to the rapid rotation of Jupiter, the various spots and markings follow each other so closely that one might readily imagine that what he saw was subject to change under his eye.

The great red spot, which has been an object of so much interest since 1879, becomes visible, in the Chicago telescope, at 2h. 25m. from the meridian of the planet, when its length is about one second of arc. As the rotation carries it further on the disc, it gradually increases in size, until, when on the meridian, it subtends an angle at opposition, of 15 seconds. The smaller spots and markings, of course, become most conspicuous when near the meridian of the disc.

The visibility of objects depend, very much, also, on the condition of the seeing. Sometimes the smaller spots are invisible for weeks, simply because the seeing is not good enough with limited optical power, and not because there has been any radical change on the surface of the planet. Its distance from the earth is another important element in modifying the appearance of phenomena. After conjunction, the great Equatorial Belt and Red Spot are first seen and, as the earth approaches nearer, other markings gradually appear, until the time of opposition, the greatest variety of phenomena is noticeable.

From September, 1879, when micometer measurements were first begun, with the Chicago Refractor, on the markings of the disc, considerable change has taken place in its appearance at different times. But all changes, whether due to the distance of the planet from the earth, variable seeing, or other causes, have been slow and gradual.

The most noticeable change has taken place in belt No. 3 situated 6″ north of the equator. This belt, which was not conspicuous in 1879, gradually increased in width and distinctness in 1880, until at the present time its width is about 2″.5 of arc, and of the same color as the equatorial belt, viz.; reddish brown.

The equatorial region situated between the two outlines of the equatorial belt has been subject to considerable change, but the margins of the belt have not sensibly varied in width or latitude during the past three oppositions.

The great red spot, a conspicuous object even in a small telescope, is alleged to have materially changed in length during 1879, and again in 1880, but numerous micrometer measurements do not confirm this statement.

The following are the mean results, reduced to the mean distance.

	Length. ″	No. of Obs.	Breadth. ″	No. of Obs.	Latitude. ″	No. of Obs.
1879.......	12.25	9	3.46	8	—6.95	8
1880.......	11.55	20	3.54	10	—7.14	12
1881.......	11.50	8	3.49	3	—7.41	7

These numbers indicate a small possible displacement of the center in latitude, but it would be premature to assume such to be the case.

The color of the spot is reddish-brown; however, when the seeing is unusually good, it appears almost a light pink.

The oval-shaped white spots, a number of which were observed in 1880, are quite numerous at the present time. They are about one second of arc in length and are generally difficult objects to observe.

The following spots have been seen on belt No. 6. Latitude 9″. 5 to 12″. 6. They pass the meridian of Jupiter after the great red-spot as follows:

h.	h.	h.	h.	h.	h.	h.	h.
+ 2.8	+ 3.0	+ 3.3	+ 4.0	+ 4.7	+ 5.2	+ 5.5	+5.8

There are also two white spots—more easily seen—near the great red spot in latitude 9″. 63 and longitude 0h. 36m. and +0h. 24m.

The two white spots situated in latitude 3″. 0 south of the equator, which were observed in 1879 and 1880, were first seen this year on July 22. They appear to make a complete revolution around the planet in about forty-five days, corresponding to a rotation period of 9h. 50m. 9 sec.

These spots, which are both occasionally seen at the same time, appear to be fixed relatively to each other.

The difference of longitude was measured with the micrometer as follows:

1880.
July 24, +23.5m.
Nov. 8, +22.6m.
1881.
July 22, +27.5m.
Nov. 26, +27.5m.
Dec. 10, +23.0m.

The fact that they have maintained for a year and a half the same relative position, and at the same time apparently drifted with a velocity of over 260 miles per hour, would seem to disprove the old theory that they are clouds floating in the atmosphere of the planet.

From observations made during the present opposition, it is probable that all the matter between the two margins of the equatorial belt, whether in the form of white spots or dark ones, moves with the same velocity, viz.: a period of 9h. 50m. 9 sec. And it is possible that the belt itself partakes of this motion.

The rotation period of the planet, deduced from our observations on the red spot, made in 1879 and 1880, was 9h. 55m., 33.2 sec. + 0.09 sec. $\sqrt{t}$, in which t is the number of days after Sept. 25, 1879. The observations during 1880 showing that the spot was retrograding with an accelerated velocity.

This formulæ is found to be essentially correct for the present opposition.

The "mean" period for Dec. 14, 1881, comprising an interval of 811 days, being 9h. 55m., 35.80 sec. from observation and 9h. 55m. 35.76 sec. from the formulæ

Assuming the rotation period as above, the centre of the spot has retrograded more than fifty degrees since Sept. 1879, not uniformly, but with an accelerated velocity. It seems difficult to account for this fact on any known hypothesis.

IMPROVEMENTS OF PLANTE AND FAURE'S STORAGE BATTERY.

In a previous number of "Science" No. 57, July 30th, 1881, we gave excellent directions for making Planté and Faure's storage batteries.—In a recent paper before the "Society of Arts, of London, Professor S. P. Thompson states that almost any oxide or hydrate of lead will answer for use in the Faure battery—Litharge will answer if sufficiently finely divided for being painted on. Litharge mixed with a small proportion of binoxide of manganese works well. The most satisfactory cells I have yet tried were made by painting the lead plates with a coat of the brown peroxide itself, which is obtainable in commerce, although its cost is greater than that of red lead or litharge.

SCIENCE

Vol. II—No. 1. January 8, 1881. Price 10 Cents.

SCIENCE:

A WEEKLY JOURNAL OF SCIENTIFIC PROGRESS.

ILLUSTRATED.

To Correspondents.

All communications should be addressed to the Editor—box 3838, P. O., New York—with name and address of writer, not necessarily for publication without consent.

Scientific papers and correspondence intended for publication should be written *legibly* on one side only of the paper. Articles thus received will be returned when found unsuitable for the Journal.

Those engaged in Scientific Research are invited to make this Journal the medium of recording their work, and facilities will be extended to those desirous of publishing original communications possessing merit.

Proceedings of Scientific Societies will be recorded, but the abstracts furnished must be signed by the Secretaries.

Both questions and answers in "Notes and Queries" should be made as brief as possible; an answer appearing to demand an elaborate reply may be written in the form of an article.

To Subscribers.

Terms of subscriptions for SCIENCE will be $4 a year, payable in advance. Six months, $2.50. Single copies 10 cents.

Subscriptions forwarded by mail should be addressed to the Editor, Box 3838, P. O., New York, and Post-office Orders made payable to "John Michels."

To Advertisers.

Terms for advertising may be obtained at the office of the Journal, 229 BROADWAY, New York.

A WEEKLY JOURNAL OF SCIENTIFIC PROGRESS.

ILLUSTRATED.

To Correspondents.

All communications should be addressed to the Editor—box 3838, P. O., New York—with name and address of writer, not necessarily for publication without consent.

Scientific papers and correspondence intended for publication should be written *legibly* on one side only of the paper. Articles thus received will be returned when found unsuitable for the Journal.

Those engaged in Scientific Research are invited to make this Journal the medium of recording their work, and facilities will be extended to those desirous of publishing original communications possessing merit.

Proceedings of Scientific Societies will be recorded, but the abstracts furnished must be signed by the Secretaries.

Both questions and answers in "Notes and Queries" should be made as brief as possible; an answer appearing to demand an elaborate reply may be written in the form of an article.

To Subscribers.

Terms of subscriptions for SCIENCE will be $4 a year, payable in advance. Six months, $2.50. Single copies 10 cents.

Subscriptions forwarded by mail should be addressed to the Editor, Box 3838, P. O., New York, and Post-office Orders made payable to "John Michels."

To Advertisers.

Terms for advertising may be obtained at the office of the Journal, 229 BROADWAY, New York.

BOOKS AT TRADE PRICE.

Among the facilities we offer to *regular subscribers* is the purchase of BOOKS at trade prices, making a reduction ranging from 20 to 40 per cent. on the publishing prices. Buyers of a few books may thus, during a year, save the full cost of subscription to "SCIENCE." Send name of Book, Author and Publisher and in reply a postal card will be sent, stating amount to be remitted.

URANIA.

AN INTERNATIONAL JOURNAL OF ASTRONOMY.

Under the above title we intend from January next to publish a Journal for astronomical research, for which undertaking we are anxious to obtain your co-operation.

What chiefly induces us to increase the number of scientific periodicals by a new one is the circumstance that every year many astronomical papers and memoirs of great value are published in Transactions or Proceedings of Learned Societies, and, in consequence, remain unknown to many astronomers. In publishing *Urania* it is our aim to provide a receptacle for papers of this kind, which, we trust, will thereby become more generally known, and by preparing reviews or abstracts of all papers of any importance published in places where they seem likely to be overlooked, we shall endeavor to keep our readers as fully acquainted as possible with the progress of astronomical research. At the same time observations or ephemerides of planets, comets, etc., will not be excluded, and in addition to purely astronomical subjects, the essentially cosmical phenomena of magnetism as connected with Aurorae will also meet with their share of attention.

The journal will be printed in Dublin, and will be issued in numbers of from 16 to 24 pages each, demy 4to, whenever we have material enough for a number. Longer memoirs will not be cut up in several parts, but will be printed together in one number, or carried through two numbers without interruption. Shorter numbers will be issued whenever subjects of more immediate interest shall require it, and in particular ephemerides of comets, etc., will be issued on advance sheets, if necessary. Twelve numbers will contain 240 pages, and will form a volume.

The numbers will be sent by post to all subscribers. The subscription for one volume, including postage to all countries in the postal union, is Sixteen Shillings, payable in advance to the undersigned, J. L. E. DREYER. Post Office Orders to be made payable at the General Post Office, Dublin. Intending subscribers are requested to send in their subscription as soon as possible, in order that the number of copies to be printed may be known at once. No. I. will be published early in January.

We have already secured the co-operation of eminent men of science both at home and abroad. Thus the two first numbers will contain contributions from Lord Rosse, Lord Lindsay, Professor Klinkerfues, Professor Schjellerup, Dr. R. S. Ball, Dr. Börgen, and others. Papers written in French, German, or Italian will be printed in the original language (German MSS. are requested to be written in Roman characters).

RALPH COPELAND,
Observatory, Dunecht, Aberdeen.

J. L. E. DREYER,
Observatory, Dunsink, Co. Dublin.

JEWETT'S
Portable Crock Filter.

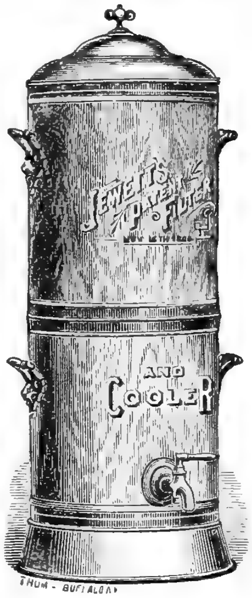
Pat. Nov. 16, 1869, *Oct.* 15, 1878.

PATENT PENDING.

The Latest Improvement

consists in placing the filtering material in a separate vessel or crock. The advantage being this, viz ;

That whenever the filter part gives out, a new crock can be obtained, which will make the whole complete as when first purchased. We, therefore, recommend parties at a distance (instead of attempting to get the Filter re-packed) that they should purchase a new filter crock, the cost of which is moderate, and no more than the cost of repacking.



The Original and Genuine.

ALL OTHERS ARE IMITATIONS.

Over 100,000 now in use.

Acknowledged the only complete Filter and Cooler in the world.

JEWETT'S
PORTABLE CROCK
FILTER
WITH PORCELAIN-LINED
COOLER.

This is the only Filter having the Patent Removable Filtering Cup attached, which holds all sediment that would otherwise pass into the filter.

This celebrated Filter will take river, lake, pond, rain or other impure water, and render the same of

ISAAC S. WILLIAMS & Co., 728 Market Street, Philadelphia, Pa.—We have sold your "Patent Water Filter" for the last six years. Our sales in that time having reached upwards of five thousand, and in no instance have we heard of any failure in performing all you claim for them.

BOARD OF HEALTH, *Washington, D. C., Aug.* 27, 1877.

WEBB & BEVERIDGE:—I am just in receipt of your favor of yesterday, requesting my opinion of the "Jewett Filter" purchased of you several months ago for my personal use, and am pleased to say that it has fully answered your expressed estimate of its value. As a cleanser and purifier of drinking water it is certainly not excelled by any mechanical arrangement known to me. THE FOREGOING REMARKS APPLY EQUALLY TO THE LARGE FILTER OF THE SAME MAKE PURCHASED FOR THE BOARD OF HEALTH.

Very respectfully yours, CHRIS. C. COX, M. D.

Manufactured only by JOHN C. JEWETT & SONS, Buffalo, New York.

FOR SALE IN NEW YORK CITY BY KING, BRIGGS & CO., 596 Broadway. J. H. BALDWIN & CO., 21 Murray Street. L. HEYNIGER, 18 Fulton Street. CHARLES JONES, 020 Broadway. LEWIS & CONGER, 601 Sixth Avenue.

BOOKS AT TRADE PRICE.

Among the facilities we offer to *regular subscribers* is the purchase of BOOKS at trade prices, making a reduction ranging from 20 to 40 per cent. on the publishing prices. Buyers of a few books may thus, during a year, save the full cost of subscription to "SCIENCE." Send name of Book, Author and Publisher and in reply a postal card will be sent, stating amount to be remitted.

SCIENCE

A WEEKLY RECORD OF SCIENTIFIC PROGRESS

ILLUSTRATED.

Entered in the Office of the Librarian of Congress, at Washington, D. C.

No. 35—Vol. II. February 26, 1881. Price 10 Cents.

SCIENCE:

A WEEKLY JOURNAL OF SCIENTIFIC PROGRESS.

ILLUSTRATED.

To Correspondents.

All communications should be addressed to the Editor—box 3838, P. O., New York—with name and address of writer, not necessarily for publication without consent.

Scientific papers and correspondence intended for publication should be written *legibly* on one side only of the paper. Articles thus received will be returned when found unsuitable for the Journal.

Those engaged in Scientific Research are invited to make this Journal the medium of recording their work, and facilities will be extended to those desirous of publishing original communications possessing merit.

Proceedings of Scientific Societies will be recorded, but the abstracts furnished must be signed by the Secretaries.

Both questions and answers in "Notes and Queries" should be made as brief as possible; an answer appearing to demand an elaborate reply may be written in the form of an article.

To Subscribers.

Terms of subscriptions for SCIENCE will be $4 a year, payable in advance. Six months, $2.50. Single copies 10 cents.

Subscriptions forwarded by mail should be addressed to the Editor, Box 3838, P. O., New York, and Post-office Orders made payable to "John Michels."

To Advertisers.

Terms for advertising may be obtained at the office of the Journal, 229 BROADWAY, New York.

JEWETT'S

Portable Crock Filter.

Pat. Nov. 16, 1869, *Oct.* 15, 1878.

PATENT PENDING.

The Latest Improvement

consists in placing the filtering material in a separate vessel or crock. The advantage being this, viz ;

That whenever the filter part gives out, a new crock can be obtained, which will make the whole complete as when first purchased. We, therefore, recommend parties at a distance (instead of attempting to get the Filter re-packed) that they should purchase a new filter crock, the cost of which is moderate, and no more than the cost of repacking.

The Original and Genuine.

ALL OTHERS ARE IMITATIONS.

Over 100,000 now in use.

Acknowledged the only complete Filter and Cooler in the world.

JEWETT'S

PORTABLE CROCK

FILTER

WITH PORCELAIN-LINED

COOLER.

This is the only Filter having the Patent Removable Filtering Cup attached, which holds all sediment that would otherwise pass into the filter.

This celebrated Filter will take river, lake, pond, rain or other impure water, and render the same of

Sparkling Transparency and Purity.

READ THE TWO MOST CONVINCING TESTIMONIALS.

ISAAC S. WILLIAMS & Co., 728 Market Street, Philadelphia, Pa.—We have sold your "Patent Water Filter" for the last six years. Our sales in that time having reached upwards of five thousand, and in no instance have we heard of any failure in performing all you claim for them.

BOARD OF HEALTH, *Washington, D. C., Aug.* 27, 1877.

WEBB & BEVERIDGE:—I am just in receipt of your favor of yesterday, requesting my opinion of the "Jewett Filter" purchased of you several months ago for my personal use, and am pleased to say that it has fully answered your expressed estimate of its value. As a cleanser and purifier of drinking water it is certainly not excelled by any mechanical arrangement known to me. THE FOREGOING REMARKS APPLY EQUALLY TO THE LARGE FILTER OF THE SAME MAKE PURCHASED FOR THE BOARD OF HEALTH.

Very respectfully yours, CHRIS. C. COX, M. D.

Manufactured only by JOHN C. JEWETT & SONS, Buffalo, New York.

BOOKS AT TRADE PRICE.

Among the facilities we offer to *regular subscribers* is the purchase of BOOKS at trade prices, making a reduction ranging from 20 to 40 per cent. on the publishing prices. Buyers of a few books may thus, during a year, save the full cost of subscription to "SCIENCE." Send name of Book, Author and Publisber and in reply a postal card will be sent, stating amount to be remitted.

SCIENCE

A WEEKLY RECORD OF SCIENTIFIC PROGRESS.

ILLUSTRATED.

Entered in the Office of the Librarian of Congress, at Washington, D. C.

No. 40—Vol. II. April 2, 1881. Price 10 Cents.

SCIENCE:

A WEEKLY JOURNAL OF SCIENTIFIC PROGRESS.

ILLUSTRATED.

To Correspondents.

All communications should be addressed to the Editor—box 3838, P. O., New York—with name and address of writer, not necessarily for publication without consent.

Scientific papers and correspondence intended for publication should be written *legibly* on one side only of the paper. Articles thus received will be returned when found unsuitable for the Journal.

Those engaged in Scientific Research are invited to make this Journal the medium of recording their work, and facilities will be extended to those desirous of publishing original communications possessing merit.

Proceedings of Scientific Societies will be recorded, but the abstracts furnished must be signed by the Secretaries.

Both questions and answers in "Notes and Queries" should be made as brief as possible; an answer appearing to demand an elaborate reply may be written in the form of an article.

To Subscribers.

Terms of subscriptions for SCIENCE will be $4 a year, payable in advance. Six months, $2.50. Single copies 10 cents.

Subscriptions forwarded by mail should be addressed to the Editor, Box 3838, P. O., New York, and Post-office Orders made payable to "John Michels."

To Advertisers.

Terms for advertising may be obtained at the office of the Journal, 229 BROADWAY New York.

SCIENCE:

A WEEKLY JOURNAL OF SCIENTIFIC PROGRESS.

ILLUSTRATED.

To Correspondents.

All communications should be addressed to the Editor—box 3838, P. O., New York—with name and address of writer, not necessarily for publication without consent.

Scientific papers and correspondence intended for publication should be written *legibly* on one side only of the paper. Articles thus received will be returned when found unsuitable for the Journal.

Those engaged in Scientific Research are invited to make this Journal the medium of recording their work, and facilities will be extended to those desirous of publishing original communications possessing merit.

Proceedings of Scientific Societies will be recorded, but the abstracts furnished must be signed by the Secretaries.

Both questions and answers in "Notes and Queries" should be made as brief as possible; an answer appearing to demand an elaborate reply may be written in the form of an article.

To Subscribers.

Terms of subscriptions for SCIENCE will be $4 a year, payable in advance. Six months, $2.50. Single copies 10 cents.

Subscriptions forwarded by mail should be addressed to the Editor, Box 3838, P. O., New York, and Post-office Orders made payable to "John Michels."

To Advertisers.

Terms for advertising may be obtained at the office of the Journal, 229 BROADWAY New York.

BOOKS AT TRADE PRICE.

Among the facilities we offer to *regular subscribers* is the purchase of BOOKS at trade prices, making a reduction ranging from 20 to 40 per cent. on the publishing prices. Buyers of a few books may thus, during a year, save the full cost of subscription to "SCIENCE." Send name of Book, Author and Publisher, and in reply a postal card will be sent, stating amount to be remitted.

New York Herald, June 29, 1880:

"Science—A Weekly Record of Scientific Progress." It is a handsome, well-printed quarto sheet of 12 pages, with 4 addditional pages for advertisements serving as a cover. It counts among its list of contributors Professors Baird and Coues, of the Smithsonian Institution; Holden, of the Naval Observatory, Washington; Marsh, of Yale; Wilder, of Cornell; Young, of Princeton; Abbe, of the Signal Office; Morse, of Salem; Drs. Hammond and Spitzka, of New York, and a considerable number of well-known scientific experts. IT CLAIMS, WITH TRUTH, TO OCCUPY A HITHERTO UNOCCUPIED FIELD IN AMERICAN PERIODICAL LITERATURE, AS THE ONLY FIRST-CLASS WEEKLY JOURNAL IN THE UNITED STATES DEVOTED TO SCIENCE.

JUST READY.

Illusions:

A PSYCHOLOGICAL STUDY. By JAMES SULLY, author of 'Sensation and Intuition,' 'Pessimism,' etc. International Scientific Series. 12mo, cloth, price $1.50.

"The present volume takes a wide survey of the field of error, embracing in its view not only the illusions of sense, dealt with in treaties on psychological optics, etc., but also other errors familiarly known as illusions, and resembling the former in their structure and mode of origin."—*From Preface.*

"This is not a technical work, but one of wide popular interest, in the principles and results of which every one is concerned. The illusions of perception of the senses and of dreams are first considered, and then the author passes to the illusions of introspection, errors of insight, illusions of memory, and illusions of belief. The work is a noteworthy contribution to the original progress of thought, and may be relied upon as representing the present state of knowledge on the important subject to which it is devoted."—*Popular Science Monthly.*

"Mr. Sully's analysis of his whole subject leaves us at the close impressed with the ability of the writer's statement.—*Saturday Review.*

For sale by all booksellers, or sent by mail. post-paid, on receipt of price.

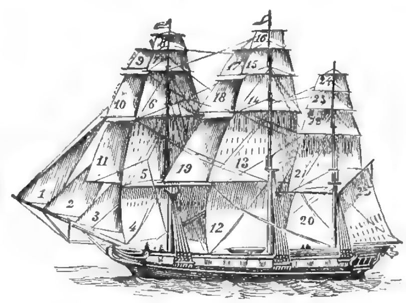
WEBSTER.

The following from Webster, page 1164, shows the value of the Illustrative Definitions in

Webster's Unabridged Dictionary



1, flying jib; **2,** jib; **3,** fore-top-mast-stay sail; **4,** fore-course; **5,** foretop sail; **6,** foretop-gallant sail; **7,** fore-royal; **8,** fore sky-sail; **9,** fore-royal studding sail; **10,** foretop-gallant studding-sail; **11,** foretop-mast studding-sail; **12,** main-course; **13,** maintopsail; **14,** maintop-gallant sail; **15,** main-royal; **16,** main sky-sail; **17,** main royal studding-sail; **18,** main top-gallant studding-sail; **19,** maintop-mast studding sail; **20,** mizzen-course; **21,** mizzen-top sail; **22,** mizzen-top-gallant sail; **23,** mizzen-royal; **24,** mizzen sky-sail; **25,** mizzen-spanker.

The pictures in Webster under the **12** words, **Beef, Boiler, Castle, Column, Eye, Horse, Moldings, Phrenology, Ravelin, Ships,** (pages 1164 and 1219) **Steam engine, Timbers,** define **343** words and terms far better than they could be defined in words.

New Edition of WEBSTER, has 118,000 Words, 3000 Engravings, 4600 New Words and Meanings, Biographical Dictionary of over 9700 Names.

Published by **G. & C. MERRIAM,** Springfield, Mass.

THE FAMOUS "HUB PUNCH."

Handy to have in the House.

HUB PUNCH

Warranted to contain only the best of Liquors, Choice Fruit Juices and Granulated Sugar.

A Delicious Drink with fresh Milk, Ice, Soda or Hot Water, Lemonade or with Fine Ice.

COOL ON ICE.

GOOD AT ALL TIMES

AND JUST THE THING FOR USE BY

Families, Hotels, Clubs, Picnic, Camping, Yachting, Excursion, Sleighing and Surprise Parties.

Invaluable for a little treat when a friend drops in.—*N. Y. Evening Post.*

Connoisseurs pronounce it Unrivalled.

Messrs. Acker, Merrall & Condit and Park & Tilford, the well-known family grocers and wine merchants of New York, write as follows concerning it:

Messrs. C. H. Graves & Sons, Boston. DEAR SIRS: The increased sales of Hub Punch among our always *most critical* customers is evidence of its *superior merit.*
ACKER, MERRALL & CONDIT.

Hub Punch is growing in favor among our customers, and we hear many complimentary opinions on its merits. The increasing popularity of the article is pleasant testimony to your success in using exclusively the *best* and *purest* components.
PARK & TILFORD.

It is made from the best imported Rum and Brandy, the juice of Lemons, Limes and other fruits, and the finest quality of granulated Sugar.

THE HUB PUNCH.

"Punch and the Holidays are the most intimate friends, going together as naturally as man and wife. But it is a great trouble to make Punch, and many people who like the beverage lack the *savoir faire* to brew it. Hub Punch is indispensable where ever its merits are known."—*Spirit of the Times, N. Y.*

This is prepared from an original recipe by an adept for his friends, but now given to the world as a standard article.

It is a most convenient addition to family stores, and heads of families, in making up their list of supplies, should not forget to order it of their grocer, druggist or wine merchant. Added to the good things of the table it undeniably enlarges the pleasures of life, and encourages good fellowship and good nature if rightly enjoyed."—*Springfield Republican.*

Our success in selling your Hub Punch has indeed surprised us, we having sold within the past three months a larger quantity than we anticipated selling in twelve. Our large jobbing trade now call freely for it,—both here and in Chicago. We have heard from all sources the highest econiums passed upon it.—*Smith & Vanderbeek*, New York, Chicago and Paris.

THE HUB PUNCH is prepared solely by Messrs. C. H. GRAVES & SONS, 35 Hawkins Street, Boston. It is sold in bottles only, is quite as palatable in winter with hot water as it is in summer with cold. The manufacturers guarantee the purity of the liquors of which it is made, as they are of their own importation. Every precaution has been taken against counterfeiting what must inevitably become one of the most popular preparations of Punch among connoisseurs.—*Saturday Evening Gazette.*

It is, in short, the **perfection** of **Punches,** purer, more delicious, healthful and invigorating than any other article of mixed drink that has ever been devised.

"A sip is like nectar."—*Boston Courier.*

"Delicious beyond description."—*Boston Transcript.*

CAUTION.—The name and title—"**HUB PUNCH**"—is adopted as a Trade Mark. All unauthorized use of this Trade Mark will be promptly prosecuted. C. H. GRAVES & SONS, Boston, Mass.

DELICIOUS "HUB PUNCH."

See that you get the Genuine, and take no Substitute offered.

SOLD BY ALL FIRST-CLASS GROCERS AND WINE MERCHANTS.

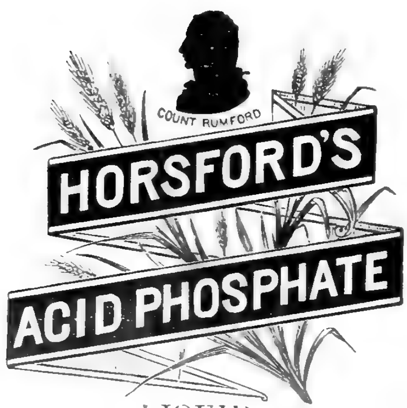
SCIENCE

A WEEKLY JOURNAL OF SCIENTIFIC PROGRESS.

Vol. II, No. 59, - - - - August 13, 1881.

CONTENTS.

SUBSCRIPTION, FOUR DOLLARS A YEAR. SINGLE NUMBERS, TEN CENTS.



(LIQUID.)

FOR DYSPEPSIA, MENTAL and PHYSICAL EXHAUSTION, NERVOUSNESS, DIMINISHED VITALITY, URINARY DIFFICULTY, etc.

FORMULA:

Each fluid drachm contains

5 1-2 grains free Phosphoric Acid (PO_5.)
3 grains Phosphate of Lime (3 CaO PO_5.)
1-2 grain Phosphate of Magnesia (3 MgO PO_5.)
1-8 grain Phosphate of Iron (Fe_2 O_3 PO_5.)
1-4 grain Phosphate of Potash (3 KO, PO_5.)

Total amount of Phosphoric Acid in one fluid drachm, free and combined, 7 grains.

It contains no pyro-phosphate, or meta-phosphate of any base whatever.

Prepared according to the directions of Prof. E. N. HORSFORD, of Cambridge, Mass.

There seems to be no difference of opinion in high medical authority of the value of phosphoric acid, and no preparation has ever been offered to the public which seems to so happily meet the general want as this.

It is not nauseous, but agreeable to the taste.

No danger can attend its use.

Its action will harmonize with such stimulants as are necessary to take.

It makes a delicious drink with water and sugar only.

Prices reasonable. Pamphlet giving further particulars mailed free on application to manufacturers.

Physicians desiring to test it will be furnished a bottle free of expense, except express charges, if they mention "SCIENCE."

MANUFACTURED BY THE

RUMFORD CHEMICAL WORKS, PROVIDENCE, R. I.

W. A. HAMMOND, M.D., late Surgeon-General U. S. Army, said that under the use of arsenic and Horsford's Acid Phosphate, a young lady rescued her reasons who had been rendered insane by a dream.

DR. M. H. HENRY, of New York, says: Horsford's Acid Phosphate possesses claims as a beverage beyond anything I know of in the form of medicine, and in nervous diseases I know of no preparation to equal it.

DR. REUBEN A. VANCE, of New York: The preparation on which I place the most reliance is Horsford's Acid Phosphate.

The late WINSLOW LEWIS, M.D., of Boston, said: Having in my own person experienced those ills for which the Acid Phosphate is prescribed, I having found great relief and alleviation by its use, most cheerfully attest my appreciation of its excellence.

The Anglo-Swiss Condensed Milk Co., of Cham, Switzerland, the largest manufacturers of Condensed Milk in the world, having discovered a superior method of combining milk and cereal foods, have begun the manufacture of a reliable food for infants and invalids. In order that the medical profession and others interested may know precisely what the constituent parts of this preparation are, a chemical analysis is printed on the lable of every can. Persons interested are invited to [illegible] this article and compare the results with those obtained from other foods. The advantages offered by the Anglo-Swiss Company are scientific preparation upon a large scale, thus assuring superior quality at a reasonable price. The name is

ANGLO-SWISS MILK FOOD.

The *Anglo-Swiss* brand of Condensed Milk is also a superior article; 25 *millions of cans sold in* 1880.

Ask your Druggist or Grocer for one of the little pamphlets issued by the Anglo-Swiss Company, telling how Condensed Milk and Milk Food should be prepared for infants. It has saved many lives.

☞ The starchy constituents, ordinarily objectionable in Infants' Food, are changed to Dextrine and Sugar, and rendered soluble and easily digestible by heating Anglo-Swiss Milk Food.

THE TRADE SUPPLIED BY H. K. & F. B. THURBER & CO.,

WHO WILL MAIL PAMPHLET IF NOT OBTAINABLE ELSEWHERE.

DR. SCOTT'S ELECTRIC HAIR BRUSH.—A good hair brush cannot be bought for much less than the sum for which Dr. Scott's electric brush can be secured. This brush, aside from the curative properties claimed for it, is a well made article, handsome in appearance and first-class in every respect. It is not a metallic brush, but is made of pure bristles. Its electrical qualities are very strong, and will manifest themselves by causing the needle of a magnetic compass to vibrate even with a thick book on the top of a table intervening. Violent vibrations of the needle can be caused by passing the brush quickly back and forth within four or five inches of the compass. It is claimed for this brush that its use will cure headaches and neuralgia, will remove dandruff, and in most cases will prevent the hair from falling or turning gray. In support of this claim many testimonials from responsible persons are adduced. Evidently its use would be of great benefit wherever electricity would prove beneficial, and could not in any event result in harm.—*Boston Journal, May* 28, 1881.

A WEEKLY JOURNAL OF SCIENTIFIC PROGRESS.

Vol. II, No. 62, - - - September 3, 1881.

CONTENTS.

Subscription, Four Dollars a Year. Single Numbers, Ten Cents.

THE FAMOUS "HUB PUNCH."

Handy to have in the House.

HUB PUNCH

Warranted to contain only the best of Liquors, Choice Fruit Juices and Granulated Sugar.

A Delicious Drink with fresh Milk, Ice, Soda or Hot Water, Lemonade or with Fine Ice.

COOL ON ICE.

GOOD AT ALL TIMES

AND JUST THE THING FOR USE BY

Families, Hotels, Clubs, Picnic, Camping, Yachting, Excursion, Sleighing and Surprise Parties.

Invaluable for a little treat when a friend drops in.—*N. Y. Evening Post.*

Connoisseurs pronounce it Unrivalled.

Messrs. Acker, Merrall & Condit and Park & Tilford, the well-known family grocers and wine merchants of New York, write as follows concerning it:

Messrs. C. H. Graves & Sons, Boston. DEAR SIRS: The increased sales of Hub Punch among our always *most critical* customers is evidence of its *superior merit.*
ACKER, MERRALL & CONDIT.

Hub Punch is growing in favor among our customers, and we hear many complimentary opinions on its merits. The increasing popularity of the article is pleasant testimony to your success in using exclusively the *best* and *purest* components.
PARK & TILFORD.

It is made from the best imported Rum and Brandy, the juice of Lemons, Limes and other fruits, and the finest quality of granulated Sugar.

It is, in short, the **perfection of Punches,** purer, more delicious, healthful and invigorating than any other article of mixed drink that has ever been devised.

"A sip is like nectar."—*Boston Courier.*

"Delicious beyond description."—*Boston Transcript.*

THE

HUB PUNCH.

"Punch and the Holidays are the most intimate friends, going together as naturally as man and wife. But it is a great trouble to make Punch, and many people who like the beverage lack the *savoir faire* to brew it. Hub Punch is indispensable where ever its merits are known."—*Spirit of the Times, N. Y.*

This is prepared from an original recipe by an adept for his friends, but now given to the world as a standard article.

It is a most convenient addition to family stores, and heads of families, in making up their list of supplies, should not forget to order it of their grocer, druggist or wine merchant. Added to the good things of the table it undeniably enlarges the pleasures of life, and encourages good fellowship and good nature if rightly enjoyed."—*Springfield Republican.*

Our success in selling your Hub Punch has indeed surprised us, we having sold within the past three months a larger quantity than we anticipated selling in twelve. Our large jobbing trade now call freely for it,—both here and in Chicago. We have heard from all sources the highest econiums passed upon it.—*Smith & Vanderbeek,* New York, Chicago and Paris.

THE HUB PUNCH is prepared solely by Messrs. C. H. GRAVES & SONS, 35 Hawkins Street, Boston. It is sold in bottles only, is quite as palatable in winter with hot water as it is in summer with cold. The manufacturers guarantee the purity of the liquors of which it is made, as they are of their own importation. Every precaution has been taken against counterfeiting what must inevitably become one of the most popular preparations of Punch among connoisseurs.—*Saturday Evening Gazette.*

CAUTION.—The name and title—**"HUB PUNCH"**—is adopted as a Trade Mark. All unauthorized use of this Trade Mark will be promptly prosecuted. C. H. GRAVES & SONS, Boston, Mass.

DELICIOUS "HUB PUNCH."

☞ ***See that you get the Genuine, and take no Substitute offered.***

SOLD BY ALL FIRST-CLASS GROCERS AND WINE MERCHANTS.

Dr. SCOTT'S ELECTRIC HAIR BRUSH

IS GUARANTEED TO CURE

NERVOUS AND BILIOUS HEADACHE IN 5 MINUTES,

NEURALGIA and TOOTHACHE in 5 MINUTES,

CURES DANDRUFF AND PREVENTS BALDNESS

PRICE, $3.00. Of All Dealers, or of

GEORGE A. SCOTT, 842 BROADWAY, N. Y.

CAUTION. —*An attempt has been made to put so-called "Electro Magnetic" Brushes upon the market, but the Post-Office authorities at Washington have published the company as a fraud. We therefore caution the Public to be careful that "Dr. Scott's" name is on the box and "Electric" on the Brush. Ours is not wire, but a pure bristle Brush.*

DR. SCOTT'S ELECTRIC HAIR BRUSH.

A MARVELLOUS SUCCESS!!

NOW RECOMMENDED BY OUR BEST PHYSICIANS.)

Which has won its way to Royal favor in England, been cordially indorsed by the Prince and Princess of Wales, and written upon by the Rt. Hon. W. E. Gladstone, is now brought to the notice of the American public. It cures by natural means, will always do good, never harm, and is a remedy lasting for many years. It should be used daily in place of the ordinary Hair Brush. The Brush Handle is made of a new odorless composition resembling ebony; a combination of substances PRODUCING A PERMANENT ELECTRO-MAGNETIC CURRENT WHICH ACTS IMMEDIATELY UPON THE HAIR GLANDS AND FOLLICLES. This power can always be tested by a silver compass which accompanies each Brush.

IT IS WARRANTED TO

- Cure Nervous Headache in 5 Minutes!!
- Cure Bilious Headache in 5 Minutes!!
- Cure Neuralgia in 5 Minutes!!
- Prevent Falling Hair and Baldness!!
- Cure Dandruff and Diseases of the Scalp!!
- Promptly Arrests Premature Grayness!!
- Makes the Hair grow Long and Glossy!!
- Immediately Soothes the Weary Brain!!
- Money returned if not as represented!!

It rarely fails to produce a rapid growth of hair on bald heads, where the glands and follicles are not totally destroyed.

Proprietors: The Pall Mall Electric Association of London. New York Branch: 842 Broadway.

[From Rev. Dr. Bridgeman.]

BROOKLYN.

'*Gents*:—I have never before given a testimonial, but am willing to encourage the use of an honest remedy. I am so pleased with your Hair Brush that I deem it my duty to write you recommending it most cordially. My hair, about a year since, commenced falling out, and I was rapidly becoming bald; but since using the Brush a thick growth of hair has made its appearance, quite equal to that which I had previous to its falling out. I have tried other remedies, but with no success. After this remarkable result I purchased one for my wife, who has been a great sufferer from headache, and she finds it a prompt and infallible remedy. A. C. Bridgeman, D.D."

[From the Mayor of Saratoga.]

"I cheerfully testify to the merits of Dr. Scott's Electric Hair Brush. It cures my headaches within a few minutes. I am so pleased with it I purchased another for my wife. It is an excellent Hair Brush, well worth the price, aside from its curative powers." JAS. B. CHAPMAN.

"I would Not take $1,000 for my Brush

if I could not replace it. Its effect is marvellous." PLINY F. SMITH, 218 Fulton Street, N. Y.

Mr. Smith is a gentleman well known in this City as a Law Publisher, and also as a Director in several Public Institutions of New York.

Head Office "Domestic" Sewing Machine Co., New York.

DR. GEO. A. SCOTT—*Dear Sir:* Permit me to add the testimony of my wife to that of the many others who have been benefited by the use of your Electric Brush. She has for years been a sufferer from Neuralgia in an acute form, but since I obtained for her one of your Brushes, she has experienced entire relief. Please accept her sincere thanks. HENRY BARTLETT.

Over 7,000 similar Testimonials can be seen at our office.

ASK FOR DR. SCOTT'S BRUSH. TAKE NO OTHER. See that name is on the box.

Mention this Paper.

A BEAUTIFUL BRUSH, LASTING FOR YEARS.

We will send it on trial, postpaid, on receipt of $3.00, which will be returned if not as represented.

Inclose 10 cents extra and we guarantee safe delivery into your hands; or will send it by express, C. O. D., at your expense, with privilege of opening and examining. But expressage adds considerably to your cost. Or request your nearest Druggist or Fancy Store to obtain one for you, and be sure Dr. Scott's name is on the Box.

MONEY RETURNED IF NOT AS REPRESENTED.

As soon as you receive the Brush, if not well satisfied with your bargain, write us, and we will return the money. What can be fairer? The Proprietors of this Publication know Dr. Scott to be respectable and trustworthy, a Brush has been placed in the hands of Mayor Cooper and Postmaster James of New York, as a guarantee of good faith.

Remittances should be made payable to GEO. A. SCOTT, 842 Broadway, New York. They can be made in Checks, Drafts, Post Office Orders, Currency, or Stamps. LIBERAL DISCOUNT TO THE TRADE. Agents Wanted in every Town.

Send for a Circular of our Dr. Scott's Electric Flesh Brush.

JUST READY. JUST READY.

THE SUN.

By C. A. YOUNG, Ph. D., LL. D., Professor of Astronomy in the College of New Jersey.

With numerous Illustrations.

"International Scientific Series." One vol. 12mo., cloth. Price, $2.00.

CONTENTS: I. The Sun's Relation to Life and Activity upon the Earth; II. Distances and Dimensions of the Sun; III. Methods and Apparatus for Studying the Surface of the Sun; IV. The Spectroscope and the Solar Spectrum; V. Sun Spots and the Solar Surface; VI. Periodicity of Sun Spots, &c.; VII. The Chromisphere and the Prominences; VIII. The Corona; IX. The Sun's Life and Heat; X. Summary of Facts.

"It is my purpose in this little book to present a general view of what is known and believed about the sun, in language and manner as unprofessional as is consistent with precision. I write neither for scientific readers as such, nor, on the other hand, for the masses, but for that large class in the community who, without being themselves engaged in scientific pursuits, yet have sufficient education and intelligence to be interested in scientific subjects when presented in an untechnical manner; who desire, and are perfectly competent, not only to know the results obtained, but to understand the principles and methods on which they depend, without caring to master all the details of the investigation."—*Extract from Preface.*

D. APPLETON & CO., Publishers, - - - - - 1, 3 & 5 BOND STREET, New York.

Dr. Scott's Electric Hair Brush.—A good hair brush cannot be bought for much less than the sum for which Dr. Scott's electric brush can be secured. This brush, aside from the curative properties claimed for it, is a well made article, handsome in appearance and first-class in every respect. It is not a metallic brush, but is made of pure bristles. Its electrical qualities are very strong, and will manifest themselves by causing the needle of a magnetic compass to vibrate even with a thick book on the top of a table intervening. Violent vibrations of the needle can be caused by passing the brush quickly back and forth within four or five inches of the compass. It is claimed for this brush that its use will cure headaches and neuralgia, will remove dandruff, and in most cases will prevent the hair from falling or turning gray. In support of this claim many testimonials from responsible persons are adduced. Evidently its use would be of great benefit wherever electricity would prove beneficial, and could not in any event result in harm.—*Boston Journal, May* 28, 1881.

SCIENCE.

A WEEKLY RECORD OF SCIENTIFIC PROGRESS, ILLUSTRATED.

TERMS:

Four Dollars a Year. **Two Dollars Six Months.**
One Dollar Three Months. **Single Number Ten Cents.**

This journal was established on the 1st of July, 1880, for the purpose of providing a first-class weekly scientific journal, and affording a rapid means of communication between scientific men.

Sixty-eight weekly numbers have been so far issued, and the editor has received letters of congratulations and offers of support from gentlemen representing all branches of science.

Volume one was completed on the 31st of December, 1880, and was provided with an index of 5,000 references. The present volume (II) was commenced on the 1st of January, 1881, and will be completed on the 31st of December. It will be a handsome volume of seven hundred papers, having index with about 10,000 references.

As a standard work of scientific reference the annual volume of "SCIENCE" will stand unsurpassed, will be a valuable addition to every library, and as a scientific handbook should be within the reach of every working scientist and practical man.

The most convenient manner of taking "SCIENCE" is to subscribe, but it can be ordered at your nearest news dealer. It then arrives every week presenting you with the current scientific events, a series of original papers of the highest value, and interesting discussions.

"SCIENCE" is of convenient size for binding, being of the same dimensions as NATURE, and as a work of reference can be handled with ease.

Electro-plates have been taken of every number since the commencement; new subscribers need not therefore at once purchase the back numbers, as they can complete their sets at any time.

We have not made a habit of publishing congratulatory letters, as we have trusted to the merits of the publication to secure support; the following unsolicited indorsements may however be given, as representing the feeling of the scientific men of this country in regard to this journal:

"UNITED STATES SENATE CHAMBER,
"WASHINGTON, Sept. 19th, 1881.

"——On my return to Washington, a few days ago, I found my file of 'SCIENCE' complete, and have since gone through the numbers with much pleasure. I sincerely trust that the publication is permanently established, for it has already made a name and place for itself, as one which no working scientist would wish to be without. It seems to me to be up to the times, as well as "up to the mark," and can therefore hardly fail to achieve the lasting success which it obviously merits. "ELLIOTT COUES."

"WASHINGTON, Aug. 24th, 1881.

"——I am glad to be able to add my voice to those of others in congratulating you upon the success which has attended SCIENCE. I have no doubt that the periodical is destined to occupy in America the same position held by NATURE in England.
"ALEXANDER GRAHAM BELL."

"UNIVERSITY OF PENNSYLVANIA.

"—— 'SCIENCE' is a credit to all concerned.—GEORGE F. BARKER."

THE EDITORIAL DEPARTMENT is conducted by Mr. John Michels, with the valuable assistance of many of the leading scientific specialists of the United States.

OFFICES OF PUBLICATION.
Tribune Building (Room 17) New York City.

European readers are directed to Mr. Deacon, 150 Leadenhall Street, London, England.
Sample copy sent free from chief office, or can be ordered of any news dealer (Price ten cents) in the United States. If any difficulty is found in obtaining "SCIENCE" send to head quarters.

SCIENCE AND MEDICINE.

A few words on the relation of the natural sciences to med cine, as one of the greatest aids for the achievement of success, should be welcome reading to all members of the medical profession whose aspirations are above the dead level of mediocrity.

The physician may at first sight desire to stifle all discussion on this point by saying, that the requirements of study involved in acquiring a knowledge of medical practice *per se* occupy too much of his time to admit of his taking up outside issues, which he considers mere refinements of practice. There are others who take the absurd view that, to add a knowledge of the natural sciences is to become in the highest sense of the word a Chemist, a Physicist, or a Biologist. Seeing that the attainment of a complete knowledge of either of these sciences, is a work of a life time, it is argued, that they are to be shunned as impossibilities.

The path of the would-be scientific medical man is made clear by the encouraging words of one of his own profession, Dr. G. Vivian Poore, M.R.C.P., who says, there is a minimum of knowledge in this respect which is sufficient to endow the physician with a *scientific grasp of his art*. What is really wanted, is sufficient knowledge to enable a medical man to read these various sciences with intelligible results for himself, *when he needs* and as often as he desires to consult them, to show him as objectively as possible, those great principles which have already found application in his healing art. This will lead him to think and enable him to act with precision in any great emergency.

Let it be understood that there is no necessity for cramming the head with a mass of details, and that our object is to enrich and not encumber the mind of the medical practitioner.

To those who are ignorant of the advantages of some knowledge of the natural sciences in medical practices, the following observations of Dr. Poore may be read with interest.

"There are those who hold that the student of medicine has but little need of special training in the natural sciences, but such a position I believe to be untenable, and if I have to say one thing more emphatically than another to the first year's students, it is to advise them, not on any account to neglect their purely scientific studies. They are the very foundation of your professional knowledge, and without a solid foundation, no firm or worthy superstructure can be raised.

How can a man hope to rightly comprehend that most complicated of all machines, the human body, with its levers, pumps,and elastic canals, unless he be first furnished with the principles of mechanics and hydraulics? Who will say that a proper knowledge of the eye, or of the many optical instruments used in medicine, is attainable without some acquaintance with the laws of light; or that the intricacies of the ear, and the art of auscultation can at all be understood by him, who knows nothing of the laws of sound. The laws of heat must be studied in order to appreciate the difficult problems afforded by the animal temperature, its variations in health and disease, and the means of influencing it by therapeutic agents. Without the principles of chemistry we should be intellectually lost in the human laboratory, and unable to employ chemical agencies in the treatment of disease; and electricity is so correlated with the other physical sciences, and of so much service both in diagnosis and treatment, that its separate study has also become essential. Neither can we altogether neglect geology and meteorology, since conditions of soil and atmosphere are now recognized as important factors in the causation and relief of suffering.

It is scarcely necessary to insist on a knowledge of those sciences which are called "biological." *Anatomy* and *Histology*, formerly the mere handmaids of medicine, but now recognized as sciences worthy of independent study, are as necessary to us as is a chart to the navigator; while *Physiology*, which teaches us the use and mode of action of the anatomical and histological elements, is the medical practitioner.

Zoology and botany are not so absolutely necessary for us as are the other sciences, but it is evident that they are very necessary as preliminary studies for the biologist, to whom we look for instruction, for without a study of the simple forms and conditions of life a proper understanding of human anatomy and physiology is not attainable, and in so far as they teach us the conditions of existence of the various vegetable and animal parasites which affect the human body, from micrococci upwards, they are necessary for us as *surgeons and physicians*. This list of sciences is truly formidable, but I nevertheless assert that there can be no true study of medicine without a knowledge of the principles of all of them; and, for my own part, I have never had any difficulty, as a teacher of clinical medicine, in discriminating easily, by a perusal of their clinical reports, between those students who have, and those who have not, had an insight into the principles of pure science.

Scientific principles are to the physician and surgeon what the sextant and compass are to the navigator. Without them he cannot rise above the rank of a lighterman or a ferryman, but must be content to remain a mere "pill-monger," or a chirurgeon of a base mechanic sort. With them he may fearlessly launch his bark upon unknown seas, and may have the good fortune to extend the frontiers of science, or discover, as it were, new continents, to give a wider scope to the art which he professes."

To the medical man who would reap the advantages held out by Dr. Poore, *we confidently suggest the value of this journal* as a means of accomplishing the ends desired, at the least cost, and most convenient form. The impecunious can thus avoid the purchase of the mass of scientific literature with which the market is flooded, and the overworked practitioner receiving the journal weekly is not embarrassed by redundancy, and yet can safely rely on passing nothing of importance, while articles of special interest to the profession will be constantly brought before his notice.

In the previous numbers of "SCIENCE" may be found valuable articles by Professors Burt G. Wilder and Sage, of Cornell; Drs. Hammond and Spitzka, of New York; Dr. Clemenger, of Chicago; Dr. J. A. Mason, of Newport, and many other specialists of equal merit.

Now the value of a knowledge of science, as a means of "getting on" as Huxley terms it, is indubitable, and while there are few trades in which some knowledge of *science* may not be profitably applied to the pursuer of his occupation, we think that the words of Dr. Poore must carry conviction, that the *student* or Physician who would attain the higher stages of development of his art, must be kept "*au courant*" with such facts and principles, which are weekly published in "SCIENCE," for they will probably find their application in every intelligible diagnosis and discussion on medical practice.

"SCIENCE," November 5th, 1881.

DR. SCOTT'S ELECTRIC HAIR BRUSH.—A good hair brush cannot be bought for much less than the sum for which Dr. Scott's electric brush can be secured. This brush, aside from the curative properties claimed for it, is a well made article, handsome in appearance and first-class in every respect. It is not a metallic brush, but is made of pure bristles. Its electrical qualities are very strong, and will manifest themselves by causing the needle of a magnetic compass to vibrate even with a thick book on the top of a table intervening. Violent vibrations of the needle can be caused by passing the brush quickly back and forth within four or five inches of the compass. It is claimed for this brush that its use will cure headaches and neuralgia, will remove dandruff, and in most cases will prevent the hair from falling or turning gray. In support of this claim many testimonials from responsible persons are adduced. Evidently its use would be of great benefit wherever electricity would prove beneficial, and could not in any event result in harm.—*Boston Journal, May* 28, 1881.

NEW YORK HERALD, June 29, 1880:

"SCIENCE—A Weekly Record of Scientific Progress." It is a handsome, well-printed quarto sheet of 12 pages, with 4 additional pages for advertisements serving as a cover. It counts among its list of contributors Professors Baird and Coues, of the Smithsonian Institution; Holden, of the Naval Observatory, Washington; Marsh, of Yale; Wilder, of Cornell; Young, of Princeton; Abbe, of the Signal Office; Morse, of Salem; Drs. Hammond and Spitzka, of New York, and a considerable number of well-known scientific experts. IT CLAIMS, WITH TRUTH, TO OCCUPY A HITHERTO UNOCCUPIED FIELD IN AMERICAN PERIODICAL LITERATURE, AS THE ONLY FIRST-CLASS WEEKLY JOURNAL IN THE UNITED STATES DEVOTED TO SCIENCE.

A WEEKLY JOURNAL OF SCIENTIFIC PROGRESS.

Vol. II, No. 75, - - - December 3, 1881.

CONTENTS.

SCIENCE.

A WEEKLY RECORD OF SCIENTIFIC PROGRESS, ILLUSTRATED.

TERMS:

Four Dollars a Year. Two Dollars Six Months.
One Dollar Three Months. Single Number Ten Cents.

This journal was established on the 1st of July, 1880, for the purpose of providing a first-class weekly scientific journal, and affording a rapid means of communication between scientific men.

Sixty-eight weekly numbers have been so far issued, and the editor has received letters of congratulations and offers of support from gentlemen representing all branches of science.

Volume one was completed on the 31st of December, 1880, and was provided with an index of 5,000 references. The present volume (II) was commenced on the 1st of January, 1881, and will be completed on the 31st of December. It will be a handsome volume of seven hundred papers, having index with about 10,000 references.

As a standard work of scientific reference the annual volume of "SCIENCE" will stand unsurpassed, will be a valuable addition to every library, and as a scientific handbook should be within the reach of every working scientist and practical man.

The most convenient manner of taking "SCIENCE" is to subscribe, but it can be ordered at your nearest news dealer. It then arrives every week presenting you with the current scientific events, a series of original papers of the highest value, and interesting discussions.

"SCIENCE" is of convenient size for binding, being of the same dimensions as NATURE, and as a work of reference can be handled with ease.

Electro-plates have been taken of every number since the commencement; new subscribers need not therefore at once purchase the back numbers, as they can complete their sets at any time.

We have not made a habit of publishing congratulatory letters, as we have trusted to the merits of the publication to secure support; the following unsolicited indorsements may however be given, as representing the feeling of the scientific men of this country in regard to this journal:

"UNITED STATES SENATE CHAMBER,
"WASHINGTON, Sept. 19th, 1881.

"———On my return to Washington, a few days ago, I found my file of 'SCIENCE' complete, and have since gone through the numbers with much pleasure. I sincerly trust that the publication is permanently established, for it has already made a name and place for itself, as one which no working scientist would wish to be without. It seems to me to be up to the times, as well as "up to the mark," and can therefore hardly fail to achieve the lasting success which it obviously merits. "ELLIOTT COUES."

"WASHINGTON, Aug. 24th, 1881.

"———I am glad to be able to add my voice to those of others in congratulating you upon the success which has attended SCIENCE. I have no doubt that the periodical is destined to occupy in America the same position held by NATURE in England.

"ALEXANDER GRAHAM BELL."

"UNIVERSITY OF PENNSYLVANIA.

"——— 'SCIENCE' is a credit to all concerned.—GEORGE F. BARKER."

THE EDITORIAL DEPARTMENT is conducted by Mr. John Michels, with the valuable assistance of many of the leading scientific specialists of the United States.

OFFICES OF PUBLICATION.
Tribune Building (Room 17) New York City.

European readers are directed to Mr. Deacon, 150 Leadenhall Street, London, England.
Sample copy sent free from chief office, or can be ordered of any news dealer (Price ten cents) in the United States. If any difficulty is found in obtaining "SCIENCE" send to head quarters.

SCIENCE

A WEEKLY JOURNAL OF SCIENTIFIC PROGRESS.

Vol. II, No. 78, - - - December 24, 1881.

CONTENTS.

SCIENCE.

A WEEKLY RECORD OF SCIENTIFIC PROGRESS, ILLUSTRATED.

TERMS:

Four Dollars a Year. Two Dollars Six Months.
One Dollar Three Months. Single Number Ten Cents.

This journal was established on the 1st of July, 1880, for the purpose of providing a first-class weekly scientific journal, and affording a rapid means of communication between scientific men.

Sixty-eight weekly numbers have been so far issued, and the editor has received letters of congratulations and offers of support from gentlemen representing all branches of science.

Volume one was completed on the 31st of December, 1880, and was provided with an index of 5,000 references. The present volume (II) was commenced on the 1st of January, 1881, and will be completed on the 31st of December. It will be a handsome volume of seven hundred papers, having index with about 10,000 references.

As a standard work of scientific reference the annual volume of "SCIENCE" will stand unsurpassed, will be a valuable addition to every library, and as a scientific handbook should be within the reach of every working scientist and practical man.

The most convenient manner of taking "SCIENCE" is to subscribe, but it can be ordered at your nearest news dealer. It then arrives every week presenting you with the current scientific events, a series of original papers of the highest value, and interesting discussions.

"SCIENCE" is of convenient size for binding, being of the same dimensions as NATURE, and as a work of reference can be handled with ease.

Electro-plates have been taken of every number since the commencement; new subscribers need not therefore at once purchase the back numbers, as they can complete their sets at any time.

We have not made a habit of publishing congratulatory letters, as we have trusted to the merits of the publication to secure support; the following unsolicited indorsements may however be given, as representing the feeling of the scientific men of this country in regard to this journal:

"UNITED STATES SENATE CHAMBER,
"WASHINGTON, Sept. 19th, 1881.

"——On my return to Washington, a few days ago, I found my file of 'SCIENCE' complete, and have since gone through the numbers with much pleasure. I sincerly trust that the publication is permanently established, for it has already made a name and place for itself, as one which no working scientist would wish to be without. It seems to me to be up to the times, as well as "up to the mark," and can therefore hardly fail to achieve the lasting success which it obviously merits. "ELLIOTT COUES."

"WASHINGTON, Aug. 24th, 1881.

"——I am glad to be able to add my voice to those of others in congratulating you upon the success which has attended SCIENCE. I have no doubt that the periodical is destined to occupy in America the same position held by NATURE in England.
"ALEXANDER GRAHAM BELL."

"UNIVERSITY OF PENNSYLVANIA.

"—— 'SCIENCE' is a credit to all concerned.—GEORGE F. BARKER."

THE EDITORIAL DEPARTMENT is conducted by Mr. John Michels, with the valuabl assistance of many of the leading scientific specialists of the United States.

OFFICES OF PUBLICATION.
Tribune Building (Room 17) New York City.

European readers are directed to Mr. Deacon, 150 Leadenhall Street, London, England.

Sample copy sent free from chief office, or can be ordered of any news dealer (Price ten cents) in the United States. If any difficulty is found in obtaining "SCIENCE" send to hea quarters.

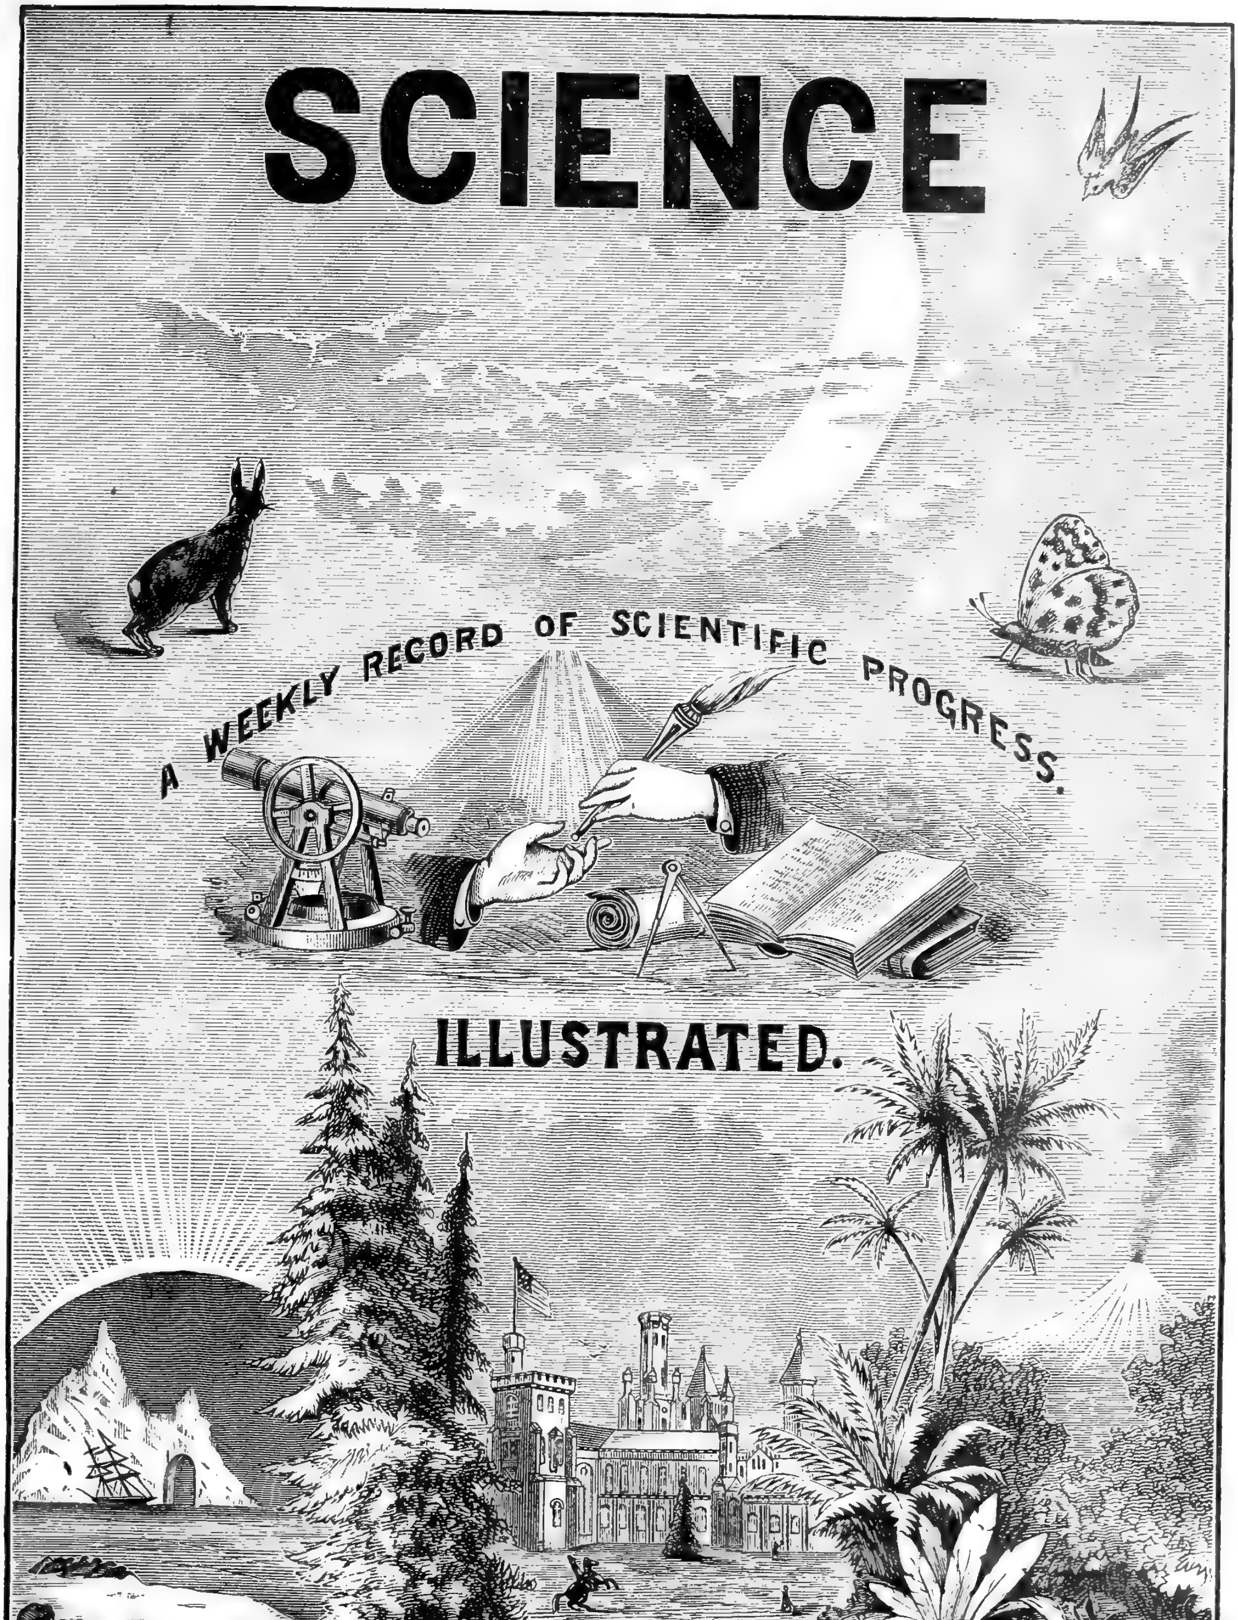
SCIENCE

A WEEKLY JOURNAL OF SCIENTIFIC PROGRESS.

Vol. II, No. 76, - - - December 10, 1881.

CONTENTS.

Vol. 3.] Whole Number 80. JANUARY 14th, 1882. [Price 10 Cents.



Published at "Tribune" Building (Room 17), New York.

NEW YORK HERALD, June 29, 1880:

"SCIENCE—A Weekly Record of Scientific Progress." It is a handsome, well-printed quarto sheet of 12 pages, with 4 additional pages for advertisements serving as a cover. It counts among its list of contributors Professors Baird and Coues, of the Smithsonian Institution; Holden, of the Naval Observatory, Washington; Marsh, of Yale; Wilder, of Cornell; Young, of Princeton; Abbe, of the Signal Office; Morse, of Salem; Drs. Hammond and Spitzka, of New York, and a considerable number of well-known scientific experts. IT CLAIMS, WITH TRUTH, TO OCCUPY A HITHERTO UNOCCUPIED FIELD IN AMERICAN PERIODICAL LITERATURE, AS THE ONLY FIRST-CLASS WEEKLY JOURNAL IN THE UNITED STATES DEVOTED TO SCIENCE.
